Preface to Handbook of Child Psychology, Sixth Edition

WILLIAM DAMON

Scholarly handbooks play several key roles in their disciplines. First and foremost, they reflect recent changes in the field as well as classic works that have survived those changes. In this sense, all handbooks present their editors' and authors' best judgments about what is most important to know in the field at the time of publication. But many handbooks also influence the fields that they report on. Scholars—especially younger ones—look to them for sources of information and inspiration to guide their own work. While taking stock of the shape of its field, a handbook also shapes the stock of ideas that will define the field's future. It serves both as an indicator and as a generator, a pool of received knowledge and a pool for spawning new insight.

THE HANDBOOK'S LIVING TRADITION

Within the field of human development, the *Handbook of Child Psychology* has served these key roles to a degree that has been exceptional even among the impressive panoply of the world's many distinguished scholarly handbooks. The *Handbook of Child Psychology* has had a widely heralded tradition as a beacon, organizer, and encyclopedia of developmental study for almost 75 years—a period that covers the vast majority of scientific work in this field.

It is impossible to imagine what the field would look like if it had not occurred to Carl Murchison in 1931 to assemble an eclectic assortment of contributions into the first *Handbook of Child Psychology*. Whether or not Murchison realized this potential (an interesting speculation in itself, given his visionary and ambitious nature), he gave birth to a seminal publishing project that

not only has endured over time but has evolved into a thriving tradition across a number of related academic disciplines.

All through its history, the *Handbook* has drawn on, and played a formative role in, the worldwide study of human development. What does the *Handbook*'s history tell us about where we, as developmentalists, have been, what we have learned, and where we are going? What does it tell us about what has changed and what has remained the same in the questions that we ask, in the methods that we use, and in the theoretical ideas that we draw on in our quest to understand human development? By asking these questions, we follow the spirit of the science itself, for developmental questions may be asked about any endeavor, including the enterprise of studying human development. To best understand what this field has to tell us about human development, we must ask how the field itself has developed. In a field that examines continuities and changes, we must ask, for the field itself, what are the continuities and what are the changes?

The history of the *Handbook* is by no means the whole story of why the field is where it is today, but it is a fundamental part of the story. It has defined the choices that have determined the field's direction and has influenced the making of those choices. In this regard, the *Handbook*'s history reveals much about the judgments and other human factors that shape a science.

THE CAST OF CHARACTERS

Carl Murchison was a scholar/impresario who edited *The Psychological Register*; founded and edited key psychological journals; wrote books on social psychology,

politics, and the criminal mind; and compiled an assortment of handbooks, psychology texts, autobiographies of renowned psychologists, and even a book on psychic beliefs (Sir Arthur Conan Doyle and Harry Houdini were among the contributors). Murchison's initial *Handbook of Child Psychology* was published by a small university press (Clark University) in 1931, when the field itself was still in its infancy. Murchison wrote:

Experimental psychology has had a much older scientific and academic status [than child psychology], but at the present time it is probable that much less money is being spent for pure research in the field of experimental psychology than is being spent in the field of child psychology. In spite of this obvious fact, many experimental psychologists continue to look upon the field of child psychology as a proper field of research for women and for men whose experimental masculinity is not of the maximum. This attitude of patronage is based almost entirely upon a blissful ignorance of what is going on in the tremendously virile field of child behavior. (Murchison, 1931, p. ix)

Murchison's masculine allusion, of course, is from another era; it could furnish some good material for a social history of gender stereotyping. That aside, Murchison was prescient in the task that he undertook and the way that he went about it. At the time Murchison wrote the preface to his *Handbook*, developmental psychology was known only in Europe and in a few forward-looking American labs and universities. Nevertheless, Murchison predicted the field's impending ascent: "The time is not far distant, if it is not already here, when nearly all competent psychologists will recognize that one-half of the whole field of psychology is involved in the problem of how the infant becomes an adult psychologically" (Murchison, 1931, p. x).

For his original 1931 *Handbook*, Murchison looked to Europe and to a handful of American centers (or "field stations") for child research (Iowa, Minnesota, the University of California at Berkeley, Columbia, Stanford, Yale, Clark). Murchison's Europeans included a young "genetic epistemologist" named Jean Piaget, who, in an essay on "Children's Philosophies," quoted extensively from interviews with 60 Genevan children between the ages of 4 and 12 years. Piaget's chapter would provide American readers with an introduction to his seminal research program on children's conceptions of the world. Another European, Charlotte Bühler, wrote a chapter on children's social behavior. In this chapter,

which still is fresh today, Bühler described intricate play and communication patterns among toddlers, patterns that developmental psychology would not rediscover until the late 1970s. Bühler also anticipated the critiques of Piaget that would appear during the socio-linguistics heyday of the 1970s:

Piaget, in his studies on children's talk and reasoning, emphasizes that their talk is much more egocentric than social . . . that children from 3 to 7 years accompany all their manipulations with talk which actually is not so much intercourse as monologue . . . [but] the special relationship of the child to each of the different members of the household is distinctly reflected in the respective conversations. (Buhler, 1931, p. 138)

Other Europeans included Anna Freud, who wrote on "The Psychoanalysis of the Child," and Kurt Lewin, who wrote on "Environmental Forces in Child Behavior and Development."

The Americans whom Murchison chose were equally notable. Arnold Gesell wrote a nativistic account of his twin studies, an enterprise that remains familiar to us today, and Stanford's Louis Terman wrote a comprehensive account of everything known about the "gifted child." Harold Jones described the developmental effects of birth order, Mary Cover Jones wrote about children's emotions, Florence Goodenough wrote about children's drawings, and Dorothea McCarthy wrote about language development. Vernon Jones's chapter on "children's morals" focused on the growth of *character*, a notion that was to become lost to the field during the cognitive-developmental revolution, but that reemerged in the 1990s as the primary concern in the study of moral development.

Murchison's vision of child psychology included an examination of cultural differences as well. His *Handbook* presented to the scholarly world a young anthropologist named Margaret Mead, just back from her tours of Samoa and New Guinea. In this early essay, Mead wrote that her motivation in traveling to the South Seas was to discredit the views that Piaget, Levy-Bruhl, and other nascent "structuralists" had put forth concerning "animism" in young children's thinking. (Interestingly, about a third of Piaget's chapter in the same volume was dedicated to showing how Genevan children took years to outgrow animism.) Mead reported some data that she called "amazing": "In not one of the 32,000 drawings (by young 'primitive' children) was there a single case of personalization of animals, material phenomena, or

inanimate objects" (Mead, 1931, p. 400). Mead parlayed these data into a tough-minded critique of Western psychology's ethnocentrism, making the point that animism and other beliefs are more likely to be culturally induced than intrinsic to early cognitive development. This is hardly an unfamiliar theme in contemporary psychology. Mead also offered a research guide for developmental fieldworkers in strange cultures, complete with methodological and practical advice, such as the following: Translate questions into native linguistic categories; don't do controlled experiments; don't do studies that require knowing ages of subjects, which are usually unknowable; and live next door to the children whom you are studying.

Despite the imposing roster of authors that Murchison assembled for the 1931 *Handbook of Child Psychology*, his achievement did not satisfy him for long. Barely 2 years later, Murchison put out a second edition, of which he wrote: "Within a period of slightly more than 2 years, this first revision bears scarcely any resemblance to the original *Handbook of Child Psychology*. This is due chiefly to the great expansion in the field during the past 3 years and partly to the improved insight of the editor" (Murchison, 1933, p. vii). The tradition that Murchison had brought to life was already evolving.

Murchison saw fit to provide the following warning in his second edition: "There has been no attempt to simplify, condense, or to appeal to the immature mind. This volume is prepared specifically for the scholar, and its form is for his maximum convenience" (Murchison, 1933, p. vii). It is likely that sales of Murchison's first volume did not approach textbook levels; perhaps he received negative comments regarding its accessibility.

Murchison exaggerated when he wrote that his second edition bore little resemblance to the first. Almost half of the chapters were virtually the same, with minor additions and updating. (For the record, though, despite Murchison's continued use of masculine phraseology, 10 of the 24 authors in the second edition were women.) Some of the authors whose original chapters were dropped were asked to write about new topics. So, for example, Goodenough wrote about mental testing rather than about children's drawings, and Gesell wrote a general statement of his maturational theory that went well beyond the twin studies.

But Murchison also made some abrupt changes. He dropped Anna Freud entirely, auguring the marginalization of psychoanalysis within academic psychology. Leonard Carmichael, who was later to play a pivotal role

in the *Handbook* tradition, made an appearance as author of a major chapter (by far the longest in the book) on prenatal and perinatal growth. Three other physiologically oriented chapters were added as well: one on neonatal motor behavior, one on visual-manual functions during the first 2 years of life, and one on physiological "appetites" such as hunger, rest, and sex. Combined with the Goodenough and Gesell shifts in focus, these additions gave the 1933 *Handbook* more of a biological thrust, in keeping with Murchison's long-standing desire to display the hard science backbone of the emerging field.

Leonard Carmichael was president of Tufts University when he organized Wiley's first edition of the *Handbook*. The switch from a university press to the long-established commercial firm of John Wiley & Sons was commensurate with Carmichael's well-known ambition; indeed, Carmichael's effort was to become influential beyond anything that Murchison might have anticipated. The book (one volume at that time) was called the *Manual of Child Psychology*, in keeping with Carmichael's intention of producing an "advanced scientific manual to bridge the gap between the excellent and varied elementary textbooks in this field and the scientific periodical literature" (Carmichael, 1946, p. viii).

The publication date was 1946, and Carmichael complained that "this book has been a difficult and expensive one to produce, especially under wartime conditions" (Carmichael, 1946, p. viii). Nevertheless, the project was worth the effort. The *Manual* quickly became the bible of graduate training and scholarly work in the field, available virtually everywhere that human development was studied. Eight years later, now head of the Smithsonian Institution, Carmichael wrote, in the preface to the 1954 second edition, "The favorable reception that the first edition received not only in America but all over the world is indicative of the growing importance of the study of the phenomena of the growth and development of the child" (Carmichael, 1954, p. vii).

Carmichael's second edition had a long life: Not until 1970 did Wiley bring out a third edition. Carmichael was retired by then, but he still had a keen interest in the book. At his insistence, his own name became part of the title of the third edition; it was called, improbably, *Carmichael's Manual of Child Psychology*, even though it had a new editor and an entirely different cast of authors and advisors. Paul Mussen took over as the editor, and once again the project flourished. Now a two-volume set,

the third edition swept across the social sciences, generating widespread interest in developmental psychology and its related disciplines. Rarely had a scholarly compendium become both so dominant in its own field and so familiar in related disciplines. The set became an essential source for graduate students and advanced scholars alike. Publishers referred to *Carmichael's Manual* as the standard against which other scientific handbooks were compared.

The fourth edition, published in 1983, was now redesignated by John Wiley & Sons to become once again the *Handbook of Child Psychology*. By then, Carmichael had passed away. The set of books, now expanded to four volumes, became widely referred to in the field as "the Mussen handbook."

WHAT CARMICHAEL CHOSE FOR THE NOW EMERGENT FIELD

Leonard Carmichael, who became Wiley's editor for the project in its now commercially funded and expanded versions (the 1946 and 1954 *Manuals*), made the following comments about where he looked for his all-important choices of content:

Both as editor of the *Manual* and as the author of a special chapter, the writer is indebted . . . [for] extensive excerpts and the use of other materials previously published in the *Handbook of Child Psychology, Revised Edition*. (1946, p. viii)

Both the *Handbook of Child Psychology* and the *Handbook of Child Psychology, Revised Edition*, were edited by Dr. Carl Murchison. I wish to express here my profound appreciation for the pioneer work done by Dr. Murchison in producing these handbooks and other advanced books in psychology. The *Manual* owes much in spirit and content to the foresight and editorial skill of Dr. Murchison. (1954, p. viii)

The first quote comes from Carmichael's preface to the 1946 edition, the second from his preface to the 1954 edition. We shall never know why Carmichael waited until the 1954 edition to add the personal tribute to Carl Murchison. Perhaps a careless typist dropped the laudatory passage from a handwritten version of the 1946 preface and its omission escaped Carmichael's notice. Or perhaps 8 years of further adult development increased Carmichael's generosity of spirit. (It also may be possible that Murchison or his family com-

plained.) In any case, Carmichael acknowledged the roots of his *Manuals*, if not always their original editor. His choice to start with those roots is a revealing part of the *Handbook's* history, and it established a strong intellectual legacy for our present-day descendants of the early pioneers who wrote for the Murchison and Carmichael editions.

Although Leonard Carmichael took the 1946 *Manual* in much the same direction established by Murchison back in 1931 and 1933, he did bring it several steps further in that direction, added a few twists of his own, and dropped a couple of Murchison's bolder selections. Carmichael first appropriated five Murchison chapters on biological or experimental topics, such as physiological growth, scientific methods, and mental testing. He added three new biologically oriented chapters on animal infancy, physical growth, and motor and behavioral maturation (a tour de force by Myrtal McGraw that instantly made Gesell's chapter in the same volume obsolete). Then he commissioned Wayne Dennis to write an adolescence chapter that focused exclusively on physiological changes associated with puberty.

On the subject of social and cultural influences in development, Carmichael retained five of the Murchison chapters: two chapters on environmental forces on the child by Kurt Lewin and by Harold Jones, Dorothea McCarthy's chapter on children's language, Vernon Jones's chapter on children's morality (now entitled "Character Development—An Objective Approach"), and Margaret Mead's chapter on "primitive" children (now enhanced by several spectacular photos of mothers and children from exotic cultures around the world). Carmichael also stayed with three other Murchison topics (emotional development, gifted children, and sex differences), but he selected new authors to cover them. But Carmichael dropped Piaget and Bühler.

Carmichael's 1954 revision, his second and final edition, was very close in structure and content to the 1946 *Manual*. Carmichael again retained the heart of Murchison's original vision, many of Murchison's original authors and chapter topics, and some of the same material that dated all the way back to the 1931 *Handbook*. Not surprisingly, the chapters that were closest to Carmichael's own interests got the most significant updating. Carmichael leaned toward the biological and physiological whenever possible. He clearly favored experimental treatments of psychological processes. Yet he still kept the social, cultural, and psychological analyses by Lewin, Mead, McCarthy, Terman, Harold Jones, and

Vernon Jones, and he even went so far as to add one new chapter on social development by Harold and Gladys Anderson and one new chapter on emotional development by Arthur Jersild.

The Murchison and Carmichael volumes make for fascinating reading, even today. The perennial themes of the field were there from the start: the nature-nurture debate; the generalizations of universalists opposed by the particularizations of contextualists; the alternating emphases on continuities and discontinuities during ontogenesis; and the standard categories of maturation, learning, locomotor activity, perception, cognition, language, emotion, conduct, morality, and culture—all separated for the sake of analysis, yet, as authors throughout each of the volumes acknowledged, all somehow inextricably joined in the dynamic mix of human development.

These things have not changed. Yet, much in the early editions is now irrevocably dated. Long lists of children's dietary preferences, sleeping patterns, elimination habits, toys, and somatic types look quaint and pointless through today's lenses. The chapters on children's thought and language were written prior to the great contemporary breakthroughs in neurology and brain/behavior research, and they show it. The chapters on social and emotional development were ignorant of the processes of social influence and self-regulation that soon would be revealed through attribution research and other studies in social psychology. Terms such as *cognitive neuroscience*, *neuronal networks*, *behavior genetics*, *social cognition*, *dynamic systems*, and *positive youth development* were of course unknown. Even Mead's rendition of the "primitive child" stands as a weak straw in comparison to the wealth of cross-cultural knowledge available in today's *cultural psychology*.

Most telling, the assortments of odd facts and normative trends were tied together by very little theory throughout the Carmichael chapters. It was as if, in the exhilaration of discovery at the frontiers of a new field, all the facts looked interesting in and of themselves. That, of course, is what makes so much of the material seem odd and arbitrary. It is hard to know what to make of the lists of facts, where to place them, which ones were worth keeping track of and which ones are expendable. Not surprisingly, the bulk of the data presented in the Carmichael manuals seems not only outdated by today's standards but, worse, irrelevant.

By 1970, the importance of theory for understanding human development had become apparent. Looking back

on Carmichael's last *Manual*, Paul Mussen wrote, "The 1954 edition of this *Manual* had only one theoretical chapter, and that was concerned with Lewinian theory which, so far as we can see, has not had a significant lasting impact on developmental psychology" (Mussen, 1970, p. x). The intervening years had seen a turning away from the norm of psychological research once fondly referred to as "dust-bowl empiricism."

The Mussen 1970 edition—or *Carmichael's Manual*, as it was still called—had a new look and an almost entirely new set of contents. The two-volume edition carried only one chapter from the earlier books, Carmichael's updated version of his own long chapter on the "Onset and Early Development of Behavior," which had made its appearance under a different title in Murchison's 1933 edition. Otherwise, as Mussen wrote in his preface, "It should be clear from the outset . . . that the present volumes are not, in any sense, a *revision* of the earlier editions; this is a completely new *Manual*" (Mussen, 1970, p. x).

And it was. In comparison to Carmichael's last edition 16 years earlier, the scope, variety, and theoretical depth of the Mussen volumes were astonishing. The field had blossomed, and the new *Manual* showcased many of the new bouquets that were being produced. The biological perspective was still strong, grounded by chapters on physical growth (by J. M. Tanner) and physiological development (by Dorothy Eichorn) and by Carmichael's revised chapter (now made more elegant by some excerpts from Greek philosophy and modern poetry). But two other cousins of biology also were represented, in an ethological chapter by Eckhard Hess and a behavior genetics chapter by Gerald McClearn. These chapters were to define the major directions of biological research in the field for at least the next 3 decades.

As for theory, Mussen's *Handbook* was thoroughly permeated with it. Much of the theorizing was organized around the approaches that, in 1970, were known as the "three grand systems": (1) Piaget's cognitive-developmentalism, (2) psychoanalysis, and (3) learning theory. Piaget was given the most extensive treatment. He reappeared in the *Manual*, this time authoring a comprehensive (and, some say, definitive) statement of his entire theory, which now bore little resemblance to his 1931/1933 sortings of children's intriguing verbal expressions. In addition, chapters by John Flavell, by David Berlyne, by Martin Hoffman, and by William Kessen, Marshall Haith, and Philip Salapatek all gave major treatments to one or another aspect of Piaget's

body of work. Other approaches were represented as well. Herbert and Ann Pick explicated Gibsonian theory in a chapter on sensation and perception, Jonas Langer wrote a chapter on Werner's organismic theory, David McNeill wrote a Chomskian account of language development, and Robert LeVine wrote an early version of what was soon to become "culture theory."

With its increased emphasis on theory, the 1970 *Manual* explored in depth a matter that had been all but neglected in the book's previous versions: the mechanisms of change that could account for, to use Murchison's old phrase, "the problem of how the infant becomes an adult psychologically." In the process, old questions such as the relative importance of nature versus nurture were revisited, but with far more sophisticated conceptual and methodological tools.

Beyond theory building, the 1970 *Manual* addressed an array of new topics and featured new contributors: peer interaction (Willard Hartup), attachment (Eleanor Maccoby and John Masters), aggression (Seymour Feshback), individual differences (Jerome Kagan and Nathan Kogan), and creativity (Michael Wallach). All of these areas of interest are still very much with us in the new millennium.

If the 1970 *Manual* reflected a blossoming of the field's plantings, the 1983 *Handbook* reflected a field whose ground cover had spread beyond any boundaries that could have been previously anticipated. New growth had sprouted in literally dozens of separate locations. A French garden, with its overarching designs and tidy compartments, had turned into an English garden, a bit unruly but glorious in its profusion. Mussen's two-volume *Carmichael's Manual* had now become the four-volume Mussen *Handbook*, with a page-count increase that came close to tripling the 1970 edition.

The grand old theories were breaking down. Piaget was still represented by his 1970 piece, but his influence was on the wane throughout the other chapters. Learning theory and psychoanalysis were scarcely mentioned. Yet the early theorizing had left its mark, in vestiges that were apparent in new approaches, and in the evident conceptual sophistication with which authors treated their material. No return to dust bowl empiricism could be found anywhere in the set. Instead, a variety of classical and innovative ideas were coexisting: Ethology, neurobiology, information processing, attribution theory, cultural approaches, communications theory, behavioral genetics, sensory-perception models, psycholinguistics, sociolinguistics, discontinuous stage theories, and continuous memory theories all took their places, with none

quite on center stage. Research topics now ranged from children's play to brain lateralization, from children's family life to the influences of school, day care, and disadvantageous risk factors. There also was coverage of the burgeoning attempts to use developmental theory as a basis for clinical and educational interventions. The interventions usually were described at the end of chapters that had discussed the research relevant to the particular intervention efforts, rather than in whole chapters dedicated specifically to issues of practice.

This brings us to the efforts under the present editorial team: the *Handbook's* fifth and sixth editions (but really the seventh and eighth editions, if the germinal two pre-Wiley Murchison editions are counted). I must leave it to future commentators to provide a critical summation of what we have done. The volume editors have offered introductory and/or concluding renditions of their own volumes. I will add to their efforts here only by stating the overall intent of our design and by commenting on some directions that our field has taken in the years from 1931 to 2006.

We approached our editions with the same purpose that Murchison, Carmichael, and Mussen before us had shared: "to provide," as Mussen wrote, "a comprehensive and accurate picture of the current state of knowledge—the major systematic thinking and research—in the most important research areas of the psychology of human development" (Mussen, 1983, p. vii). We assumed that the *Handbook* should be aimed "specifically for the scholar," as Murchison declared, and that it should have the character of an "advanced text," as Carmichael defined it. We expected, though, that our audiences may be more interdisciplinary than the readerships of previous editions, given the greater tendency of today's scholars to cross back and forth among fields such as psychology, cognitive science, neurobiology, history, linguistics, sociology, anthropology, education, and psychiatry. We also believed that research-oriented practitioners should be included under the rubric of the "scholars" for whom this *Handbook* was intended. To that end, for the first time in 1998 and again in the present edition, we devoted an entire volume to child psychology in practice.

Beyond these very general intentions, we have let chapters in the *Handbook's* fifth and sixth editions take their own shape. We solicited the chapters from authors who were widely acknowledged to be among the leading experts in their areas of the field, although we know that, given an entirely open-ended selection process and

no limits of budget, we would have invited a large number of other leading researchers whom we did not have the space—and thus the privilege—to include. With very few exceptions, every author whom we invited agreed to accept the challenge. Our only real, and great, sadness was to hear of the passing of several authors from the 1998 edition prior to our assembly of the present edition. Where possible, we arranged to have their collaborators revise and update their chapters.

Our directive to authors was simple: Convey your area of the field as you see it. From then on, the authors took center stage—with, of course, much constructive feedback from reviewers and volume editors. No one tried to impose a perspective, a preferred method of inquiry, or domain boundaries on any of the chapters. The authors expressed their views on what researchers in their areas attempt to accomplish, why they do so, how they go about it, what intellectual sources they draw on, what progress they have made, and what conclusions they have reached.

The result, in my opinion, is still more glorious profusion of the English garden genre, but perhaps contained a bit by some broad patterns that have emerged over the past decade. Powerful theoretical models and approaches—not quite unified theories, such as the three grand systems—have begun once again to organize much of the field’s research and practice. There is great variety in these models and approaches, and each is drawing together significant clusters of work. Some have been only recently formulated, and some are combinations or modifications of classic theories that still have staying power.

Among the formidable models and approaches that the reader will find in this *Handbook* are the dynamic system theories, the life span and life course approaches, cognitive science and neuronal models, the behavior genetics approach, person-context interaction theories, action theories, cultural psychology, and a wide assortment of neo-Piagetian and neo-Vygotskian models. Although some of these models and approaches have been in the making for some time, they have now come into their own. Researchers are drawing on them directly, taking their implied assumptions and hypotheses seriously, using them with specificity and control, and exploiting their implications for practice.

Another pattern that emerges is a rediscovery and exploration of core processes in human development that had been underexamined by the generation of researchers just prior to the present one. Scientific interest

has a way of moving in alternating cycles (or spirals, for those who wish to capture the progressive nature of scientific development). In our time, developmental study has cycled away from classic topics such as motivation and learning—not in the sense that they were entirely forgotten, or that good work ceased to be done in such areas, but in the sense that they no longer were the most prominent subjects of theoretical reflection and debate. Some of the relative neglect was intentional, as scholars got caught up in controversies about whether psychological motivation was a “real” phenomenon worthy of study or whether learning could or should be distinguished from development in the first place. All this has changed. As the contents of our current edition attest, developmental science always returns, sooner or later, to concepts that are necessary for explaining the heart of its concerns, progressive change in individuals and social groups over time, and concepts such as learning and motivation are indispensable for this task. Among the exciting features of this *Handbook* edition are the advances it presents in theoretical and empirical work on these classic concepts.

The other concept that has met some resistance in recent years is the notion of development itself. For some social critics, the idea of progress, implicit in the notion of development, has seemed out of step with principles such as equality and cultural diversity. Some genuine benefits have accrued from that critique; for example, the field has worked to better appreciate diverse developmental pathways. But, like many critique positions, it led to excesses. For some, it became questionable to explore issues that lie at the heart of human development. Growth, advancement, positive change, achievement, and standards for improved performance and conduct, all were questioned as legitimate subjects of investigation.

Just as in the cases of learning and motivation, no doubt it was inevitable that the field’s center of gravity sooner or later would return to broad concerns of development. The story of growth from infancy to adulthood is a developmental story of multifaceted learning, acquisitions of skills and knowledge, waxing powers of attention and memory, growing neuronal and other biological capacities, formations and transformations of character and personality, increases and reorganizations in the understanding of self and others, advances in emotional and behavioral regulation, progress in communicating and collaborating with others, and a host of other achievements documented in this edition. Parents, teachers, and

other adults in all parts of the world recognize and value such developmental achievements in children, although they do not always know how to understand them, let alone how to foster them.

The sorts of scientific findings that the *Handbook*'s authors explicate in their chapters are needed to provide such understanding. The importance of sound scientific understanding has become especially clear in recent years, when news media broadcast story after story based on simplistic and biased popular speculations about the causes of human development. The careful and responsible discourse found in these chapters contrasts sharply with the typical news story about the role of parents, genes, or schools in children's growth and behavior. There is not much contest as to which source the public looks to for its information and stimulation. But the good news is that scientific truth usually works its way into the public mind over the long run. The way this works would make a good subject for developmental study some day, especially if such a study could find a way to speed up the process. In the meantime, readers of this edition of the *Handbook of Child Psychology* will find the most solid, insightful

and current set of scientific theories and findings available in the field today.

Acknowledgments

A work as significant as the *Handbook of Child Psychology* is always produced by the contributions of numerous people, individuals whose names do not necessarily appear on the covers or spines of the volumes. Most important, we are grateful to the more than 150 colleagues whose scholarship gave life to the Sixth Edition. Their enormous knowledge, expertise, and hard work make this edition of the *Handbook* the most important reference work in developmental science.

In addition to the authors of the chapters of the four volumes of this edition, we were fortunate to have been able to work with two incredibly skilled and dedicated editors within the Institute for Applied Research in Youth Development at Tufts University, Jennifer Davison and Katherine Connery. Their “can-do” spirit and their impressive ability to attend to every detail of every volume were invaluable resources enabling this project to be completed in a timely and high quality manner.

It may be obvious, but we want to stress also that without the talent, commitment to quality, and professionalism of our editors at John Wiley & Sons, this edition of the *Handbook* would not be a reality and would not be the cutting-edge work we believe it to be. The breadth of the contributions of the Wiley staff to the *Handbook* is truly enormous. Although we thank all these colleagues for their wonderful contributions, we wish to make special note of four people in particular: Patricia Rossi, Senior Editor, Psychology, Linda Witzling, Senior Production Editor, Isabel Pratt, Associate Editor, and Peggy Alexander, Vice President and Publisher. Their creativity, professionalism, sense of balance and perspective, and unflagging commitment to the tradition of quality of the *Handbook* were vital ingredients for any success we may have with this edition. We are also deeply grateful to Pam Blackmon and her

colleagues at Publications Development Company for undertaking the enormous task of copy editing and producing the thousands of pages of the Sixth Edition. Their professionalism and commitment to excellence were invaluable resources and provided a foundation upon which the editors’ work was able to move forward productively.

Child development typically happens in families. So too, the work of editors on the *Handbook* moved along productively because of the support and forbearance of spouses, partners, and children. We thank all of our loved ones for being there for us throughout the several years on which we have worked on the Sixth Edition.

Numerous colleagues critiqued the chapters in manuscript form and provided valuable insights and suggestions that enhanced the quality of the final products. We thank all of these scholars for their enormous contributions.

William Damon and Richard M. Lerner thank the John Templeton Foundation for its support of their respective scholarly endeavors. In addition, Richard M. Lerner thanks the National 4-H Council for its support of his work. Nancy Eisenberg thanks the National Institute of Mental Health, the Fetzer Institute, and The Institute for Research on Unlimited Love—Altruism, Compassion, Service (located at the School of Medicine, Case Western Reserve University) for their support. K. Ann Renninger and Irving E. Sigel thank Vanessa Ann Gorman for her editorial support for Volume 4. Support from the Swarthmore College Provost’s Office to K. Ann Renninger for editorial assistance on this project is also gratefully acknowledged.

Finally, in an earlier form, with Barbara Rogoff’s encouragement, sections of the preface were published in *Human Development* (April 1997). We thank Barbara for her editorial help in arranging this publication.

Preface to Volume Two

Cognition, Perception, and Language

DEANNA KUHN and ROBERT S. SIEGLER

When we were approached about beginning work on the sixth edition of the *Handbook of Child Psychology*, the two of us had the same startled reaction: “What?” It seemed not that long ago that we had regained our stride after the rush of attention devoted to completing the fifth edition, and we couldn’t believe it was time to start again. Now, another 3 years has passed, and once again we are in the final phases of completing the manuscript for the volume, this time the sixth edition; at this point, we have greater appreciation for the timeliness and value of a new edition that will appear 8 years after the previous one.

The field is growing at a prodigious rate. The number of specialized journals has increased as the field itself not only grows but becomes more segmented and specialized. New journals target a much narrower range of authors and readers than do the traditional journals *Child Development* and *Developmental Psychology*. Few researchers claim expertise and a command of the relevant literature in more than a very few subfields.

In this climate, high-quality *Handbook* chapters, written by leaders in their specialties, serve a very important function. They offer an efficient and effective means to escape the tunnel vision that has become an academic occupational hazard. The danger is that of becoming increasingly focused on one’s own narrow specialty until it absorbs all one’s awareness. Access to broad, integrative *Handbook* chapters reduces the likelihood of the field becoming a collection of diligent scholars who know more and more about less and less, their own work ultimately diminished by lack of nourishment from analogous themes, insights, and questions that emerge in other areas.

The present volume offers such a set of broad, integrative contributions. Although the interval between

publication of the 5th and 6th editions of the *Handbook* is only half as long as the interval between the 4th and 5th editions, there certainly seemed to be as much new material to be examined in this edition as there had in the previous one, again perhaps a reflection of the rapidly growing field but also a reflection of the new perspectives that are introduced. As volume editors we had a critical decision to make at the outset of planning the sixth edition—whether to ask authors of chapters in the fifth edition to update their chapters or whether to commission new chapters. We decided that we would commission all new chapters because there were so many important topics that had not been covered in the earlier edition and so many leading authorities with unique and important perspectives who had not previously contributed a chapter to this *Handbook*. Soliciting entirely new chapters also guaranteed freshly construed integrations from an early twenty-first-century vantage point for all chapters.

The Cognition, Language, and Perception volume of the sixth edition of the *Handbook of Child Psychology* contains 22 chapters, compared to 19 in the fifth edition. In a number of cases, chapters in the sixth edition represent new perspectives on literatures that were also included in the fifth edition—for example the chapters by Nelson, Thomas, and de Haan on neural bases of cognition, Kellman and Arterberry on infant visual perception, Adolph and Berger on motor development, Waxman and Lidz on early word learning, Halford and Andrews on problem solving and reasoning, and Cole on cognition in cultural context. Comparison of the corresponding chapters from the 1998 and current editions makes clear the value of offering readers a different perspective on the same research area. Comparison of the two editions

also makes clear that the chapters in the fifth edition are by no means obsolete; they continue to offer unique insights and integrative visions.

Soliciting new chapters also allowed us to include new topics that had not been the focus of chapters in the corresponding volume of the previous *Handbook* but that represent areas of growing importance in the field. These include Goldin-Meadow's chapter on nonverbal communication, Geary's chapter on mathematical development, Winner's chapter on development in the arts, Newcombe and Huttenlocher's chapter on spatial cognition, and Siegler's chapter on microgenetic studies of learning. The rapid growth of these areas, and the many intriguing theoretical debates within them, attests to the vigor of the field of child development.

Other differences between the current and the previous volume reflect a variety of other currents within the field and within the *Handbook*. We chose to omit two topics that were the subject of chapters in the previous edition: representation and individual differences. Both topics have become so fundamental that they warranted treatment within the context of almost all of the individual chapters, rather than being limited to a single chapter. We divided another topic—memory—into two chapters because a clear division has arisen between event memory, which is dominant in infancy and early childhood, and intentional, strategic memory, which becomes of critical interest in later childhood. Finally, chapters by two other authors—one on cognitive science and cognitive development by Frank Keil and one on exceptional cognitive development by Seana Moran and Howard Gardner—are new to the volume, although Keil and Gardner each contributed chapters to other volumes of the fifth edition of the *Handbook*.

We asked authors in the sixth edition to emphasize five themes. These themes help to unify the diverse topics covered in the volume. They are:

1. *The history of the area.* How has the study of your topic evolved over the years?
2. *The contemporary status of the topic.* Here you should feel free to express your own appropriately supported opinions, while acknowledging that others exist.
3. *An emphasis on mechanisms of change.* The time has passed when it is sufficient to describe development, and we must now seek to understand how this development occurs.

4. *An emphasis on individual differences.* How do children become so different from each other?
5. *Predictions and recommendations for the future with respect to your topic.*

All of our authors were conscientious and good humored about meeting deadlines and responding to suggestions for modifications, with the result that we had a final set of manuscripts in hand while all were still fresh and timely. This favorable set of circumstances gave us the opportunity to react to them as a whole. In this respect we would like to share several reactions. The major one connects to a remark that appeared in our earlier commentary in connection with the fifth edition, and that was the detection of a growing dissatisfaction with “task-bound” paradigms on the part of the chapters’ authors—in other words, lines of work whose explanatory power derives from a single experimental task. Such paradigms leave unanswered the question of whether their explanatory power extends at all beyond that particular research context.

In the present volume, we see more pronounced and multiple kinds of evidence of advances regarding task-bound paradigms. One form of evidence is the fact that the authors of many of the chapters bring multiple levels of explanation to bear on their topic and their more specific claims—neurological, biographical, anthropological, evolutionary, species comparative, and historical comparative, as well as behaviors amenable to more traditional examination in a laboratory. None of the authors looks to a single narrow form of evidence as exhaustive input for addressing the questions at hand. Tomasello, for example, emphasizes the impossibility of studying language development apart from the context of developing cognitive and social skills, and Cohen and Cashon argue that infant cognition research must incorporate neuroscience. And certainly, the combination of experimental and naturalistic methodologies is no longer unusual. At the level of the entire volume, the chapters added to the sixth edition are signs of a broadened perspective: Both nonverbal and aesthetic dimensions of cognitive development are included as offering valuable insight into what develops.

A second form of evidence is the number of authors who take an explicitly historical view. They decline to view their topic only in terms of the research paradigms most popular at the moment and instead ask how these

paradigms connect to ones in use at earlier times. Harris, for example, asks how current theory-of-mind research (and the particular false-belief task from which it arose) connects to research of several decades ago on role-taking and perspective-taking. Cohen and Cashon suggest that recent infant cognition research continues the study of object permanence and causality associated with Piaget's early work. Pressley and Hilden probe the connections between the current research they examine and early memory strategy research, while Kuhn and Franklin, Siegler, and Geary examine relations between contemporary and earlier classical learning research, and Kuhn and Franklin do the same with respect to adolescent cognition. Other authors, for example Tomasello, Newcombe and Huttenlocher, and Munakata, make explicit note of the limited explanatory power of constrained task formats.

A third and related form of evidence is the number of authors who take an extended view ontogenetically, as well as historically. In other words, even if their own area of investigation is largely limited to the early years of life, they ask what the later implications are or what further developmental course the investigated competencies may follow. Kuhn and Franklin's chapter explicitly takes the perspective of this later development, as does Moran and Gardner's, but the authors of a number of other chapters reflect their awareness that development does not stop, or cease to be interesting at age 3, or 5, or 10. Authors who have characteristically focused their attention on early development, such as Gelman and Kalish, Harris, and Bauer, now ask what might be expected in the years following early childhood. New-

combe and Huttenlocher remind us in their chapter of the value of this extended ontogenetic perspective—a value that is often overlooked in the current focus on searching for cognitive origins of competencies in the earliest years of life. Ultimately, we can only fully understand a competency to the extent that we understand where it is headed, that is, understand its mature state. As Saffran, Werker, and Werner make clear, this often entails research investigating the nature of adult competencies.

Fourth, and finally, we see in these chapters an awareness that new, enriched perspectives, and new forms of evidence, brought to bear on a topic have the potential to provide new insights into old questions, questions that may have been regarded as at a standstill. Keil makes this point explicitly in his chapter in arguing for an expanded interdisciplinary approach. But this same awareness is reflected in other chapters as well. Like Tomasello, who draws our attention to individual differences, Newcombe and Huttenlocher note that individual differences, long regarded by many simply as nuisance variance to be avoided, to the contrary stand to provide insight into the fundamental nature of the common competencies and developmental pathways that are of interest.

We are privileged to have worked with this exceptional set of authors and thank them for their dedication to their task and their contribution to the final product. We have said enough that we should at this point conclude our own remarks and let the authors speak for themselves.

THE FUTURE OF DEVELOPMENTAL COGNITIVE NEUROSCIENCE	44
REFERENCES	45

The goal of this chapter is to review what is known about the neural bases of cognitive development. We begin by discussing why developmental psychologists might be interested in the neural bases of behavior (with particular reference to cognitive development). Having established the value of viewing child development through the lens of the developmental neurosciences, we provide an overview of brain development. This is followed by a

The writing of this chapter was made possible, in part, by grants from the NIH to the first author (NS34458, NS329976), and from the John D. and Catherine T. MacArthur Foundation (through their funding of a research network on *Early Experience and Brain Development*) and to the second author from the NIMH (MH02024). The first author wishes to thank Lisa Benz for assistance in literature reviews, Eric Knudsen for sharing his insights into neural plasticity, and members of the Laboratory of Developmental Cognitive Neuroscience.

discussion of how experience influences the developing—and when appropriate, developed—brain. Within this discussion on experience-dependent changes in brain development, we briefly touch on two issues we consider to be essential for all developmental psychologists: whether the mechanisms that underlie developmental plasticity differ from those that underlie adult plasticity, and more fundamentally, what distinguishes plasticity from development.

With this basic neuroscience background behind us, we turn our attention to specific content areas, limiting ourselves to domains in which there is a corpus of knowledge about the neural underpinnings of cognitive development. We discuss learning and memory, face/object recognition, attention/executive functions, and spatial cognition, including illustrative examples from both typical and atypical development. We conclude the chapter

with a discussion of the future of developmental cognitive neuroscience.

WHY DEVELOPMENTAL PSYCHOLOGISTS SHOULD BE INTERESTED IN NEUROSCIENCE

Prior to the ascendancy of Piagetian theory, the field of cognitive development, such as it was, was dominated by behaviorism (for discussion, see Goldman-Rakic, 1987; Nelson & Bloom, 1997). As students of the history of psychology are well aware, behaviorism eschewed the nonobservable; therefore, the study of the neural bases of behavior was not pursued for the simple reason that neural processes could not be observed. Through the 1950s and 1960s, Piagetian theory gradually came to replace behaviorism as the dominant theory of cognitive development. Despite being a biologist by training, Piaget and, subsequently, his followers primarily concerned themselves with developing a richly detailed cognitive architecture of the mind—albeit a brainless mind. We do not mean this in a pejorative sense, but rather, to imply that the zeitgeist of the time was to develop elegant models of cognitive structures, with little regard for (a) whether such structures were biologically plausible or (b) the neurobiological underpinnings of such structures. (At that time, there was no way to observe the living child's brain directly.) Throughout the late 1970s and into the last decade of the twentieth century, neo- and non-Piagetian approaches came into favor. Curiously, a prominent theme of a number of investigators writing during this time was that of *nativism*; we say curiously because inherent in nativism is the notion of biological determinism, yet those touting a nativist perspective rarely if ever grounded their models and data in biological reality. It was not until the mid-1990s that neurobiology began to be inserted into a discussion of cognitive development, as reflected in Mark Johnson's eloquent contribution to this *Handbook*'s fifth edition (Johnson, 1998). This perspective has become more commonplace, although the field of developmental cognitive neuroscience is still in its infancy. (For recent overviews of this field generally, see de Haan & Johnson, 2003a; Nelson & Luciana, 2001.) Moreover, we have observed that it is still not clear to many developmental psychologists why they should be interested in the brain. This is the topic to which we next direct our attention.

Our major argument in this regard is that our understanding of cognitive development will improve as the mechanisms that underlie development are elucidated. This, in turn, should permit us to move beyond the descriptive, black box level to the level at which the actual cellular, physiologic, and eventually, genetic machinery will be understood—the mechanisms that underlie development. An example follows.

A number of distinguished cognitive developmentalists and cognitive theorists have proposed or at least implied that elements of number concept (Wynn, 1992; Wynn, Bloom, & Chiang, 2002), object permanence (Baillargeon, 1987; Baillargeon, Spelke, & Wasserman, 1985; Spelke, 2000), and perhaps face recognition (Farah, Rabinowitz, Quinn, & Liu, 2000) reflect what we refer to as experience-independent functions; that is, they reflect inborn traits (presumably coded in the genome) that do not require experience to emerge. We see several problems with this perspective. First, these arguments seem biologically implausible because they represent sophisticated cognitive abilities; if they were coded in the genome, they would surely be polygenic traits and would not reflect the action of a single gene. Given that we now know the human genome consists of approximately 30,000 to 40,000 genes, it seems highly unlikely that we could spare the genes to separately code for number concept, object permanence, or face recognition. After all, those 40,000 genes must be involved in myriad other events (e.g., the general operation of the body as a whole) far more important than subserving these aspects of cognitive development.

A second concern about this nativist perspective is that it is not developmental. To say something is innate essentially closes the door to any discussion of mechanism. More problematic is that genes do not cause behaviors; rather, genes express proteins that in turn work their magic through the brain. It seems unlikely that behaviors that are not absolutely essential to survival (of the species, not the individual) have been directly coded in the genome, given the limited number of genes that are known to exist. Far more likely is that these behaviors are subserved by discrete or distributed neural circuits in the brain. And, these circuits, in turn, most likely vary in the extent to which they depend on experience or activity for their subsequent elaboration.

We make three general points: (1) The “value added” of thinking about behavior in the context of neurobiology is that doing so provides biological plausibility to our models of behavior (to be discussed further later).

(2) Viewing behavioral development through the lens of neuroscience may shed light on the mechanism(s) underlying behavior and behavioral development, thereby moving us beyond the descriptive level to the process level. (3) When we insert the molecular biology of brain development into the equation, a more holistic view of the child becomes possible—genes, brain, and behavior. This, in turn, permits us to move beyond simplistic notions of gene-environment interactions to talk about the influence of specific experiences on specific neural circuits, which in turn influence the expression of particular genes, which influence how the brain functions and how the child behaves.

BRAIN DEVELOPMENT AND NEURAL PLASTICITY: A PRÉCIS TO BRAIN DEVELOPMENT

Before discussing the details of neural development, it is important to understand that brain development, at the species level, has been shaped over many thousands of generations by selective pressures that drive evolution. According to Knudsen (2003b), this portion of biological inheritance is responsible for nearly all the genetic influences that shape the development and function of the nervous system, the majority of which have proven to be adaptive for the success of any given species. These influences determine both the properties of individual neurons and the patterns of neural connections. As a result, these selective pressures delimit an individual's cognitive, emotional, sensory, and motor capabilities.

There is, however, a small portion of biological inheritance that is unique to the individual, resulting from the novel combination of genes that the child receives from the parents. Because there is no history to this gene pattern, any new phenotype that is produced has never been subjected to the forces of natural selection and is unlikely to confer any selective advantage for that individual. However, this small portion of biological inheritance is particularly important for driving evolutionary change, as novel combinations of genes or mutations that do confer a selective advantage will increase in the gene pool, while those that result in maladaptive phenotypes will die out (Knudsen, 2003a, 2003b).

The brain develops according to a complex array of genetically programmed influences. These include

both molecular and electrical signals that arise spontaneously in growing neural networks. By *spontaneously*, we mean signals that are inherent in the circuitry and are entirely independent of any outside influence. These molecular and electrical signals establish neural pathways and patterns of connections that are remarkably precise and that make it possible for animals to carry out discrete behaviors beginning immediately after birth. They also underlie instinctive behaviors that may appear much later in life, often associated with emotional responses, foraging, sex, and social interactions. Beyond the scope of this chapter, but certainly worth considering, is which human behaviors fall into this category of “instinctive.” Our bias is that these are most likely going to be behaviors that have enormous implications for survival or reproductive fitness, such as the ability to experience fear, to avoid predators or to experience pleasure and conversely, the reduction of displeasure, to become attached to a caregiver.

To return to our discussion of nativism, there is no question that genetics has an enormous influence over who we are. To a large extent, human characteristics reflect evolutionary learning, which is exhibited in patterns of neural connections and interactions that have been shaped adaptively by evolution over thousands of generations. In addition to adaptive capacities, however, genetics (through mutations) can lead to deficits in brain function, such as impairments of sensation, cognition, emotion, and movement. We provide examples of both in subsequent sections of this chapter.

Genes specify the properties of neurons and neural connections to different degrees in different pathways and at different computational levels. On one hand, the extent of genetic determination reflects the degree to which the information processed at a particular connection is predictable from one generation to the next. On the other hand, because many aspects of an individual's world are not predictable, the brain's circuitry must rely on experience to customize connections to serve the needs of the individual. Experience shapes these neural connections and interactions but always within the constraints imposed by genetics.

Brain Development

The construction and development of the human brain occurs over a very protracted period beginning shortly after conception and, depending on how we view the end of

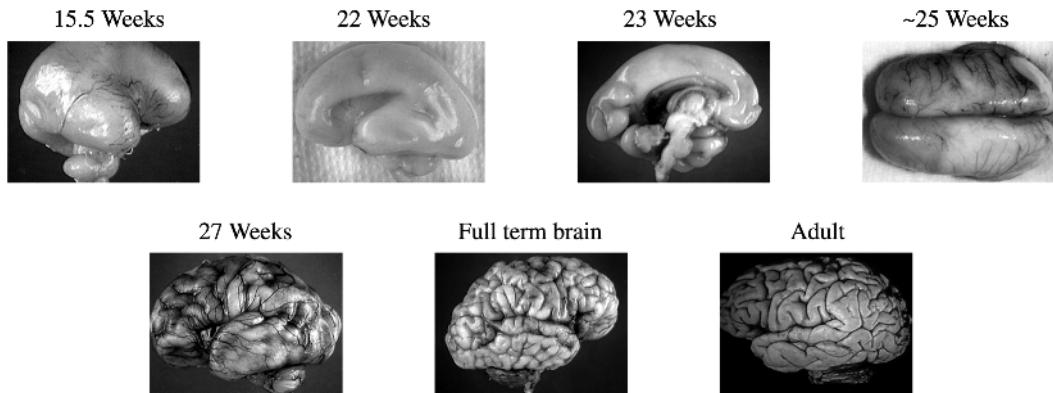

Figure 1.1 Overview of human brain development, beginning the 15th prenatal week and continuing to term and then adult.

development, continuing through at least the end of adolescence (for overviews, see Figure 1.1 and Table 1.1).

Shortly after conception, embryonic tissue forms from the two-celled zygote (specifically, from the blastocyst, the ball of cells created through multiplying cells). The outer layer of the embryo gives rise to, among other things, the central (brain and spinal cord) and peripheral nervous systems. It is this outermost layer we will be concerned with in this chapter.

Neural Induction and Neurulation—Typical Development

The process of transforming the undifferentiated tissue lining the dorsal side of the ectoderm into nervous system tissue is referred to as *neural induction*. In contrast, the dual processes called primary and secondary *neurulation* refer to the further differentiation of this neural tissue into, respectively, the brain and the spinal cord (for recent review of neural induction and neurulation, see Lumsden & Kintner, 2003).

The thin layer of undifferentiated tissue that lines the ectoderm is gradually transformed into an increasingly thick layer of tissue that will become the *neural plate*. A class of chemical agents referred to as transforming growth factors is responsible for the subsequent transformation of this undifferentiated tissue into nervous system tissue (Murloz-Sanjuan & Brivanfou, 2002). What one observes morphologically is the shift from neural plate to neural tube. Specifically, the neural plate buckles, forming a crease down its longitudinal axis. The tissue then folds inward, the edges rise up, and a tube is formed. This process begins on approximately Day 22 of gestation (Keith, 1948), fusing first at the midsection and progressing outward in either direc-

tion until approximately Day 26 (Sidman & Rakic, 1982). The rostral portion of the tube eventually forms the brain, and the caudal portion develops into the spinal cord.

Cells trapped inside the tube typically go on to comprise the central nervous system (CNS); however, there is a cluster of cells trapped between the outside of the neural tube and the dorsal portion of the ectodermal wall that is referred to as the *neural crest*. Neural crest cells typically develop into the autonomic nervous system (ANS).

A fair amount is now known about the genes that regulate many aspects of brain development, including neurulation. Much of this knowledge is based on studies of invertebrates and vertebrates, in which alterations in morphogenesis are observed after genes are selectively deleted (“knock-out”) or in a more recently developed method, added (“knock-in”). Although at first glance, one might be suspicious about the generalizability of such work to the human, reassurance can be found in the observation that humans share more than 61% of their genes with fruit flies and 81% with mice. Of course, not everything we know is based on animal models: Increasingly our knowledge of the molecular biology of brain development is based on careful genetic analysis of nervous system tissue that has failed to develop correctly.

The patterning of the neuroaxis (i.e., head to tail) is for the most part completed by about the 5th prenatal week. Based on mouse studies, many of the transcription factors¹ responsible for this process are well known. As reviewed by Levitt (2003), some of the genes involved

¹Transcription factors refer to the regulation of the proteins involved in the transcription of other genes.

TABLE 1.1 Neurodevelopmental Timeline from Conception through Adolescence

Developmental Event	Timeline	Overview of Developmental Event
Neurulation	18–24 prenatal days	Cells differentiate into one of three layers: endoderm, mesoderm, and ectoderm, which then form the various organs in the body. The neural tube (from which the central nervous system is derived) develops from the ectoderm cells; the neural crest (from which the autonomic nervous system is derived) lies between the ectodermal wall and the neural tube.
Neuronal migration	6–24 prenatal weeks	Neurons migrate at the ventricular zone along radial glial cells to the cerebral cortex. The neurons migrate in an inside-out manner, with later generations of cells migrating through previously developed cells. The cortex develops into six layers.
Synaptogenesis	3rd trimester–adolescence	Neurons migrate into the cortical plate and extend apical and basilar dendrites. Chemical signals guide the developing dendrites toward their final location, where synapses are formed with projections from subcortical structures. These connections are strengthened through neuronal activity, and connections with very little activity are pruned.
Postnatal neurogenesis	Birth–adulthood	The development of new cells in several brain regions, including: –Dentate gyrus of the hippocampus –Olfactory bulb –Possibly cingulate gyrus; regions of parietal cortex
Myelination	3rd trimester–middle age	Neurons are enclosed in a myelin sheath, resulting in an increased speed of action potentials.
Gyrification	3rd trimester–adulthood	The smooth tissue of the brain folds to form gyri and sulci.
Structural development of the prefrontal cortex	Birth–late adulthood	The prefrontal cortex is the last structure to undergo gyrification during uterine life. The synaptic density reaches its peak at 12 months; however, myelination of this structure continues into adulthood.
Neurochemical development of the prefrontal cortex	Uterine life–adolescence	All major neurotransmitter systems undergo initial development during uterine life and are present at birth. Although it is not well studied in humans, it is thought that most neurotransmitter systems do not reach full maturity until adulthood.

in dorsal patterning include members of the emx, Pax, and ihx families of genes, whereas nkh and dlx gene families may play a role in ventral patterning.

Atypical Development

Unfortunately, errors do occur in neural induction and neurulation. *Neural tube defects* are disorders of primary neurulation and include *craniorachischisis totalis* (in which there is a total failure of neural induction), *anencephaly* (where the anterior portion of the neural tube fails to close completely), *holoprosencephaly* (where there is one undifferentiated forebrain, rather than a forebrain that has two halves), and most commonly, *myelomeningocele* (where the posterior portion of the neural tube fails to close normally). Holoprosencephaly appears to be due to mutations in the sonic hedgehog transcription factor (ZIC2 genes; e.g., S. A. Brown et al., 1998), whereas myelomeningocele (also referred

to as *spina bifida*) may be due to mutations in the Pax1 gene (Hof et al., 1996). Importantly, neural tube defects generally have been associated with a deficiency of folic acid, and supplementing the diet of pregnant women with this nutrient appears to have reduced the incidence of these disorders in the general population.

Proliferation

Once the neural tube has closed, cell division leads to a massive proliferation of new neurons (neurogenesis), generally beginning in the 5th prenatal week, and peaking between the 3rd and 4th prenatal months (Volpe, 2000; for review, see Bronner-Fraser & Hatten, 2003). The term *massive* barely captures this process. It has been estimated, for example, that at its peak, several hundred thousand new nerve cells are generated *each minute* (M. Brown, Keynes, & Lumsden, 2001). Proliferation begins in the innermost portion of the neural

tube, referred to as the ventricular zone (Chenn & McConnell, 1995), a region that is derived from the subependymal location that lines the neural tube. In a process called *interkinetic nuclear migration*, new neural cells travel back and forth between the inner and outer portions of the ventricular zone. The new cell first travels toward the outer portion of the ventricular zone—the so-called S phase of mitosis—where DNA is synthesized, creating a duplicate copy of the cell. Once the S phase has been completed, the cell migrates downward toward the innermost portion of the ventricular zone where it divides into two cells (for a generally accessible description of these phases, see Takahashi, Nowakowski, & Caviness, 2001). Each of these new cells then begins the process again. As cells divide, a new zone is created, the marginal zone, which contains processes (axons and dendrites) from the cells of the ventricular zone. During the second phase of proliferation, neurons actually begin to form. However, for each dividing cell, only one daughter cell will continue to divide; the nondividing cell goes on to migrate to its final destination (Rakic, 1988).

Before turning to disorders of proliferation, three points should be noted. First, with the exception of cells that comprise the olfactory bulb, the dentate region of the hippocampus, and possibly regions of the neocortex, virtually every one of the estimated 100 billion neurons we possess (Naegele & Lombroso, 2001) are of prenatal origin (see section on postnatal neurogenesis); glia follow this same general pattern, although the development of glia (with the exception of radial glial cells; see section on migration that follows) lags somewhat behind neuronal development. What needs to be underscored about this observation is its importance in the context of plasticity: Unlike all other cells, the brain *generally* does not make new neurons after birth, which means that the brain does not repair itself in response to injury or disease by making new neurons.

Second, as cells continue to proliferate, the general shape of the neural tube undergoes a dramatic transformation—specifically, three distinct vesicles are formed: the *proencephalon* (forebrain), *mesencephalon* (midbrain), and *rhombencephalon* (hindbrain). Further proliferation leads to the proencephalon splitting into the *telencephalon*, which will give rise to the cerebral hemispheres, and the *diencephalon*, which gives rise to the thalamus and hypothalamus. The rhombencephalon will in turn give rise to the metencephalon (from which the pons and cerebellum are derived) and the myel-

cephalon (which will give rise to the medulla). The mesencephalon gives rise to the midbrain.

Finally, our knowledge of the molecular biology of cell proliferation is gradually advancing. The *Foxg1* gene has been implicated in this process (Hanashima, Li, Shen, Lai, & Fishell, 2004), but undoubtedly many other genes are involved as well.

Disorders of Neurogenesis

There are a number of examples of errors of cell proliferation, although most fall into two categories: microencephaly (small brain) and macroencephaly (large brain; see Volpe, 2000). Microencephaly is generally thought to occur during the asymmetric period of cell division, generally the 6th through 18th weeks of gestation. The cause of the microencephalies can be either genetic or environmental; examples of the latter include rubella, irradiation, maternal alcoholism, excessive vitamin A, and human immunodeficiency virus (e.g., Kozlowski et al., 1997; Warkany, Lemire, & Cohen, 1981). Macroencephaly is generally thought to be due to an underlying genetic disorder; for example, if genes that regulate normal cellular proliferation do not turn off, this failure could lead to an overproduction of new cells. Assuming survival, both micro- and macroencephaly generally lead to varying degrees of mental and physical retardation/impairment.

Postnatal Neurogenesis

With the exception of cells in the olfactory bulb, it was assumed until recently that the nervous system at birth had virtually all the neurons it would ever have, and that no new neurons were added. Like many aspects of neuroscience, we have now had to revise this view, due in part to the advent of new methods—specifically, the use of new staining methods for looking at DNA turnover (e.g., 5'-Bromo-2-deoxyuridine [BrdU]). Based on work with both human (e.g., Gage, 2000) and nonhuman primates (e.g., Bernier, Bédard, Vinet, Lévesque, & Parent, 2002; Gould, Beylin, Tanapat, Reeves, & Shors, 1999; Kornack & Rakic, 1999) and rodents (Gould et al., 1999), there is now widespread agreement that in certain regions of the brain, new cells are added for many years after birth. Where this agreement breaks down is in determining precisely which regions experience this postnatal birth of new neurons. There is little controversy that the dentate gyrus of the hippocampus experiences this process; controversy exists, however, concerning regions of the neocortex, such as the cingulate gyrus and

segments of the parietal cortex (for review and discussion, see Gould & Gross, 2002). There is also a recent report of postnatal neurogenesis in the amygdala, piriform cortex, and inferior temporal cortex in nonhuman primates (Bernier et al., 2002), although to date these findings have not been replicated (for a highly readable review of postnatal neurogenesis generally, see Barinaga, 2003).

Particularly relevant to this chapter is the observation that the addition of such cells can be influenced by experience (e.g., Gould et al., 1999; Mirescu, Peters, & Gould, 2004). For example, the number of cells produced in the rodent dentate gyrus is increased when rats are placed in contexts in which demands are placed on learning and memory. Similarly, the presence of the hormone prolactin in pregnant rats appears to increase the number of new cells in the forebrain subventricular zone. Because this zone gives rise to olfactory neurons, it has been assumed that this adaptive response may facilitate olfactory recognition of offspring (see Shingo et al., 2003). In contrast, stress in adulthood (e.g., the presence of novel odors such as the smell of a fox) appears to down-regulate neurogenesis in the rat dentate gyrus. Moreover, when rodents are housed together, dominance hierarchies develop, and the dominant animals produce more new neurons than the nondominant animals (Gould, 2003). Interestingly, if these same animals are then housed in complex environments (see subsequent section on plasticity), there is an up-regulation of neurogenesis in the dentate, although the dominant animals continue to fare better than the nondominant animals. Finally, inflammation (which commonly occurs following brain injury) can lead to a down-regulation of dentate hippocampal cells (Ekdahl, Claassen, Bonde, Kokaia, & Lindvall, 2003). Collectively, experience appears to have a profound influence on postnatal neurogenesis.

Postnatally derived cells may differ in several respects from prenatally derived cells. For example, the former differentiate and appear to be normal in all respects, although these cells may have a relatively short half-life (Gould, Vail, Wagers, & Gross, 2001). Furthermore, it is not yet clear how such cells might work their way into existing synaptic circuits (although Song, Stevens, & Gage, 2002, have demonstrated that postnatally derived cells both express neurotransmitter and form synaptic connections, which is a requirement for cell functioning). Finally, this revised view of neurogenesis is not without its critics (e.g., Rakic, 2002a,

2002b). (For an enlightened discussion of this topic, the reader is encouraged to see a special issue of the *Journal of Neuroscience*, 2002, vol. 22, issue 3.) Resolution of this matter will prove vitally important to our understanding of plasticity and to the development of interventions and therapeutics; regarding the latter, for example, there is strong evidence that exercise (in rodents) leads to an up-regulation of neurogenesis in the dentate gyrus of the hippocampus (for a general discussion of the possible link between postnatal neurogenesis and therapeutics, see Lie, Song, Colamarino, Ming, & Gage, 2004).

Cell Migration

The cortex proper (arguably the seat of cognition) is formed by a process whereby newly formed cells migrate out beyond their birthplace to ultimately give rise to a six-layered cortex. As discussed by M. Brown et al. (2001), the ventricular zone (the epithelium that lines the lateral ventricular cavities) gives rise to cells that undergo cell division, with the postmitotic cell migrating through the intermediate zone to its final point of destination. The cells born earliest take up residence in the preplate (the first layer of cortical neurons), which subsequently divides into the subplate and the marginal zone, both of which are derived from the cortical plate.

The postmitotic cells move in an inside-out (ventricular-to-pial) direction, such that the earliest migrating cells occupy the deepest layer of the cortex (and play an important role in the establishment of cortical connections), with subsequent migrations passing through the previously formed layer(s) (note that this rule applies only to the cortex; the dentate gyrus and the cerebellum are formed in an outside-in pattern). At approximately 20 weeks gestation, the cortical plate consists of three layers, and by the 7th prenatal month the final contingent of six layers can be seen (Marin-Padilla, 1978).

There are two types of migratory patterns—radial and nonradial (generally tangential). Radial migration generally refers to the propagation of cells from the ventricular zone outward, or from the deepest to most superficial layers of the cortex. Approximately 70% to 80% of migrating neurons use this radial pathway. In contrast, cells adopting a tangential migratory pattern (generally interneurons for the cortex and nuclei of the brain stem) move along a tangential (“across”) path. Pyramidal neurons, the major projection neurons in the brain, along with oligodendrocytes and astrocytes, enlist radial glial cells to migrate through the layers of

cortex (Kriegstein & Götz, 2003), whereas cortical interneurons (for local connections) migrate via tangential migration within a cortical layer (Nadarajah & Parnavelas, 2002). Radial migration is particularly noteworthy for several reasons. First, there are different types of radial migration. *Locomotion* is characterized by migration along a radial glial fiber. In *somal translocation* the cell body (soma) of a cell advances toward the pial surface by way of a leading process. Finally, cells that move from the intermediate zone (IZ) to the subventricular zone (SVZ) appear to migrate using *multipolar* migration (Tabata & Nakajima, 2003). A number of genes are involved in the regulation of migratory movement (see Hatten, 2002, and Ridley et al., 2003 for recent reviews).

Disorders of Cell Migration

There are many examples of disorders of cell migration (for review, see Naegele & Lombroso, 2001; Tanaka & Gleeson, 2000; Volpe, 2000). *Subcortical band heterotopia* (also known as X-linked *lissencephaly*), in which neural tissue is misplaced (e.g., cell bodies where only axons should exist) has been associated with mental retardation and epilepsy, and with the DCX gene. *Schizencephaly* is a case in which there is a cleft in the frontal cortex, whereas in *holoprosencephaly* the telencephalon fails to cleave, resulting in one undifferentiated hemisphere. Perhaps the best known disorder of migration is agenesis of the corpus callosum, in which the corpus callosum (the major bundle of fibers that connects the two hemispheres) is partially or entirely absent. As a class, disorders of cell migration generally result in varying degrees of behavioral or psychological disturbance; a case in point may be the psychiatric disorder schizophrenia, which has been hypothesized to result from a migrational disorder (see Elvevåg & Weinberger, 2001).

The Growth and Development of Processes—Axons and Dendrites

Once a neuron has completed its migratory journey, it generally proceeds along one of two roads: The cell can differentiate and develop axons and dendrites (the topic of this section), or it can be retracted through the normative process of *apoptosis* (programmed cell death), a phenomenon that is widespread (e.g., 40% to 60% of all neurons may die; for review, see Oppenheim & Johnson, 2003).

The Development of Axons

Growth cones, small structures that sit on top of axons, appear to play a key role both in developing the axon and in guiding it to its target (e.g., Raper & Tessier-Lavigne, 1999; for review, see Raper & Tessier-Lavigne, 2003). Using cues from the extracellular matrix surrounding the neuron (Jessell, 1988), and possibly local gene expression (Condron, 2002), the growth cone directs the axon toward some targets and away from others.

As Raper and Tessier-Lavigne (1999) discuss, *lamellipodia* and *filopodia* play primary roles in axon guidance. Lamellipodia are thin fan-shaped structures, whereas filopodia are long, thin spikes that radiate forward. In both cases, these structures provide the axon with the ability to move through parenchymal (brain) tissue micrometer by micrometer until the axon is within synapse range of a neighboring neuron. They do so by sampling the local environment for molecular cues (e.g., aminin, tenascin, collagen; see Bixby & Harris, 1991; de Castro, 2003; Erskine et al., 2000; Hynes & Lander, 1992; Schachner, Taylor, Bartsch, & Pesheva, 1994, for discussion).

Over and above these molecular cues, there are also molecules that sit on the surface of established axons and act as guides (Tessier-Lavigne & Goodman, 1996). An example is *cell adhesion molecules* (CAMs; Rutishauser, 1993; Takeichi, 1995). Whether the molecules reside in the extracellular matrix or on the axon proper, axons are guided toward (attractant cues) or away from (repellent cues) neighboring neurons (Tessier-Lavigne & Goodman, 1996).

The Development of Dendrites

Recent work has indicated that the gene calcium-regulated transcriptional activator (*CREST*) plays an important role in the development of dendrites (Aizawa et al., 2004). The earliest dendrites make their appearance as thick processes with few spines (small protuberances) extending from the cell body. As dendrites mature, spine number and density increase, thereby increasing the chance of making contact with a neighboring axon. Not surprisingly, dendrites grow and develop in conjunction with axons. Dendritic sprouting begins to occur at approximately 15 weeks, about the same time that axons reach the cortical plate. Between the 25th and 27th weeks of gestation, dendritic spines begin appearing on both pyramidal and nonpyramidal neurons. This sprouting continues to expand through the 24th postnatal month in

some cortical regions (Mrzljak, Uylings, Kostovic, & VanEden, 1990). Additionally, there appears to be an overproduction of both axons and dendrites during development with the final number achieved through competitive elimination.

Disorders of Axon and Dendrite Development

There are a number of environmental agents that lead to disorders associated with errors in axonal and dendritic development, including oxygen deprivation, toxins, malnutrition, or genetic anomalies (Webb, Monk, & Nelson, 2001). In addition, genetic disorders such as Angelman syndrome, fragile X syndrome, autism, and Duchenne muscular dystrophy show possible errors in dendritic development (Volpe, 1995).

Synaptogenesis

Background. Synapses generally refer to the point of contact between two neurons. Depending on the receiving neuron, the resulting action can be excitatory (promoting an action potential) or inhibitory (reducing the likelihood of an action potential).

Development. The first synapses are generally observed by about the 23rd week of gestation (Molliver, Kostovic, & Van der Loos, 1973), although the peak of production does not occur until sometime in the 1st year of life (for review, see Webb et al., 2001). It is now well known that there is a massive overproduction of synapses distributed across broad regions of the brain, followed by a gradual reduction in synapses; it has been estimated that 40% more synapses are produced than exist in the final (adult) complement of synapses (see Levitt, 2003). The peak of the overproduction varies by brain area. For example, in the visual cortex, a synaptic peak is reached between roughly the 4th and 8th postnatal months (Huttenlocher & de Courten, 1987), whereas in the middle frontal gyrus (in the prefrontal cortex) the peak synaptic density is not obtained until after 15 postnatal months (Huttenlocher & Dabholkar, 1997).

There is evidence that the overproduction of synapses is largely under genetic control, although little is known about the genes that regulate synaptogenesis. For example, Bourgeois and colleagues (Bourgeois, Reboff, & Rakic, 1989) have reported that being born prematurely or even removing the eyes of monkeys prior to birth has little effect on the overproduction of synapses in the monkey visual cortex. Thus, in both cases the absolute number of synapses is the same as if the monkey experi-

enced a typical, full-term birth. This suggests a highly regularized process with little influence by experience. As we demonstrate, however, the same cannot be said for synaptic pruning and the cultivating of synaptic circuits, both of which are strongly influenced by the environment.

Synaptic Pruning. The process of retracting synapses until some final (and presumably optimal) number has been reached is dependent in part on the communication among neurons. Pruning appears to follow the Hebbian principle of use/disuse: Thus, more active synapses tend to be strengthened and less active synapses tend to be weakened or even eliminated (Chechik, Meilijson, & Ruppin, 1999). Neurons organize and support synaptic contact through neurotransmitter receptors (both excitatory and inhibitory) on the presynaptic cell (the cell attempting to make contact) and through neurotrophins expressed by the postsynaptic cell (the cell on which contact is made). Synapses are modulated and stabilized by the distribution of excitatory and inhibitory inputs (Kostovic, 1990). The adjustments that are made in the pruning of synapses can either be quantitative (reducing the overall number of synapses) or qualitative (refining connections such that incorrect or abnormal connections are eliminated; for review, see Wong & Lichtman, 2003).

As has been thoroughly reported in both the lay and scientific press, the pruning of synapses appears to vary by area. As seen in Figure 1.2, synapse numbers in the human occipital cortex peak between 4 and 8 months of age and are reduced to adult numbers by 4 to 6 years of age. In contrast, synapses in the middle frontal gyrus of the human prefrontal cortex reach their peak closer to

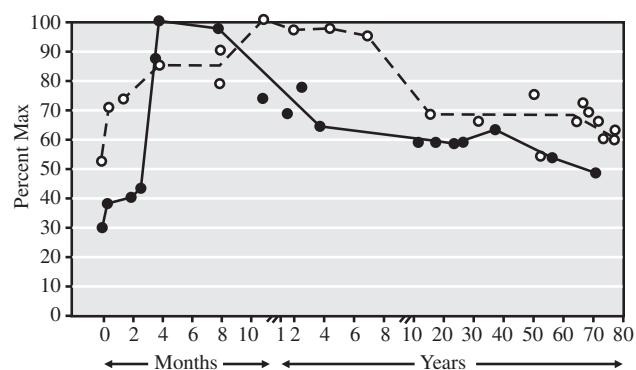

Figure 1.2 Synapse overproduction and elimination in the occipital and frontal cortices.

one to 1½ years of age, but are not reduced to adult numbers until mid to late adolescence. Unfortunately, these data are based on relatively few brains (thus leaving open the question of the range of individual differences) and relatively old methods (i.e., density of synapses per unit area, which increases the risk that nonsynaptic and even nonneuronal elements may be counted, such as glial cells). We should expect improved figures in the years to come with advances in new methods, a point that applies to much of the literature reviewed thus far.

Synaptic Plasticity. The initial development of synapses is generally quite tenuous. Thus, it is only after a synapse has been activated repeatedly that it becomes stabilized; frequently, synapses that do not receive confirmation are eliminated or reabsorbed (Changeux & Danchin, 1976). Moreover, synapse stabilization also depends on chemical communication, such as the local release of neurotrophins by postsynaptic cells (Huang & Reichardt, 2001) or through the activation of receptors such as glutamate that in turn mediate postsynaptic activation of cortical cells. Finally, even in the mature brain, synaptic plasticity is driven by synaptic activity. For example, reducing activity in a given neuron *before* a synapse has been formed leads to a reduction in functional inputs to that neuron (from neighboring neurons); in contrast, reducing activity to a given neuron *after* a synapse has been established leads to an increase in synaptic input (Burrone, O'Byrne, & Murthy, 2002).

Disorders of Synaptogenesis

There are several disorders of synaptogenesis, with fragile X syndrome being perhaps the best known. In fragile X, it appears that the disruption in the transcription of the FMR1 gene may be responsible for the abnormality in synapses (perhaps due in part to an exuberance in dendritic spines, e.g., Churchill, Beckel-Mitchener, Weiler, & Greenough, 2002).

Myelination

Myelin is a lipid/protein substance that wraps itself around an axon as a form of insulation and, as a result, increases conduction velocity. *Oligodendroglia* produce myelin in the CNS, whereas *schwann* cells produce myelin in the ANS. Myelination occurs in waves beginning prenatally and ending in young adulthood (and in some regions, as late as middle age; see Benes, Turtle, Khan, & Farol, 1994). Historically, myelin was examined in postmortem tissue using staining methods. From

such work, it was revealed that myelination begins prenatally with the peripheral nervous system, motor roots, sensory roots, somesthetic cortex, and the primary visual and auditory cortices (in this chronological order). During the first postnatal year, regions of the brain stem myelinate, as does the cerebellum and splenium of corpus callosum; by 1 year, myelination of all regions of the corpus callosum is underway.

Although staining for myelin is undoubtedly the most sensitive metric for examining the course of myelination, an obvious disadvantage to this procedure is that it can only be done on a relatively small number of postmortem brains; in addition, as is the case with human synaptogenesis, it is also of concern how representative these brains are of the general population. Fortunately, advances in magnetic resonance imaging (MRI) have now made it possible to acquire detailed information about myelination in living children; importantly, several longitudinal studies have examined the course of myelination from early childhood through early adulthood (Giedd, Snell, et al., 1996; Giedd, Vatzis, et al., 1996; Jernigan, Trauner, Hesselink, & Tallal, 1991; Paus et al., 1999; Sowell et al., 1999; Sowell, Thompson, Holmes, Jernigan, & Toga, 2000). The results of this work paint the following picture: The pre- through postadolescent period witnesses an increase in gray matter volume, followed by a decrease, whereas white matter shows first a decrease and then an increase.² During this same age period (pre-post adolescence), particular changes of note occur in the dorsal, medial, and lateral regions of the frontal lobes, whereas relatively smaller changes are observed in the parietal, temporal, and occipital lobes. This suggests, not surprisingly, that the most dramatic changes in myelination occur in the frontal lobes through the adolescent period (for a general overview, see Durston et al., 2001).

Summary

Overall, brain development begins within weeks of conception and continues through the adolescent period.

²Gray matter is composed primarily of cell bodies and neuropil, whereas white matter consists mostly of axons. An increase in gray matter, therefore, suggests that there is an increase in new neurons, whereas a decrease in gray matter would likely be due to an increase in apoptosis (and corresponding loss of neurons). An increase in white matter refers to an increase in the number of myelinated axons or simply the amount of myelin present on such axons.

This general statement does not do justice to the age-specific changes that occur during the first 2 decades of life. Thus, the assembly of the basic architecture of the brain occurs during the first two trimesters of fetal life, with the last trimester and the first few postnatal years reserved for changes in connectivity and function. The most prolonged changes occur in the wiring of the brain (synaptogenesis) and in making the brain work more efficiently (myelination), both of which show dramatic, nonlinear changes from the preschool period through the end of adolescence.

NEURAL PLASTICITY

Having established how the anatomical and physiological properties of the brain are laid down over the first 2 decades of life, we may have inadvertently created the impression that these events simply unfold of their own accord—that is, they are largely maturational in nature. Although that is true to a great extent prenatally, it vastly underrepresents the powerful role of experience in sculpting the fine architecture of the brain. Before providing specific examples of experience-induced changes in brain development and brain function, we must first provide some background.

It is important to understand at the outset that experiences don't just happen to the brain; rather, experience is the product of an ongoing, reciprocal interaction between the environment and the brain. Second, experience has typically been defined by the properties of the environment in which an individual lives. Here it must be stressed that experience is not simply a function of the environment *per se*, but is the result of a complex, bidirectional interaction between that environment and the developing brain. Third, experience interacts importantly with genetics. Two examples suffice, one from the rodent literature, one from the human literature. Regarding the former, Francis, Szegda, Campbell, Martin, and Insel (2003) cross-fostered two strains of mice with one another, either prenatally (in which hours-old embryos from one strain were implanted in the mothers of the other strain) and postnatally (in which newborn pups from one strain were placed with the mothers of the other strain). The offspring of the two original (noncross-fostered) strains served as controls. All animals were tested at 3 months of age. As expected, the control animals differed reliably from one another on four dimensions: (1) differences in explo-

ration of an open field; (2) relative time on the open arms of a plus maze; (3) latency to find a hidden platform in the Morris water maze; and (4) acoustic startle prepulse inhibition. Animals that had been cross-fostered prenatally or postnatally did not exert any effects on the expected phenotype. However, mice that had been prenatally *and* postnatally cross-fostered exhibited the same behavioral phenotype as the adopted strain, despite differing genetically from the adopted strain. The fact that the mice that had been cross-fostered prenatally did not show this effect supported the authors' contention that the effects of the combined cross-fostering must be due to nongenetic factors, and the powerful role of experience on gene expression.

Moving to the human, Turkheimer, Haley, Waldron, D'Onofrio, and Gottesman (2003) examined IQ in 7-year-old twins, a substantial number of whom were drawn from families living at or below the poverty level. The authors reported that the heritability of IQ varied nonlinearly as a function of socioeconomic standard (SES). Thus, among twins living in impoverished environments, a substantial portion of the variance was accounted for by environmental factors, with relatively little variance accounted for by genetics; in contrast, this effect was nearly completely reversed among twins living in affluent families.

Collectively, these two studies demonstrate the powerful role of the environment in moderating and mediating effects of genes on behavior. Animal studies, adopting both knockout and knock-in molecular tools, coupled with careful rearing studies will undoubtedly shed light on the pattern of gene expression and non-genetic inheritance patterns.

Within this context, any given experience can vary enormously under identical environmental conditions, depending on the history, maturation, and state of the individual's brain. Even the experience that results from a simple physical manipulation, for example, may vary widely depending on the background and state of the individual involved.

The relative maturity of the brain also has an enormous impact on experience. Different areas of the central nervous system mature at different rates. A young child who is exposed to information before his or her brain is capable of processing that information will not have the same experience as an older child who has more advanced capability. A less mature brain is affected largely by more fundamental features of the environment, such as patterned light or the speech train. As the

brain matures and changes with experience, more detailed aspects of the environment influence it. Thus, as an individual's brain changes, particularly during the early developmental periods, the same physical environment can result in very different experiences.

Certain properties of the brain differ dramatically across individuals and within individuals over time. Therefore, because experience is defined as the interaction of the brain with the environment, a scientific description of an experience must include a description of the background, developmental stage, and state of the brain as well as a description of the specific experience to which the individual is exposed. By the same token, an analysis of the effect of an experience also must take into account variability in those same factors.

The impact of experience on the brain is not constant throughout life. As the brain passes through its different developmental stages, its sensitivity to experience varies accordingly—hence the concept of *sensitive periods* (see Knudsen, 2003a). Early experience often exerts a particularly strong influence in shaping the functional properties of the immature brain. Many neural connections pass through a period during development when the capacity for experience-driven modification is greater than it is in adulthood. Thus, individual capabilities reflect the combined influences of both evolutionary learning and personal experience.

In the following sections, we will deconstruct plasticity into two types: developmental and adult. By this, we simply mean plastic processes that operate during the time of brain *development* (presumably the first 2 decades of life) versus the postdevelopmental period (when the brain is certainly capable of *changing* but not in the same fashion as the child's brain). We revisit this simplistic view at the end of this section by discussing whether the plastic processes that operate during development are the same as or different from those that operate during adulthood.

We, and others, have recently provided overviews to the myriad ways experience influences the developing and developed brain (Black, Jones, Nelson, & Greenough, 1998; Cline, 2003; de Haan & Johnnson, 2003a; Grossman, Churchill, Bates, Kleim, & Greenough, 2002; Huttenlocher, 2002; Knudsen, 2003b, in press; Nelson, 1999, 2000a, 2002; Nelson & Bloom, 1997). Our purpose is simply to provide a brief overview to this topic, beginning with a discussion of developmental plasticity and proceeding to a discussion of adult plasticity. Within each of these sections, we draw on a range of

species, although we focus mainly on rodents, monkeys, and humans. Finally, we limit our discussion to perceptual and cognitive functions, and do not discuss aspects of plasticity from social and emotional development.

Developmental Plasticity

Auditory Function

Sur and Leamey (2001) published a rather amazing example of plasticity in the auditory system. Normal retinal inputs pass through the lateral geniculate nucleus (LGN) of the thalamus on their way to the visual cortex, whereas normal auditory inputs pass through the medial geniculate nucleus (MGN) on their way to the auditory cortex. In this study, retinal projections in the young ferret were routed through the MGN. When electrophysiological recordings were made from the auditory cortex, normal *visual* responses were observed; for example, these auditory cells showed orientation selectivity to visual stimuli.

Recently, Cheng and Merzenich (2003) reported that infant rats reared in an environment of continuous, moderate-level noise were delayed in the organization of the auditory cortex; specifically, the auditory receptive fields differed from what would be expected under normal auditory rearing conditions. When these rats reached young adulthood, the auditory cortex appeared to be very similar to infants—that is, the auditory receptive fields had not yet crystallized into the adult pattern and had retained their juvenile appearance. To test the hypothesis that rearing the rats in continuous noise from birth delayed the closing of the critical period for organizing the auditory cortex, the authors exposed some of the same rats to a 7 kHz tone train for 2 weeks. This led to a reorganization of the auditory cortex, supporting the hypothesis that degraded acoustic inputs early in life delayed the organizational maturation of the auditory cortex. This led the authors to speculate that early exposure to abnormal auditory inputs (e.g., loud noise) could contribute to some auditory and/or linguistic delays in human children.

It has been known for some time that human adults have great difficulty in discriminating speech contrasts from various nonnative languages. This differs dramatically from the ceiling-level ability to discriminate speech contrasts from their own (English) language. Importantly, between 6 and 12 months of life, the infants' ability to discriminate phonemes from languages to which they are not exposed declines dramatically (for

review, see Saffran, Werker, & Werner, Chapter 2, this *Handbook*, this volume; Werker & Vouloumanos, 2001). It appears however, that the door does not shut completely on retaining the ability to discriminate nonnative contrasts; for example, Kuhl and colleagues (Kuhl, Tsao, & Liu, 2003) have reported that if before 12 months of age infants are given additional experience with speech sounds in a nonnative language, this ability is retained. Collectively, these speech data have been interpreted to suggest that the speech system remains open to experience for a certain period, but if experience in a particular domain (such as hearing speech contrasts in different languages) is not forthcoming, the window begins to close within the 1st year of life.

Linguistic Function

There has long been great controversy over the sensitive period for acquiring a second (or third or fourth) language. Dehaene et al. (1997) have reported that the neural representation of a second language is identical to that of a first language in truly bilingual individuals. However, if linguistic competence of the second language is not as strong as the first, then the functional neuroanatomy (based on PET data) is different. Since the bilinguals studied in this work had acquired their second language early in life, the initial conclusion was that the second language needed to be acquired early to be represented in the brain in the same location as the first language. This conclusion has recently been challenged, however. Perani et al. (1998) asked whether it was the *age* at which the second language was acquired that was the critical variable, or the *proficiency* with which this language was spoken. In this study, the age at which the second language had been mastered covaried with how well this language was spoken. The authors reported that it was the latter dimension that was most critical. Thus, regardless of when the second language was acquired, speaking this language with equal proficiency as the first language led to shared neural representation for both languages. Importantly, similar findings have been obtained with congenitally deaf individuals who are proficient in sign language; thus, the areas of the brain involved in sign are identical to those of hearing speakers using spoken language (Petitto et al., 2000).

Is there a critical period for acquiring American sign language (ASL)? Mayberry, Lock, and Kazmi (2002) have reported that proficiency in sign language among deaf individuals was far greater among subjects who had

been exposed to either sign language early in life (among those born congenitally deaf) or individuals exposed to spoken language early in life but who subsequently lost their hearing than among congenitally deaf individuals *not* exposed to either signed or spoken language early in life. Furthermore, Newman, Bavelier, Corina, Jezzard, and Neville (2002) have reported that ASL is represented in the same location as spoken language only among individuals who acquired ASL before puberty. Thus, although there does not appear to be a sensitive period for acquiring ASL in general, there does appear to be a sensitive period for representing ASL in the same regions of the brain as spoken language, and for signing with a high level of proficiency.

Visual Function

The development of stereoscopic depth perception is made possible by the development of ocular dominance columns, which represent the connections between each eye and layer IV of the visual cortex. If the two eyes are not aligned properly, or can't move together (vergence movements), then the ocular dominance columns that support normal stereoscopic depth perception fail to develop normally. If this situation is not corrected by 4 to 5 years of age—when the number of synapses begins to reach adult values—the child will not develop normal stereoscopic vision. Thus, normal visual input to an intact visual system during a sensitive period is necessary for the development of binocular vision.

Another example of sensitive periods for visual development can be found in an elegant series of studies by Maurer and colleagues (Maurer, Lewis, Brent, & Levin, 1999). These authors have reported on a longitudinal study of children with cataracts. A particularly attractive feature of this work is that some infants are born with cataracts, and others acquire them a few years after birth; moreover, some have their cataracts removed in the first months of life, and others undergo this procedure a few years later. The authors have reported that among infants born with cataracts that are removed and new lenses placed within months of birth, even just a few minutes of visual experience leads to a dramatic change in visual acuity. The longer the cataracts are left untreated, reducing the amount of visual experience, the less favorable the outcome. Note, however, that although most visual functions undergo dramatic improvements following early cataract removal, some aspects of *face* processing remain impaired for years (Le Grand, Mondloch, Maurer, & Brent,

2001). From this observation comes the idea of a differential sensitive period: specifically, the sensitive period for visual acuity may differ from that of face processing.

Learning and Memory Function

Hormones have long been associated with mediating cognitive differences between males and females due to their organizing effect on the brain. This association can even be observed prenatally. For example, Shors and Miesegaes (2002) capitalized on previous findings in which exposure to stressful and traumatic events enhances new learning in adult male rats, but impairs new learning in adult female rats. In the present study, the authors performed two experiments. In the first, male rats were castrated at birth, whereas female rats were injected with testosterone; both groups were then tested on a hippocampal-dependent learning task (trace eye-blink conditioning). The castrated male rats still exhibited enhanced learning, *as did the testosterone-injected females* (opposite the normal pattern of response, in which reduced learning is typically observed for females). In the second experiment, pregnant female rats were injected with a testosterone antagonist, thereby depriving the offspring of testosterone. The male and female offspring were subsequently tested as adults on the same learning task following exposure to a stressor (loud noise bursts). Male and female rats now both exhibited reduced learning, pointing to the powerful role of early experience with testosterone.

Adult Plasticity

For many years, it was commonly believed that once the brain was fully developed (thought to be the end of adolescence), its ability to be molded by experience and to recover from injury was greatly limited. This view has been turned on its head in recent years; indeed, research on so-called adult plasticity is currently receiving tremendous attention in the field of neuroscience. In this section, we provide an overview to several domains in which the adult brain is now known to be plastic.

Motor Learning

Countless examples could be offered about the plasticity of motor functions, many of which have been reviewed elsewhere (e.g., Nelson, 1999, 2000a; Nelson & Bloom, 1997). Three will suffice. First, Elbert and colleagues (Elbert, Pantev, Wienbruch, Rockstroh, & Taub, 1995)

have reported (using MEG) that the somatosensory cortex representing the fingers of the left hand (used for fine finger board movements) in highly proficient stringed instrument players is larger than (a) the analogous area in the opposite hemisphere representing the right hand (used to bow) and (b) the analogous area in nonmusicians. Similarly, Stewart et al. (2003) reported a study in which musically naive subjects were scanned using functional magnetic resonance imaging (fMRI) before and after they had been taught to read music and play keyboard. When subjects played melodies from musical notation after training, activation was seen in a cluster of voxels within the right superior parietal cortex consistent with the view that music reading involves spatial sensorimotor mapping. Third, Draganski et al. (2004) have recently reported that individuals who had been given 3 months to learn to juggle showed increased neural activation (as revealed by fMRI) bilaterally in the midtemporal area and in the left posterior intraparietal sulcus; importantly, 3 months after this group of jugglers stopped juggling, there was a decrease in activation. There was a dose/response effect between juggling performance and gray matter changes. Finally, nonjugglers over the 6-month period showed no changes in brain activation.

Visual and Auditory Function

As was the case for motor functions, just a few examples will be provided for adult visual plasticity. First, it has been well established that congenitally blind individuals show activation of the visual cortex when reading Braille or performing other tactile discrimination functions (Lanzenberger et al., 2001; Sadato et al., 1998; Uhl, Franzen, Lindinger, Lang, & Deecke, 1991). Interestingly, a Braille-reading woman blind since birth who subsequently suffered a bilateral stroke of the visual cortex in adulthood lost the ability to read Braille although other somatosensory functions remained intact (Hamilton, Keenan, Catala, & Pascual-Leone, 2000). And, Sadato, Okada, Honda, and Yonekura (2002) have now reported that among Braille-reading individuals who lost their sight *after* age 16, activation of the V1 cortex was absent, whereas such activation was present among those who lost their sight *before* age 16. Such findings are consistent with a sensitive period for visual function. Finally, Finney, Fine, and Dobkins (2001) have reported that deaf individuals show activation of the auditory cortex to visual stimuli.

Collectively, it appears that the somatosensory, visual, and auditory cortices are capable of reorganizing well into adulthood, although there is some hint that there may still be a sensitive period for such reorganization.

Learning and Memory Function

No area of plasticity has received more attention in the neuroscience literature than that of learning and memory. It has been known for over 30 years, for example, that rats raised in complex laboratory environments (those containing lots of toys and social contacts) perform certain cognitive tasks better than rats reared in isolation (e.g., Greenough, Madden, & Fleischmann, 1972). Looking closely at the brain reveals that (a) several regions of the dorsal neocortex are heavier and thicker and have more synapses per neuron; (b) dendritic spines and branching patterns increase in number and length; and (c) there is increased capillary branching, thereby increasing blood and oxygen volume (for examples of both original findings and overviews, see Black, Jones, Nelson, & Greenough, 1998; Greenough & Black, 1992; Greenough et al., 1972; Greenough, Juraska, & Volkmar, 1979; Kolb & Whishaw, 1998).

Moving up to the systems level of the nervous system, Erickson, Jagadeesh, and Desimone (2000) have reported a study in which multicolored complex stimuli (some familiar, some novel) were presented to monkeys. Neuronal activity was recorded from the perirhinal cortex, an area known to be strongly involved in episodic memory (see later section on memory). After only 1 day of experience viewing the stimuli, performance of neighboring neurons became highly correlated, whereas viewing novel stimuli revealed little correlated neuronal activity. These findings suggest that visual experience leads to functional changes in an area of the brain known to be involved in memory.

Perhaps the most dramatic example of experience-induced changes in the neural architecture underlying memory is the now well-known “London cabdriver study.” Here structural MRI scans were obtained from London cabdrivers, all highly expert at navigating the streets of London. The authors (Maguire et al., 2000) reported that the posterior hippocampus (hypothesized to serve as the storage location for spatial representations) of these drivers was larger than in a comparison group. Not surprisingly, there was also a positive correlation between hippocampal volume and the amount of experience the driver had.

Overall, there are now ample data to suggest that learning and memory are correlated with changes in the brain at multiple levels, from changes in pre- and postsynaptic functioning mediated by glutamate receptors to the molar changes at the level of anatomy. There is no sense that there is a sensitive period for learning and memory to occur (for a tutorial on the *development* of learning and memory, see Nelson, 1995, 2000b). Indeed, there is some sense that activities that engage the learning and memory system may confer some protection on lifelong learning and memory function (see Nelson, 2000b, and later for discussion).

What Are the Effects of Enriched Environments on Brain Development and Function?

Although a great deal is known about the effects of deprivation on brain development and function, very little is known about enrichment. Indeed, in the work on complex environments discussed earlier, such environments, while enriched relative to typical laboratory conditions, are still impoverished relative to real-world environments. Over and above the challenge of defining what is meant by enrichment (e.g., what may be considered enriched in one context may be impoverished in another), there is also the challenge of employing measures that possess the sensitivity to detect such effects. One example of enrichment effects on human brain function can be found in a recent study by Colcombe et al. (2004). These authors have reported that highly aerobically fit older adults or providing aerobic training to older adults who were previously unfit was associated with improved performance on a test of executive function, and with increases in task-related activity in the superior and middle frontal gyrus, the superior parietal lobule, and reduced activity in the anterior cingulate cortex, regions all associated with attentional control. This not only speaks to the plasticity of these cortical regions well into the life span, but also demonstrates that enrichment confers benefits on brain function over and above typical living conditions (in which many older Americans lack cardiovascular fitness).

What Is the Difference between Development and Plasticity?

At a deep neurobiological level, one might argue that the molecular processes that underlie plasticity (e.g.,

changes in the neurochemical profile of a synapse, anatomical changes such as growth of an axon or sprouting new dendritic spines) are no different in the developing brain than they are in the mature brain. Once the cellular machinery is in place, it generally operates the same regardless of the age of its container. Similarly, the sprouting of new dendritic spines in response to complex environments may be the same regardless of the age of the brain involved—and the molecular events that underlie changes in dendritic function are also likely the same or vastly similar. However, there are still a number of fundamental differences in the way plastic processes might work in the developing brain and in the developed brain.

First, the local cellular, anatomical, and metabolic environment in which plastic processes operate are vastly different early in the life span versus later in the life span. Thus, the newborn brain has countless more neurons and synapses than an adult brain, and many of these are not yet committed to particular functions. Thus, an axon that is growing toward its target has a very different terrain to negotiate in the newborn brain than in the adult brain. Similarly, modifying already-committed synapses (i.e., rewiring the brain) is quite different from committing synapses to a particular circuit for the first time (i.e., wiring the brain).

An example of this point can be found in a paper by Carleton, Petreanu, Lansford, Alvarez-Buylla, and Lledo (2003). These authors report that the development of the electrophysiological properties of neurons born in adulthood differ from those born pre- or perinatally. For example, spiking activity (the excitability of the cell) was delayed in late-born versus early-born cells; that is, this was not observed until the cell was nearly fully mature. The authors argue that this could be due to the need to make sure the late-born new cell does not interrupt the existing circuit until it is ready to be part of that circuit. Suffice to say, this illustrates a fundamental difference between neurogenesis in the developing brain versus the developed brain.

A second example of this point can be found in the work on postnatal neurogenesis. For example, Gould (2003) has reported that the number of prenatally derived cells tends to be fairly stable across development, with only a slight reduction with aging. In contrast, cells derived in adulthood (see earlier section on postnatal neurogenesis) tend to be massively produced but relatively short-lived (e.g., the adult rodent dentate

gyrus may contain a total of 1.5 million cells, with 250,000 of these being generated anew each month).

Another way to illustrate the difference between developmental versus adult plasticity can be found at a more systems or behavioral level. The goal of infancy is to develop neural circuits in the service of some behavior. In the adult, however, these systems are already in place and must simply be reconfigured for a different, albeit related, purpose such as acquiring a second or third language. Thus, second language learning may in fact be fundamentally different from first language learning because, in the former case, there is already a scaffold on which to build, whereas in the latter case there is not. This example builds on our first point, as second language learning may involve either *rewiring* or extending existing neural circuits to a new, albeit related, domain, whereas learning a first language surely involves new wiring.

There is a third point that illustrates the possible difference between developmental versus adult plasticity: specifically, whether there is a difference between development versus plasticity. Developmental psychologists are familiar with the principles that underlie behavioral change across age. Yet neuroscientists are also aware that the molecular, anatomic, physiologic, and neurochemical changes that underlie changes in behavior generally are likely operating in the background. Thus, if the processes that mediate changes in behavior in general at the cellular/anatomical level are the same as those that mediate changes across age, then what is the difference between development and plasticity? We would contend that these terms are fundamentally the same; the difference, however, is that we view plasticity as lifelong, whereas we view development as something that happens over the first 2 (or so) decades of life. If this is true, it then raises the possibility that the plastic processes that exist throughout life may be different from those operating to direct development during the first 2 decades of life (and surely there are differences within this developmental plastic process within this timeframe).

Admittedly, our answer to the question of whether developmental and adult plasticity are different is not fully satisfying; we remain somewhat on the fence, although leaning toward arguing for a difference. It is our hope that a more satisfying answer to this question will be found in the coming years as research in neural plasticity increases. But, it is important to ponder this ques-

tion as developmental theory gradually becomes more neurobiological in its orientation.

THE NEURAL BASES OF COGNITIVE DEVELOPMENT

Having laid the foundation for how the human brain develops, we now turn our attention to the neural bases of specific cognitive functions. As is the case with many of the topics targeted for review in this chapter, the reader is encouraged to consult more comprehensive treatises (e.g., de Haan & Johnson, 2003b; Johnson, 2001; Nelson & Luciana, 2001). Also note that because the focus of our discussion is on the *neural bases* of cognitive development, we restrict our discussion to the literature that directly relates a specific cognitive ability to brain development; the basic cognitive developmental behavioral literature is thoroughly reviewed in other chapters contained in this and previous volumes.

Memory

Why Is Memory Important?

We begin our discussion of brain and cognitive functions with a discourse about memory and lead with the question of why memory is important.

Memory is a cornerstone ability on which many general cognitive functions are assembled. Our knowledge of the world is predicated on a store of information that is acquired through acts of memory. Thus, it would seem important to delineate the developmental trajectory of this ability, particularly since our understanding of the cognitive and neural processes that underlie intelligence is not well established.

The abilities to encode and subsequently recall information are likely ones that have been conserved across species and have proved reproductively adaptive. Three examples suffice. First, in migratory birds, it is imperative that a bird return to its breeding ground to give birth to and provide care for the next generation. How does a bird remember the location of the breeding ground after many months? Mettke-Hofmann and Gwinner (2003) demonstrated that migrant birds can recall the location of a particular feeding site for 12 months, whereas nonmigrant birds can do so for only 2 weeks. More importantly, among migrant birds, the hippocam-

pus increases in size from the first to the 2nd year of life as the bird reaches sexual maturity, whereas no such increase is observed among nonmigrants. Thus, the ability of the hippocampus to adapt to the bird's environmental niche represents an example of the evolutionary significance of memory.

A similar and equally impressive example of memory can be found in a report by Tomizawa et al. (2003). These authors note that the hormone oxytocin, which has typically been associated with inducing labor and facilitating caregiving behavior, has also been associated with two cognitive functions: social recognition (Ferguson, Aldag, Insel, & Young, 2001; Ferguson et al., 2000) and improved spatial memory (Kinsley et al., 1999). Tomizawa et al. (2003) demonstrated that in hippocampal slices perfused with oxytocin, long-term potentiation (LTP)³ was facilitated, and among hippocampal slices taken from mice that had previously given birth (and in which no exogenous oxytocin was administered), CREB phosphorylation (the gene expression cascade believed to contribute to memory formation) was increased. Moreover, spatial memory could be improved in mice that had never given birth but were treated with oxytocin. In contrast, an oxytocin antagonist administered to mice who *had* given birth impaired spatial memory.

A final example of the adaptive significance of memory may be found in the observation that the young of many species appear to have a proclivity to attend disproportionately to novelty; indeed, Nelson (2000b) has speculated that (a) this proclivity may be obligatory and ensures that infants continually add to their knowledge base, and (b) this preference for novelty early in life may set the stage for the lifelong facility for memory formation.

In light of the ontogenetic and evolutionary importance of memory, let us turn to what is known about the neural bases of memory. Before addressing this question, a brief tutorial on what we mean by memory is in order.

Memory Systems

Tulving (1972) opened the door to questioning the prevailing dogma that memory was a unitary trait by proposing that there are two memory systems, which he termed *semantic* and *episodic*. Tulving's argument was

³Based on Hebbian principles, LTP is thought to reflect one of the molecular mechanisms underlying memory formation.

based on behavioral dissociations, although over the next 30 years this was augmented by experimental work with nonhuman animals and neuroimaging data from human adults. However, perhaps the turning point was the data derived from patient H. M. As Eichenbaum and colleagues discuss, H. M. (who underwent a bilateral resection of the temporal lobes for relief of intractable epilepsy; see Scoville & Milner, 1957, for original report, or Corkin, 2002, for recent report) provided crucially important data to the argument in favor of multiple memory systems (Eichenbaum, 2002; Eichenbaum et al., 1999). For example, although H. M. suffers from a severe deficit in encoding new facts, he can learn new motor skills, although he has no conscious recollection of having done so.

Since Tulving's seminal paper in 1972, countless studies of rodents, monkeys, and humans have collectively pointed to a major dissociation of two types of memory: Explicit or declarative memory, on one hand, and implicit or nondeclarative memory (also sometimes referred to as procedural memory) on the other. The standard definition of the former generally refers to memory for facts and events that can be brought to conscious awareness and that can be expressed explicitly. In contrast, implicit or nondeclarative memory generally refers to the acquisition of skills or procedures that are expressed nonconsciously through motor activity or changes in processing speed. Not surprisingly, there are different types of memory within each of these systems; thus, traditional recognition and recall memory fall under the rubric of explicit memory, whereas both priming and procedural learning fall under the rubric of implicit memory.

Additional evidence for the segregation of these two memory systems can be found in the neuroscience literature. For example, at least in the adult, the explicit memory system appears to involve select neocortical areas (e.g., visual cortex for visual explicit memory), the cortical areas that surround the hippocampus (e.g., entorhinal cortex, parahippocampal gyrus), and the hippocampus proper. In contrast, nondeclarative memory involves circuits specific to the particular type of memory (although the medial temporal lobe tends not to be involved). The acquisition of habits and skills appears to depend on the neostriatal system, whereas sensory-to-motor adaptations and the adjustment of reflexes appear to depend disproportionately on the cerebellum (for recent reviews, see Eichenbaum, 2003).

Like many dichotomies, this distinction between memory systems is not wholly satisfying, as there are many gray areas that fall between and within systems. As Cycowicz (2000) discusses, the distinction between recognition memory (a type of explicit memory) and repetition priming (a type of implicit memory) has more to do with the instructions issued to the subject than anything inherent in memory itself. Thus, in tests of recognition memory, subjects are explicitly asked to identify previously experienced stimuli or events (e.g., by verbal response, pressing a button), whereas in tests of repetition priming, subjects are typically asked to perform an incidental task (e.g., "press button A if the stimulus is oriented normally and button B if the stimulus is inverted"), and priming is inferred by speeded reaction times to previously experienced (albeit often unconsciously) stimuli. In addition, there can be overlap in the neural circuits that underlie each system (e.g., the visual cortex is required in both visual recognition memory and repetition priming for visual stimuli). Still, the field of memory has by and large accepted this distinction, various pitfalls notwithstanding.

The Development of Memory Systems—Some Background

Drawing on data from both juvenile and mature nonhuman primates, neuropsychological and neuroimaging data with adult humans, and the limited neuroimaging literature with developing humans, Nelson (1995) proposed that explicit *qua* explicit memory begins to develop some time after the first half year of life, as inferred from tasks such as deferred imitation, cross-modal recognition memory, delayed nonmatch-to-sample (DNMS), modified "oddball" designs in which event-related potentials (ERPs) are recorded, and preferential looking and habituation procedures that impose delays between familiarization (or habituation) and test. As is the case with the adult, this system depends on a distributed circuit that includes neocortical areas (such as the inferior temporal cortical area TE), the tissue surrounding the hippocampus (particularly the entorhinal cortex), and the hippocampus proper. However, Nelson also proposed that the development of explicit memory is preceded by an earlier form of memory referred to as *preexplicit* memory. What most distinguishes *preexplicit* from explicit memory is that the former (a) appears at or shortly after birth, (b) is most evident in simple novelty preferences (often reflected in the visual paired compar-

TABLE 1.2 Neural Bases of Memory Development

General System	Subsystems	Tasks	Neural Systems Related to Tasks
Implicit memory (nondeclarative memory)	Procedural learning	Serial reaction time task	Striatum, supplementary motor association, motor cortex, frontal cortex
Implicit memory (nondeclarative memory)	Procedural learning	Visual expectation paradigm	Frontal cortex, motor areas
Implicit memory (nondeclarative memory)	Conditioning	Conditioning	Cerebellum, basal ganglia
Implicit memory (nondeclarative memory)	Perceptual representation system	Perceptual priming paradigms	Modality dependent: parietal cortex, occipital cortex, inferior temporal cortex, auditory cortex
Explicit memory system	Preexplcit memory	Novelty detection in habituation and paired comparison tasks	Hippocampus, possibly entorhinal cortex
Explicit memory system	Semantic (generic knowledge)	Semantic retrieval, word priming, and associative priming	Left prefrontal cortex, anterior cingulate
Explicit memory system	Semantic (generic knowledge)	Semantic retrieval, word priming, and associative priming	Hippocampal cortex
Explicit memory system	Episodic (autobiographical)	Episodic encoding	Left prefrontal cortex, left orbitoprefrontal cortex
Explicit memory system	Episodic (autobiographical)	Recall and recognition	Right prefrontal, anterior cingulate, parahippocampal gyrus, entorhinal cortex

ison procedure), and (c) is largely dependent on the hippocampus proper.

These proposals (subsequently updated and elaborated by Nelson & Webb, 2003) were built less on direct visualization of brain-behavior relations than on the integration of data from many sources. This renders the model a useful heuristic, albeit one that would benefit from more data and less speculation. The challenge is that relatively little is known about the development of the circuitry purported to be involved in different memory systems and different types of memory; similarly, there are relatively few investigators using neuroimaging tools of any sort to examine brain-memory relations. Nevertheless, advances over the past decade in the testing of developing nonhuman and human primates have provided much needed additional information.

Table 1.2 summarizes our current thinking about the neural bases of memory development. We focus first on the development of explicit memory, and then turn our attention to implicit memory.

Current Findings—Explicit Memory in the Mature Brain

Although there is no consensus in the adult literature on the neural circuitry involved in explicit memory, Eichen-

baum's model (2003) is nicely representative of the field, and of our own thinking about development.⁴ According to Eichenbaum, the parahippocampal region (composed of the entorhinal, perirhinal, and parahippocampal cortices) is disproportionately involved in mediating the representation of isolated items, and is capable of holding these items in memory for short periods (e.g., several minutes). In contrast, the hippocampus proper appears to play a more prominent role in mediating the relational and representational properties of the stimuli: For example, during the time the parahippocampal region is holding individual items in memory, the hippocampus would be comparing these items to others already in memory; similarly, the hippocampus will be involved in extracting similar information across multiple exemplars or across multiple contexts. Data from studies of human adults and

⁴Extending adult models of memory function to infants or children is problematic for many reasons, not the least of which is that we are uncertain about whether the structure-function relations that hold in the adult will hold in the developing child. Nevertheless, it is more useful to begin with the adult configuration and then modify and expand accordingly than to start from the ground up. As attractive as the latter is, there are currently too few studies on brain-memory relations to permit adequate model building.

developing and adult monkeys with select hippocampal lesions indicate that the hippocampus also mediates novelty preferences (e.g., Manns, Stark, & Squire, 2000; McKee & Squire, 1999). Finally, the neocortex is likely the storage site for long-term information, and in the case of the frontal cortex, the site that facilitates storage through mnemonic strategies (e.g., chunking, and so on; for review of the neuroimaging literature on declarative memory, see Yancey & Phelps, 2001).

Current Findings—Explicit Memory in the Developing Brain

As is the case with studies of the mature organism, it is critical to consider the task being used to evaluate memory in deriving an understanding of what structure or circuit is involved. As discussed by Nelson (1995), Nelson and Webb (2003), and most recently, Hayne (2004), the very same task, used in different ways, could impose different task demands on the subject and recruit different underlying circuitry (see discussion of the DNMS task later in this chapter).

There is now very good evidence from the monkey literature that lesions of the hippocampus lead to disruptions in visual recognition memory, at least under certain circumstances, and at least as inferred from novelty preferences. Pascalis and Bachevalier (1999) have reported that in monkeys, neonatal lesions of the hippocampus (but not amygdala; see Alvarado, Wright, & Bachevalier, 2002) impair visual recognition memory as tested in the Visual Paired Comparison (VPC) procedure, at least when the delay between familiarization and test is more than 10 seconds. Nemanic, Alvarado, and Bachevalier (2004) have reported similar effects in adult monkeys. Specifically, lesions of the hippocampus, perirhinal cortex, and the parahippocampal cortex all impair performance on the VPC, although differentially so. Thus, lesions of the perirhinal cortex, parahippocampal cortex, and hippocampus proper lead to impairments when the delay between familiarization and test exceeds 20 seconds, 30 seconds, and 60 seconds, respectively. These findings are consistent with those from the human adult, where, for example, individuals with known damage to the hippocampus also show deficits in novelty preferences under short delay conditions (McKee & Squire, 1993). Importantly, in the human adult work, the same individuals who hours later fail to show novelty preferences *do* show intact recognition memory (Manns et al., 2000). Moreover, patient Y.R. with selective hip-

pocampal damage shows impairments on the VPC task but relatively intact recognition memory (Pascalis, Hunkin, Holdstock, Isaac, & Mayes, 2004). Together, these results suggest that recognition memory per se may be mediated by *extra-hippocampal* tissue (a point to which we will return), whereas novelty preferences are likely mediated by the hippocampus proper. The monkey data are only partially consistent with this view, as they suggest that the hippocampus *and* surrounding cortex all play a role in novelty preferences, although differentially so, at least in the adult.

Further evidence for the role of the hippocampus in encoding the relations among stimuli (versus encoding individual stimuli, which may be the domain of the parahippocampal region) can be found in a recent paper by A. J. Robinson and Pascalis (2004). These authors tested groups of 6-, 12-, 18-, and 24-month-old infants using the VPC. Rather than evaluate memory for individually represented stimuli, the authors required infants to encode the properties of stimuli in context. During familiarization, stimuli were presented against one background, and during testing the same stimulus, paired with a novel stimulus, was presented against the same or a different background. The authors report that although all age groups showed strong novelty preferences when the background was the same, only the 18- and 24-month-olds showed novelty preferences when the backgrounds were changed. This would suggest that this particular function of the hippocampus—studying the relations among stimuli or encoding stimuli in context—is somewhat slower to develop than recognizing stimuli in which the context is the same.⁵ Support for this claim can be found in the developmental neuroanatomy literature. Specifically, although the hippocampus proper, the entorhinal cortex, and the connections between them are known to mature early in life (e.g., Serres, 2001), it is also known that the development of dentate gyrus of the hippocampus matures more slowly (see Serres, 2001), as does the perirhinal cortex (see Alvarado & Bachevalier, 2000). Thus, if Pascalis and colleagues are correct that their context-dependent task is dependent on the hippocampus, then in theory the delayed maturation observed on this task reflects the delayed maturation of

⁵In theory, an alternative interpretation of these data is that the backgrounds were more salient to older versus younger infants, and thus, the novelty preferences have more to do with stimulus salience generally than with relational memory qua memory.

some specific region of the hippocampus, such as the dentate gyrus.

This last observation underscores an important point, which is that although explicit memory *emerges* sometime between 6 and 12 months of life, it is far from fully developed by this age. The fact that even very young infants (i.e., a few months of age) do quite well on standard preferential looking paradigms suggests that there is either enough hippocampal function to subserve task performance (as would be inferred from the monkey work performed by Bachevalier and colleagues) *or* that perhaps the parahippocampal region (about which virtually nothing is known developmentally) is mediating task performance. Thus, consistent with the neuroscience literature, the full, adultlike expression of explicit memory awaits the subsequent development of subregions of the hippocampus along with the connections to and from associated neocortical areas.

Novelty Preferences

Because of the prominent role novelty preferences have played in evaluating memory in infants and young children, it is worth discussing at some length the putative neural bases of such preferences. As stated, we have concluded from monkey data that the hippocampus plays a prominent role in novelty preferences, primarily based on the perturbations observed in such preferences when the hippocampus is lesioned. However, we need not restrict ourselves to data from monkeys. Neuroimaging studies with human adults have also reported that the hippocampus is involved in novelty preferences (see Dolan & Fletcher, 1997; Strange, Fletcher, Hennson, Friston, & Dolan, 1999; Tulving, Markowitsch, Craik, Habib, & Houle, 1996). In contrast, Zola et al. (2000) reported that hippocampal lesions in mature monkeys did not affect novelty preferences at 1-second delays, and thus, that impairment (i.e., decline in performance) at subsequent delays was due to problems in memory, not novelty detection. Similarly, Manns et al. (2000) have shown that among intact human adults, novelty preferences and recognition memory are both intact shortly after familiarization, although with increasing delay novelty preferences disappear, and recognition memory remains intact. This work, coupled with that from Zola et al. (2000), argues for a dissociation between novelty preferences and recognition memory and raises two questions. First, are novelty preferences truly mediated by the hippocampus or perhaps by extra-hippocampal tissue, and second, what does this dissociation say about

the infancy literature in which recognition memory is typically inferred from novelty preferences?

First, it may be unwise to assume that all tasks that tap novelty preferences by default place the same demands on memory. For example, our view is that in tasks that require the subject to generalize discrimination across multiple exemplars of the same category of stimuli (e.g., to distinguish male faces from female faces), novelty preferences may depend on the ability to examine the relations among stimuli, and thus, depend disproportionately on the hippocampus. In contrast, if the task simply requires one to discriminate two individual exemplars (e.g., one female face from another), then perhaps the parahippocampal region is involved. Second, novelty preferences and recognition memory may not represent the same or different processes as much as related ones. Thus, in the VPC procedure, perceptual support is provided by presenting the familiar and novel stimuli simultaneously. In so doing, recognition may be facilitated at very short delays, perhaps due to some iconic store rather than the need to compare the novel stimulus to one stored in memory. This may occur in short-term memory and be supported by the parahippocampal region.

Whereas it is easy to dissociate novelty preferences from recognition memory in children or adults (in whom instructions can be given), the same is not true for infants, particularly when behavioral measures are employed. However, using ERPs, Nelson and Collins (1991, 1992) appeared to dissociate these processes to some degree. Four- through 8-month-old infants were initially familiarized to two stimuli; during the test trials, one of these stimuli was presented on a random 60% of the trials (frequent-familiar), the other on a random 20% of the trials (infrequent-familiar), and on each of the remaining 20% of the trials, a different novel stimulus (infrequent-novel) was presented. In theory, if recognition memory is independent of how often a stimulus is seen (i.e., its probability of occurrence), then all infants should treat the two familiar stimuli as equivalent, regardless of how often they are presented during the test trials. The authors reported that it was not until 8 months that infants responded equivalently to the two classes of familiar events and differently to the novel events. In contrast, at 6 months infants responded differently to the two classes of familiar events and differently yet again to the novel events. These findings were interpreted to reflect an improvement in memory from 6 to 8 months, specifically, the ability to ignore how often a stimulus is

seen (inherent in novelty responses) from whether the stimulus is familiar (inherent in recognition memory).

At this point in time, it is difficult to say with certainty whether, in human children, it is the hippocampus or parahippocampal region that subserves novelty preferences and whether novelty preferences reflect a subroutine involved in recognition memory or reflect a proxy for recognition memory per se. These are questions that await further study.

Delayed Non-Match-to-Sample

What about other tasks that have been thought to reflect explicit memory, such as the DNMS task? Here a subject is presented with a sample stimulus, and following some delay (during which the stimulus cannot be observed), the sample and a novel stimulus are presented side by side. In the case of monkeys, the animal is rewarded for retrieving the novel stimulus; in the case of humans, some investigators implement a similar reward system and essentially adopt the animal-testing model (e.g., see Overman, Bachevalier, Sewell, & Drew, 1993), whereas others have modified the task such that no reward is administered and looking at the novel stimulus rather than reaching for it serves as the dependent measure (see A. Diamond, 1995).⁶ In the classic DNMS task, it is generally reported that monkeys do not perform at adult levels until they approach 1 year of age, and performance among children does not begin to resemble adults until they are approximately 4 years of age (assuming the standard 1:4 ratio of monkey to human years, these data are remarkably consistent). Interestingly, Pascalis and Bachevalier (1999) have reported that neonatal lesions of the hippocampus do *not* impair performance on the DNMS task, suggesting that the DNMS likely depends on extra-hippocampal structures and does *not* depend on just novelty preferences (i.e., unlike the VPC task, the DNMS task requires the subject to coordinate action schemes with what is represented in memory, and as well, inhibit a response to the familiar stimulus). Support for this can be found in studies reported by Málková, Bachevalier, Mishkin, and Saunders (2001) and Nemanic et al. (2004), in which lesions of the perirhinal cortex in adult monkeys led to impairments in

⁶It must be acknowledged that by modifying the task in this way, the task requirements change dramatically, and thus, it is difficult to argue that the two tasks are the same. This makes it difficult to compare across species.

visual recognition memory as inferred from the DNMS; importantly, data from the Nemanic et al. (2004) study suggests that lesions of the hippocampus and parahippocampal regions have little effect on DNMS performance. Of note is the observation that these data contradict those reported by other groups (e.g., Zola et al., 2000), where hippocampal lesions in adult monkeys *do* lead to impairments on DNMS performance. Our group has reported hippocampal activation in human adults tested with the DNMS task (Monk et al., 2002). What is to account for these differences? First, it could be that there is a fundamental difference in structure function relations in young versus mature subjects (see footnote 4); thus, the same function could be subserved by a different structure in the developing versus the developed individual. Second, it could mean that the demands of the DNMS task differ (or are interpreted differently) depending on developmental age (e.g., the reward value of reinforcing stimuli could differ; how the child/juvenile monkey interprets the task demands could be different from how the adult/mature monkey interprets the task demands). Third, earlier studies of hippocampal lesions in adult monkeys could have included lesions of the surrounding cortex, thus making it difficult to distinguish between impairments due to the hippocampus or perirhinal cortex.⁷ Finally, in the Monk et al. (2002) neuroimaging work, it was difficult to distinguish the hippocampus from adjacent cortex, and therefore, it is possible that the surrounding cortex was most involved in performance on the DNMS task.

Elicited Imitation

Deferred or elicited imitation is a task that has now received considerable attention by memory researchers. In the case of humans, a sequence of events is modeled, and following some delay, and without benefit of practice, the subject is then presented with the props used in

⁷Until approximately the late 1990s, most surgical approaches to lesioning the hippocampus involved going through the surrounding cortex, thereby damaging this region (e.g., entorhinal cortex) and fibers of passage. As a result, it was often difficult to ascertain whether it was lesions of the hippocampus proper that led to perturbations in performance, lesions of the surrounding cortex, or the severing of connections between the hippocampus and surrounding cortex. Recent methodological advances now employ the administration of neurotoxins directly to the targeted structure, destroying cell bodies but leaving fibers of passage intact.

the original sequence. Correct scores are given for the number of steps in the sequence that are correctly “recalled.” Used extensively by Bauer and colleagues (see Bauer, Chapter 9, this *Handbook*, this volume), Hayne and colleagues (e.g., Collie & Hayne, 1999; Hayne, Boniface, & Barr, 2000), and Meltzoff and colleagues (e.g., Meltzoff, 1985, 1988, 1995), among others, the prevailing evidence is that there is dramatic improvement in this ability starting at 6 months and continuing through at least 24 months. In this case, improvement is defined as the ability to reproduce longer sequences of objects over increasing delays. Indeed, as infants traverse their first birthday, under certain circumstances memory for temporal order is retained over months.

Of particular relevance to this chapter is a trio of related observations. First, McDonough, Mandler, McKee, and Squire (1995) have reported that human adults with bilateral damage to the medial temporal lobe (including the hippocampus) perform poorly on this task. Similarly, individuals who sustained bilateral hippocampal damage during childhood show impairments on the same task, although interestingly, the impairments are not so severe as those observed in adults by McDonough et al. (1995; Adlam, Vargha-Khadem, Mishkin, & de Haan, 2004). Second, Eichenbaum and colleagues (e.g., Agster, Fortin, & Eichenbaum, 2002; Fortin, Agster, & Eichenbaum, 2002) have reported that rodents trained to remember a sequence of odors show impairments in distinguishing one sequence from another when the hippocampus proper is lesioned. Finally, our group (e.g., DeBoer, Georgieff, & Nelson, in press; de Haan, Bauer, Georgieff, & Nelson, 2000) has demonstrated impairments in elicited imitation in populations of infants presumed to have experienced pre- or perinatal damage to the hippocampus (e.g., those born very prematurely or experiencing hypoxia-ischemia prenatally). Consistent with conclusions drawn by Bauer and colleagues (e.g., Bauer, Wenner, Dropik, & Wewerka, 2000; Bauer, Wiebe, Carver, Waters, & Nelson, 2003; Carver, Bauer, & Nelson, 2000), Nelson (1995) and Hayne (2004), these data would appear to support the view that performance on elicited or deferred imitation tasks depend on the integrity of the hippocampus. However, as recently discussed by Nelson and Webb (2003), like the DNMS task, the elicited imitation task is complex and comprises a collection of subtasks. Infants must encode not just the properties of the objects but as well, the order in which these objects are presented.

Historically, it has long been known that lesions of the frontal cortex perturb the ability to reproduce a sequence of events in the correct order (for review, see Lepage & Richer, 1996). In addition to recalling the sequence in which objects are presented, the participants must also encode the physical actions performed on the objects. Here again, the frontal cortex may be involved; Nishitani and Hari (2000) found that observing and imitating manual actions activated the left inferior prefrontal cortex as well as the premotor cortex and the occipital cortex. The supplementary motor area has also been implicated in motor sequencing and may encode the numerical order of components (Clower & Alexander, 1998). Collectively, although the hippocampus may underlie elements of the elicited imitation task (perhaps the recognition or recall memory of specific components, such as recognizing a familiar object or recalling a familiar sequence; see Carver et al., 2000), other components of the task may be under control of the prefrontal cortex (and presumably the basal ganglia for the coordination of the reaching and memory components). As with much of the developmental literature on memory, further insight into the neural correlates of elicited imitation will have to await our ability to image the brain in action.

What of the Role of Frontal Cortex in Explicit Memory?

In the context of development, virtually nothing is known about the role of the prefrontal cortex in explicit memory. It is well known in the adult, however, that damage to frontal cortex impairs performance on tasks that require strategies or organizational manipulation (for discussion, see Yancey & Phelps, 2001). The ability to transform, manipulate, or evaluate memories appears to be a distinctly frontal lobe function (see Milner, 1995). In this context, it should not be surprising to learn that frontal lobe damage has little if any effect on recognition memory but can have a dramatic impact on recall memory, presumably because recall involves manipulating and evaluating information. Memory tasks particularly affected by damage to the frontal lobes include *source memory* (e.g., knowing who presented the information or where the information was presented; see Janowsky, Shimamura, & Squire, 1989), *frequency memory* (e.g., which item is presented most or least often; see M. L. Smith & Milner, 1988), and consistent with our discussion of elicited imitation, *memory for*

temporal order (e.g., which item was presented most recently; see Butters, Kaszniak, Glisky, Eslinger, & Schacter, 1994). What are the implications of these observations for memory development? In brief, the ability to use strategies to encode and retrieve information and the ability to perform mental operations on the contents of one's memory are skills that develop beginning in the preschool period and continue through the immediate preadolescent period (for review of the development of prefrontal cortical functions, see Luciana, 2003). Not surprisingly, this is a period of rapid development of the prefrontal cortex, including synapse elimination and myelination. Thus, the changes that have been observed in memory across the preschool and elementary school years (for review, see Flavell, Miller, & Miller, 1993; Siegler, 1991) are likely not due to further maturation of medial temporal lobe structures, but rather to maturation of frontal lobe structures and importantly, to increased connectivity between the medial temporal lobe and the prefrontal cortex. With the ability to employ fMRI across this age range, it would be our hope that this tool will one day be applied to test this connectivity hypothesis.

Summary

Piecing together heterogeneous sources of information, it appears that an early form of explicit memory emerges shortly after birth (assuming a full-term delivery). This *preexplicit* memory is dependent predominantly on the hippocampus. As infants enter the second half of their 1st year of life, hippocampal maturation, coupled with development of the surrounding cortex, makes possible the emergence of *explicit* memory. A variety of tasks have been used to evaluate explicit memory, some unique to the human infant, others adopted from the monkey. Based on such tasks, one observes a gradual improvement in memory across the first few years of life, most likely due to changes in the hippocampus proper (e.g., dentate gyrus), to the surrounding cortex (e.g., parahippocampal cortex), and to increased connectivity between these areas. The changes one observes in memory from the preschool through elementary school years are likely due to changes in prefrontal cortex, and connections between the prefrontal cortex and the medial temporal lobe. Such changes make possible the ability to perform mental operations on the contents of memory, such as the ability to use strategies to encode and retrieve information. Finally, changes in long-term memory are likely due to the development of the

neocortical areas that are thought to store such memories, and the improved communication between the neocortex and the medial temporal lobe (MTL). It is most likely these changes that usher in the end of infantile amnesia (for elaboration, see Nelson, 1998; Nelson & Carver, 1998).

Disorders of Memory

Recent evidence suggests that bilateral hippocampal damage sustained during childhood can lead to specific impairments in memory, a condition labeled developmental amnesia (Gadian et al., 2000; Temple & Richardson, 2004; Vargha-Khadem et al., 1997).⁸ Interestingly, the neuropsychological profile of these cases appears to differ somewhat from the amnesia observed in adults following medial temporal lobe damage. One difference is that, unlike adult amnesiacs who show impairments in both recognition and recall, in at least one intensively studied case of developmental amnesia, delayed recognition memory was relatively preserved, whereas delayed recall was severely impaired (Baddeley, Vargha-Khadem, Mishkin, 2001). A second difference is that, unlike adult amnesiacs who tend to show impairments in both episodic and semantic memory, patients with developmental amnesia tend to show severe impairments in episodic memory with semantic memory remaining fairly intact (Vargha-Khadem et al., 1997).

The reason for this difference in profile between developmental and adult-onset cases remains a matter of debate. One possibility is that the patients with developmental amnesia generally show a milder memory impairment than adult amnesiacs because their damage is more selective. Many of the adult cases reported in the literature have widespread damage including additional areas within the temporal lobe and also extra-temporal brain regions. By contrast, at least within the medial temporal lobe, the perirhinal, entorhinal, and parahippocampal cortices of patients with developmental amnesia appear intact as measured by volumetric analysis (Schoppik et al., 2001). It is possible that these regions normally subserve recognition memory and semantic recall, and their preservation in developmental amnesia allows for a relative preservation of these skills (Vargha-Khadem,

⁸Here it must be stressed that in such cases the brain damage is not generally confined to the hippocampus, but rather, is somewhat more diffuse, involving a number of medial temporal lobe structures (such as the rhinal cortex).

Gadian, & Mishkin, 2001). Consistent with this view are reports that adult patients with more selective hippocampal lesions also show some preserved semantic learning (e.g., Verfaellie, Koseff, & Alexander, 2000). However, others have reported that adult patients with lesions reportedly restricted to the hippocampus show a more general memory deficit (e.g., Manns & Squire, 1999) and that a patient with more widespread damage sustained at 6 years of age also showed relatively preserved semantic learning (Brizzolara, Casalini, Montanaro, & Posteraro, 2003). These findings would suggest that age of injury, rather than extent, may be critical. Understanding the separate and combined contribution of the selectivity of damage within the MTL, the degree of extra-hippocampal damage (e.g., abnormalities in the putamen, posterior thalamus, and right retrosplenial cortex are reported in developmental amnesia; Vargha-Khadem et al., 2003) and age of injury will be important questions for future studies.

Interestingly, for early onset injuries the degree of hippocampal damage appears to affect the pattern of memory impairment (Isaacs et al., 2003). Compared with controls, patients with developmental amnesia (average bilateral hippocampal volume reduction of 40%, ranging from 27% to 56%) were impaired on tests of delayed recall, whereas preterm children (average reduction of 8% to 9%, ranging to 23%) showed no deficit in delayed recall (but did show a deficit in prospective memory and route following). These differences cannot be accounted for by general differences in ability level as the groups were matched on IQ. However, the possibility of differences in extra-hippocampal damage, which may vary as a function of degree of hippocampal damage, is not known.

Another possible explanation for the differing profiles between child- and adult-onset cases is that early-onset cases show milder impairments because the plasticity of the developing brain allows for compensation of function. In children with neonatal damage, memory impairments are not typically noted until children are of school age (Gadian et al., 2000). This would appear surprising given that the hippocampus is believed to play a critical role in memory from birth, as discussed earlier. A possible explanation is that there is a degree of compensation that allows relatively good initial memory skills but that ultimately leads to a mild form of memory impairment. A neuroimaging case study has shown that the remaining hippocampal tissue in developmental amnesia appears to be functional during memory tasks (Maguire, Vargha-Khadem, &

Mishkin, 2001). However, while intact individuals showed primarily left hippocampal activation, the patient showed bilateral activation, as well as a different pattern of connectivity of the hippocampus with other brain areas compared to controls (Maguire et al., 2001). It is thus possible that the remaining areas of functioning hippocampus organize with other brain regions to mediate the preserved memory abilities. If this is true, then one might expect that age of injury would affect the ultimate outcome, with early injury leading to better outcome than later injury due to greater plasticity. A recent report does not support this prediction, showing that delayed memory does not differ for children who sustained their injury before 1 year of age and those who sustained injury after 6 years of age (Vargha-Khadem et al., 2003). However, those with earlier lesions performed better than those with later lesions on some tests of immediate memory, suggesting that some plasticity may be operating.

Nondeclarative Memory

Nondeclarative or implicit forms of learning and memory functions represent an essential aspect of human cognition by which information and skills can be learned through mere exposure or practice, without requiring conscious intention or attention and eventually becoming automatic. Although controversy exists regarding the definition of nondeclarative memory or learning, performance on most nondeclarative tasks does not appear to depend on medial temporal lobe structures. Patients like H. M., mentioned earlier, demonstrate severe deficits in explicit memory consistent with known insults to or disruption of medial temporal lobe memory systems (see Figure 1.3). However, these patients are not impaired on classic tests of implicit memory and learning, such as perceptual priming or serial reaction time (SRT) learning (Milner, Corkin, & Teuber, 1968; Shimamura, 1986; Squire, 1986; Squire & Frambach, 1990; Squire, Knowlton, & Musen, 1993; Squire & McKee, 1993).

A multitude of tasks have emerged in the cognitive literature to assess nondeclarative cognitive functions (see Seger, 1994; Reber, 1993). Reber (1993) proposes making a distinction between two broad categories of nondeclarative function: implicit memory (the end-state representation of knowledge available to an individual, of which he or she is unaware) and implicit learning (the unintentional and unconscious acquisition of

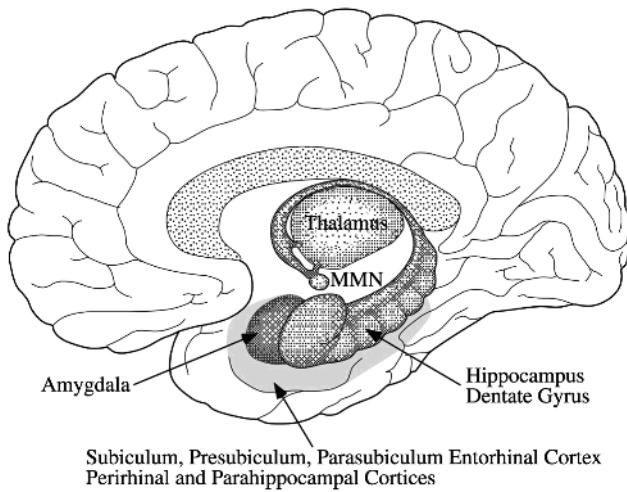

Figure 1.3 Diagram of the medial temporal lobe memory system.

knowledge). Implicit learning involves learning of underlying rules and structure in the absence of any conscious awareness of those regularities. Such learning is slow and requires repeated exposure to the information to be retained. In contrast, implicit memory may occur with a single exposure to a stimulus and results in an increased processing efficiency for subsequent presentations of that stimulus or closely related stimuli. Not only do these categories differ in their basic cognitive nature (representation versus acquisition of knowledge), but they seem to differ in their underlying neural substrates as well. In a now well-known classification of memory systems, Squire (1994) identified three primary forms of implicit learning and memory: priming, procedural learning (skills and habits), and classical conditioning (associative learning), each relying on separable neural systems.

Visual Priming

Evidence for this taxonomy comes from animal and human lesion studies as well as neuroimaging methods. For example, priming, or improvements in detecting or processing a stimulus based on a recent exposure to that stimulus, appears to rely on neocortical brain regions relevant to the stimulus of interest. That is, when healthy adults are presented with a visual stimulus repeatedly, areas of extrastriate visual cortex show decreased activity, presumably reflecting diminished processing requirements when reactivating the sensory circuit (Schacter & Buckner, 1998; Squire et al., 1992).

Similarly, priming in the context of an object classification task is associated with decreased activity in inferior temporal cortex and ventral prefrontal cortex (Buckner et al., 1998), regions previously linked to explicit object identification.

Although a number of studies have examined visual priming performance in infancy and early childhood (Drummey & Newcombe, 1995; Hayes & Hennessy, 1996; Parkin & Streete, 1988; Russo, Nichelli, Gibetoni, & Cornia, 1995; Webb & Nelson, 2001), few have applied brain-imaging methods to examine the brain bases of this function. In general, behavioral evidence overwhelmingly suggests that young children and even infants show priming effects that are very similar to those of adults, supporting the idea that implicit learning and memory functions may show very little developmental change while explicit learning and memory demonstrate protracted development. Webb and Nelson (2001) used ERP measures to assess visual perceptual priming in 6-month-old infants compared with adults. Although developmental differences were observed in ERP components between adults and infants, these differences were similar to differences observed during explicit memory function. However, ERP evidence of memory (an activity difference between new and repeated stimuli) was observed only at an early ERP component typically associated with attention, and not at the late component typically associated with explicit memory (Nelson, 1994; Nelson & Monk, 2001; see De-Boer, Scott, & Nelson, 2004 for review of infant ERP components).

Implicit Sequence Learning

In contrast to priming, implicit learning—also termed habit learning, skill learning, or procedural learning— involves the slow acquisition of a knowledge base or behavioral skill set over time. In everyday life, learning to ride a bicycle involves the gradual acquisition of a skill that is very difficult or impossible to describe verbally. Although intentionally trying to learn the skill, the learner is typically unaware of what exactly is being learned. Implicit learning has most frequently been tested using sequence learning (e.g., Nissen & Bullemer, 1987) or artificial grammar learning paradigms (Reber, 1993). In the SRT task, individuals are asked to map a set of spatial or object stimuli onto an equal number of response buttons. Reaction times to match the stimulus and the button are recorded. Unknown to the parti-

pant, whereas stimuli often appear in random order, at other times, the order of stimulus presentation follows a predictable and repeating sequence. Implicit learning is assumed when participants show reaction time improvements during the sequential trials compared with random trials, despite no conscious awareness of the underlying regularity.

Patients with temporal lobe amnesia perform normally on sequence learning tasks. However, patients with basal ganglia damage, such as those with Parkinson's or Huntington's diseases, have been shown to be impaired on the serial reaction time task (Ferraro, Balota, & Connor, 1993; Heindel, Salmon, Shults, Walicke, & Butters, 1989; Knopman & Nissen, 1991; Pascual-Leone et al., 1993). Importantly, these patients perform normally on measures of explicit memory as well as on measures of perceptual and conceptual priming (Schwartz & Hastroudi, 1991), providing support for the separability of implicit learning and implicit memory at the neural systems level. Neuroimaging data provide supporting evidence for the role of subcortical structures in serial reaction time learning. Common findings across a number of laboratories (Bischoff-Grethe, Martin, Mao, & Berns, 2001; Grafton, Hazeltine, & Ivry, 1995; Hazeltine, Grafton, & Ivry, 1997; Schendan, Searl, Melrose, & Ce, 2003) demonstrate differential activity in frontal—basal ganglia—thalamic circuits for sequential trials compared with random trials. Further evidence suggests that connections among these fronto-striatal loops and fronto-cerebellar loops may be an important aspect of implicit learning. Pascual-Leone et al. (1993) observed that, although adults with basal ganglia insults demonstrated significant reductions in implicit sequence learning, adults with cerebellar degeneration showed no evidence of learning on the SRT task.

Significant controversy exists regarding the developmental trajectory of implicit learning. In a study of SRT learning in 6- to 10-year-old children and adults, Meulemans, van der Linden, and Perruchet (1998) observed equivalent learning of a ten-step spatial sequence across age groups, despite overall reaction time differences with age. These data support the notion that implicit cognition may mature very early in infancy and show little variation or improvement with age (Reber, 1992). However, other measures of implicit pattern learning or contingency learning, as well as SRT data from an alternate group, are less clear. Maybery, Taylor, and O'Brien-

Malone (1995) report age-related improvements in covariation learning, with older children showing larger learning effects than younger children. However, Lewicki (1986) found no evidence of age-related learning effects on the original version of the same task. Similarly, Thomas and Nelson (2001) found that, although the size of the implicit learning effect was similar between 4-, 7-, and 10-year-olds who showed evidence of sequence learning on an SRT task, older children were more likely to show learning. In fact, the probability of significant learning was inversely related to age, with fully one-third of the youngest age group showing no evidence of learning (whereas all 10-year-olds showed a learning effect). Evidence for age-related improvements in implicit sequence learning come from an infant analogue of the SRT task: visual expectancy formation. In this task, infants are shown a repeating pattern of visual stimuli, and eye movements are recorded to determine whether the infant learns to anticipate the location of the upcoming stimuli over time. Although we cannot rule out the possibility that this behavior is explicitly learned, the task has many similarities to the adult SRT paradigm. Interestingly, although infants as young as 2 and 3 months of age can show reliable visual expectancy formation (Canfield, Smith, Breznyak, & Snow, 1997; Haith, Hazan, & Goodman, 1988), older infants are able to learn more complicated sequential relationships than younger children (Clohessy, Posner, & Rothbart, 2002; P. Smith, Loboschefski, Davidson, & Dixon, 1997).

In a recent pediatric imaging study of the SRT task, Thomas et al. (in press) compared the neural systems subserving implicit sequence learning in 7- to 11-year-old children and adults. Overall, results from adults were consistent with previous neuroimaging studies implicating fronto-striatal circuitry in visuomotor sequence learning. In particular, activity in the basal ganglia was positively correlated with the size of the implicit learning effect (greater learning was associated with increased activity in the caudate nucleus). Although children and adults showed many of the same regions of activity, relative group differences were observed overall, with children showing greater subcortical activity and adults showing greater cortical activity. Consistent with recent findings from adult SRT studies (Schendan et al., 2003), both adults and children showed activity in the hippocampus despite no explicit awareness of the sequence. This activity is unlikely to be either necessary or sufficient for implicit sequence

learning given the adult literature indicating spared performance following lesions to the hippocampus. Instead, this activity may reflect a sensitivity to stimulus novelty, a function of the hippocampus discussed earlier in this chapter. Children showed an inverse pattern of hippocampal activity as compared to adults (random trials elicited greater hippocampal activity than sequence trials for child participants). Interestingly, the SRT task used here produced significant developmental differences in the magnitude of the learning effect, with children demonstrating significantly less learning than adults. Unlike prior behavioral studies, this effect was not driven by a difference in the percentage of nonlearners in the two age groups. Rather, despite significant individual learning in both groups, adults learned to a greater extent with the same degree of exposure.

Finally, some evidence exists to address the effects of basal ganglia insults early in development. Although early insults may lead to lasting impairments in functions subserved by the affected systems, the plastic nature of the developing brain may also allow for redistribution of function to other regions which are unaffected. Structural neuroimaging studies have identified childhood attention-deficit/hyperactivity disorder (ADHD), as well as perinatal complications such as intraventricular hemorrhage as risk factors for disrupted basal ganglia circuitry. Castellanos et al. (2001, 2002) have reported decreases in caudate volume in children with ADHD compared with nonaffected controls. Similarly, functional imaging studies of attentional control (see Executive Functions, later in this chapter) suggest a lack of typical basal ganglia activity in children with ADHD (Vaidya et al., 1999). A recent paper addressing reading disabilities suggests a possible link between reduced motor sequence learning and symptoms of ADHD (Waber et al., 2003). Thomas and colleagues reported evidence of significant decrements in sequence learning for 6- to 9-year-old children diagnosed with ADHD (Thomas, Vizueta, Teylan, Eccard, & Casey, 2003). These authors also examined implicit sequence learning in children with perinatal histories of intraventricular hemorrhage (IVH), or bleeding into the lateral ventricles at birth. Children whose IVH was moderate (bilateral grade II or more severe) evidenced significant decrements in the magnitude of the implicit learning effect. In contrast, children whose perinatal IVH had been relatively mild (unilateral grade II or less severe) showed no difference in learning from a full-term, age- and gender-matched control group. Together, these studies suggest a potential long-term deficit in

implicit learning resulting from early insults to basal ganglia circuitry.

Conditioning or Associative Learning

In contrast to priming and implicit sequence learning, the existing knowledge regarding the brain bases of conditioning derives largely from animal studies. In conditioning paradigms, the subject learns the contingency between two previously unrelated stimuli through either association with a cue or signal (classical conditioning) or an outcome or reward (instrumental conditioning). Studies of classical eyeblink conditioning in rabbits have implicated the cerebellum and its connections to brain stem nuclei (particularly the interpositus nucleus) as key regions necessary for normal conditioning to occur (Woodruff-Pak, Logan, & Thompson, 1990). Lesions of either of these structures can completely prevent acquisition of the conditioned response, while lesions of the cerebrum have no effect on either acquisition of the response or its maintenance (Mauk & Thompson, 1987). The hippocampus also is not required for classical delay eyeblink conditioning. Patients with temporal lobe amnesia show normal performance on delay conditioning paradigms (Woodruff-Pak, 1993) whereas those with lesions of the lateral cerebellum are severely impaired in acquiring the conditioned eye-blink response (Woodruff-Pak, Papka, & Ivry, 1996). In contrast, emotional fear conditioning (pairing a neutral stimulus with a shock) appears to rely heavily on the amygdala (LaBar, Gatenby, Gore, LeDoux, & Phelps, 1998; Pine et al., 2001).

Developmentally, newborn infants (10 days old) are able to acquire a conditioned eyeblink response. Therefore, like implicit sequence learning, the basic mechanism supporting conditioned responding must be present and functional at birth, although this in no way implies that its function is fully mature. Developmental improvements are observed in conditioning paradigms. For example, with age, children can handle longer and longer delays between the neutral signal and the unconditioned stimulus (Orlich & Ross, 1968). Such developmental effects might be expected given the very protracted maturational trajectory of the cerebellum (Keller et al., 2003). Much less is known regarding the development of the amygdala response in fear conditioning. Similarly, although significant behavioral research has been conducted addressing instrumental conditioning in infancy (Rovee-Collier, 1997a), relatively little is known regarding the brain systems underlying this form of learning.

Rovee-Collier (1997b) and colleagues have observed increases in the retention duration for conditioning with age. That is, older children remember the contingencies for longer periods than younger children do (Hartshorn et al., 1998). Few, if any, studies have examined the brain bases of this form of learning in childhood.

SPATIAL COGNITION

Spatial cognition refers to a range of abilities involved in perceiving, remembering, and mentally manipulating spatial relations and orientation at several scales including features of a single object, objects and their context, and oneself in space.

Mental Rotation

Mental rotation is a form of visual imagery involving “. . . the imagined circular movement of a given object about an imagined pole in either 2 or 3 dimensional space” (Ark, 2002, p. 1). In adults, the superior parietal lobe appears to be involved in the actual act of imaginary rotation, as it is not only active during mental rotation tasks but its extent of activation is related to reaction time (Richter et al., 2000; Richter, Ugurbil, Georgopoulos, & Kim, 1997). Activations in visual area MT (M. S. Cohen et al., 1996) and motor and premotor areas in the frontal cortex (Johnston, Leek, Atherton, Thacker, & Jackson, 2004; Richter et al., 2000; Windischberger, Lamm, Bauer, & Moser, 2003) have also been observed in some, but not all, studies. These activations suggest that some of the processes involved in mental rotation overlap with processes involved in actual physical rotation of a stimulus: MT activation occurs when subjects observe objects moving, and premotor and motor areas are activated when subjects physically move objects. In support of this idea, one study demonstrated bilateral premotor activation during mental rotation of pairs of hands but only left premotor activation during mental rotation of tools (Vingerhoets, de Lange, Vandemaele, Delbaere, & Achten, 2002). This pattern suggests that participants were using motor imagery and imagined moving both hands in the hand condition and imagined using and/or moving the tools with their preferred (right) hand in the tool condition (Vingerhoets et al., 2002).

Between 8 and 12 years of age, children’s mental rotation abilities become adultlike in several respects (e.g., nature of errors, relation of reaction time to degree of rotation; see Dean, Duhe, & Green, 1983; Waber,

Carlson, & Mann, 1982). This is consistent with evidence that the parietal lobe begins to obtain adultlike status at about 10 to 12 years of age (Giedd et al., 1999). Neuroimaging studies comparing activation in children and adults confirm that parietal areas are activated in 8- to 12-year-old children as in adults (Booth et al., 1999, 2000; Chang, Adleman, Dienes, Menon, & Reiss, 2002; Shelton, Christoff, Burrows, Pelisari, & Gabrieli, 2001). Parietal areas are activated during mental rotation tasks regardless of individual differences in ability level (Shelton et al., 2001). However, differences between children and adults in the overall pattern of activation have been noted. For example, in one study, adults and 9- to 12-year-olds were asked to mentally rotate a letter or number from one of four different rotations to its upright position and then to determine whether it was forward or backward (Booth et al., 2000). Both age groups showed similar overall levels of performance and showed the typical pattern of increasing reaction time and errors with increasing degree of rotation. Despite the similarities in behavioral performance, adults showed more activation in the superior parietal and middle frontal areas, whereas children showed more activation in the supramarginal gyrus. The authors suggest that this may reflect strategy differences, with adults engaging in more mental rotation and children engaging in more processing of the noncanonical orientations of the letters and numbers. The idea that the neural processes underlying mental rotation may differ even when performance is equated is echoed in results of electroencephalogram (EEG) studies, in which greater parietal activation was reported in 8-year-old boys than girls during 2-D mental rotation despite similar levels of behavioral performance (Roberts & Bell, 2002).

It is possible that some of the differences observed between children and adults are related not to developmental change in mental rotation abilities per se, but to failure to match on gender. In adults, differences in brain areas activated during mental rotation have been noted between men and women (Roberts & Bell, 2002). Even when performance is equated, women tend to show more bilateral activation and men more right-lateralized activation in parietal regions (Jordan, Wustenberg, Heinze, Peters, Jäncke, 2003); women also tend to show greater activation in frontal regions (Thomsen et al., 2000; Weiss et al., 2003).

Consistent with neuroimaging results in children, which have reported bilateral parietal activation, both right and left hemisphere lesions in children appear to

impair performance on mental rotation tasks (Booth et al., 2000). Adults tested in those neuroimaging studies also showed bilateral activation, although other studies have reported evidence for either left or right lateralization (Harris & Miniussi, 2003; Roberts & Bell, 2002, 2003; Zacks, Gilliam, & Ojemann, 2003). Children with unilateral lesions showed activations in similar regions as healthy children and adults, but only in the intact hemisphere (Booth et al., 2000).

Spatial Pattern Processing

Spatial analysis involves the ability both to segment a pattern into a set of constituent parts and to integrate these parts into a coherent whole (Stiles, Moses, Passarotti, Dick, & Buxton, 2003). In adults, the left inferior temporal gyrus and parts of the left fusiform gyrus are more active than the homologous right hemisphere during pattern segmentation (local processing), while the homologous areas in the right are more active than those in the left during pattern integration (global processing; Martinez et al., 1997). In addition, occipito-parietal regions in the area of the intraparietal sulcus, particularly on the right, are active during both types of task, with larger areas activated during pattern integration than segmentation (Martinez et al., 1997; Sasaki et al., 2001). This latter finding is consistent with the zoom lens analogy of selective attention: Attention to local features activates cortical foveal representations, whereas attention to global aspects activates peripheral areas (Sasaki et al., 2001). Studies of adult patients with brain damage have revealed parallel results, with pattern integration being linked to right hemisphere damage and pattern segmentation to left hemisphere damage (Delis, Robertson, & Efron, 1986).

Behavioral studies indicate that processing of global information develops more quickly than processing of local information, with both types reaching adult levels by 14 years of age. Roe, Moses, and Stiles (1999) tested children aged 7 to 14 years using hierarchical stimuli and found that, while the left visual field advantage for global levels appeared sooner than the right visual field advantage for local levels, both are present in adultlike form by age 14 (but see Mondloch, Geldart, Maurer, & de Schonen, 2003). There appears to be a gradual emergence of the left hemisphere bias for local levels of forms between 7 and 14 years of age.

In children, neuroimaging studies have shown that areas similar to those activated in adults are activated in

typically developing 12- to 14-year-olds performing spatial processing tasks (Moses et al., 2002). Specifically, children, like adults, showed faster reaction time to global than to local stimuli in the left visual field/right hemisphere but the reverse pattern of reaction time to stimuli in the right visual field/left hemisphere; they also showed the adultlike pattern of lateralized occipito-temporal activation for the two tasks. However, not all children displayed this mature pattern. A subgroup of children failed to show the expected lateral differences in the split-visual field task and also showed no task-related lateral differences during the fMRI study, only a generally greater right-hemisphere activation during both types of task (Moses et al., 2002). The authors suggest that this pattern indicates that a greater degree of brain lateralization is linked to a greater degree of skill or more mature abilities.

With respect to brain lesions, several studies of pediatric patients with right or left hemisphere damage confirm the importance of these areas for global and local processing respectively. When children are shown hierarchical forms and asked to reproduce them, children with left hemisphere injury have difficulty reproducing local elements, whereas children with right hemisphere lesions have difficulty reproducing the global structure (adults: Delis et al., 1986; children: Stiles, Bates, Thal, Trauner, & Reilly, 1998); these impairments persist to school age. By contrast, children as young as 4 can reproduce both levels accurately (Dukette & Stiles, 1996). On other tasks such as block construction and copying and memory for complex figures, children with either type of lesion show delays. And, even when children eventually produce relatively accurate constructions, the strategies they use to produce them are often simplified and more representative of those seen in typically developing children at a younger age.

While damage to the developing brain can produce a pattern of deficit similar to that seen in adults, these effects may be less pronounced and show more improvement with time than in adults. While performance on block construction and complex pattern memory are clearly delayed, children eventually can produce accurate responses. To investigate the brain bases of this plasticity, Stiles, Moses, Roe, et al. (2003) investigated two children with frank parietal lesions and white matter loss more posteriorly, one with right hemisphere involvement and one with left hemisphere involvement. During tasks requiring pattern segmentation and integration, patients showed lateralization of activity to the

contralesional hemisphere, suggesting that the intact hemisphere can take on some abilities normally subserved by the damaged one.

Children initially seem to show bilateral activation during both global and local processing, and pediatric patients with unilateral lesions appear to be able to use a single hemisphere to process both types of pattern; these facts seem at odds with other findings suggesting that hemispheric biases in spatial processing are already apparent very early in life. For example, 8-month-olds tend to process configural aspects more than featural aspects of faces (e.g., Schwarzer & Zauner, 2003), and by a similar age they show a right-hemisphere bias in the processing of faces (de Haan & Nelson, 1997, 1999; de Schonen & Mathivet, 1990) but not objects (de Haan & Nelson, 1999). More direct evidence comes from studies in which the sensitivity of the right versus the left hemisphere to featural/local changes compared with configural changes has been assessed by split visual field presentation with infants. These studies also suggest that the left visual field/right hemisphere is more sensitive to global changes while the right visual field/left hemisphere is more sensitive to local changes (Deruelle & de Schonen, 1991, 1995).

The bilateral activation seen in some young children during both local and global processing may reflect less a lack of hemisphere bias and more an immature pattern in which task difficulty demands recruiting all available resources for the task at hand. Similarly, when patients with unilateral lesions are presented with these tasks, they devote all their limited resources to complete them. With development, in this view there is increasing specialization such that improved performance is related to recruitment of a smaller set of brain areas that are able to perform a particular task most efficiently (Johnson, 2001; Stiles, Moses, Roe, et al., 2003). In other words, there is a selective recruitment of resources rather than a recruitment of all available resources. Experience with processing the different types of stimuli is thought in part to drive this process. In support of this view, neuroimaging studies with adults have shown that perceptual learning is associated with an increased efficiency in the brain areas activated as expertise is acquired (Gauthier, Tarr, Anderson, Skudlarski, & Gore, 1999).

Visuospatial Working Memory

Working memory is the “moment to moment monitoring, processing and maintenance of information” (Baddeley

& Logie, 1999, p. 28). It “allows humans . . . to maintain a limited amount of information in an active state for a brief period of time and to manipulate that information” (E. E. Smith & Jonides, 1998, p. 12061). For adults, the number of items is estimated at 1 to 10 over a time span of 0 to 60 seconds (E. E. Smith & Jonides, 1998).

Working memory is often divided into three components: the central executive that controls and regulates the working memory system, and two domain-specific slave systems responsible for processing information in the phonological (phonological loop) or visuospatial (visuospatial sketchpad) forms (Baddeley, 1986; Baddeley & Hitch, 1974).

Visuospatial working memory improves with age into adolescence (e.g., Luciana & Nelson, 1998). What drives these changes? One factor that is known to be related to improvements in visuospatial working memory is phonological encoding. From about 8 years of age, children increasingly use verbal strategies during visual memory tasks (e.g., object memory); improvements in phonological encoding facilitate use of this strategy (Pickering, 2001a). However, this cannot completely account for developmental changes in visuospatial working memory as there are also developmental changes on tasks that are more purely visuospatial (e.g., Isaacs & Vargha-Khadem, 1989). These changes may be due to (a) changes in knowledge base, (b) changes in strategy, (c) changes in processing speed, and (d) changes in attentional focus (reviewed in Pickering, 2001a).

With respect to neural substrates, studies with adults show that a frontoparietal network (especially on the right) plays an important role in visuospatial working memory. There may also be a dorsal-ventral distinction in frontal areas for visual versus spatial processing (Ruchkin, Johnson, Grafman, Canoune, & Ritter, 1997; Sala, Rama, & Courtney, 2003). This has been studied mainly for visuospatial working memory, but there is some evidence for activation of similar pathways during audiospatial working memory tasks (Martinkuuppi, Rama, Aronen, Korvenoja, & Carlson, 2000; though single-cell studies suggest different but parallel populations of neurons are involved, Kikuchi-Yorioka & Sawaguchi, 2000). The visual superior posterior parietal and premotor areas may be involved in rehearsal (that can reactivate rapidly decaying contents of the storage component), while inferior posterior parietal and anterior occipital regions may mediate storage (whose contents decay rapidly). A frontoparietal network also appears to be involved in children, and in this gross

anatomical sense, there are similarities between children and adults (Casey et al., 1995; Kwon, Reiss, & Menon, 2002; Nelson, Lin, et al., 2000; Thomas et al., 1999; Zago & Tzourio-Mazoyer, 2002). However, there are also changes that occur with development. Older children show higher activation in the superior frontal and intraparietal cortex than younger children. Working memory capacity is significantly correlated with brain activity in these same regions (Klingberg, Forssberg, & Westerberg, 2002; Kwon et al., 2002), suggesting that increases in working memory with age are related to increases in activation in these regions. Regions thought to underlie the phonological loop are activated during spatial tasks (Kwon et al., 2002).

These studies collectively suggest that increases in working memory are associated with increases in activation in the frontoparietal network. One question that arises is whether this represents mainly the maturation or coming online of the frontoparietal network. In support of this view, diffusion tensor imaging studies in children suggest that developmental increases in gray matter activation in frontal and parietal cortices could be due to maturation of white matter connections (Olesen, Nagy, Westerberg, & Klingberg, 2003). However, studies with adults also show increased activity in these areas with improvements in working memory following training (Olesen, Westerberg, & Klingberg, 2004). These results show that increased activity in these areas can also occur as a result of experience and practice. The extent to which the increases in activation in the working memory network seen in adults following training and during normal development reflect similar or different mechanisms requires further investigation. In children, diffusion tensor imaging studies suggest that developmental increases in gray matter activation in frontal and parietal cortices could be due to maturation of white matter connections (Olesen et al., 2003). Thus, there is evidence of increased activation of the working memory network with increases in age and working memory abilities.

The developmental increases in working memory performance coincide with the timing of several neurodevelopmental processes, including a decrease in synaptic density (Bourgeois & Rakic, 1993), axonal elimination (LaMantia & Rakic, 1990), changes in global cerebral metabolism (Chugani & Phelps, 1986), myelination (Paus et al., 1999), and changes in catecholamine receptor structure and density. The inferior parietal cortex is one of the last areas to myelinate, a change that would

increase transmission locally within parietal cortex and also its communication with frontal cortex. This could result in more stable frontoparietal activity during working memory delays and cue periods, and thus less resistance to interference (Klinberg et al., 2002). Synaptic pruning and axonal pruning could also result in less competition with input from other areas, leaving the frontoparietal network more stable.

Several developmental disorders also implicate a frontoparietal network in visuospatial working memory. With respect to lesions, right frontal cortex damage at 7 years has been related to impairments in visuospatial working memory (Eslinger & Biddle, 2000). Turner's syndrome (a sex chromosome disorder affecting girls, in which one of the two X chromosomes is missing) is associated with deficits in visuospatial working memory (Cornoldi, Marconi, & Vecchi, 2001; Haberecht et al., 2001). In Turner's syndrome, imaging studies show decreased activation in the supramarginal gyrus, dorsolateral prefrontal cortex, and the caudate nucleus, with a suggestion that these abnormalities in frontoparietal and frontostriatal circuits are related to poor working memory performance (Haberecht et al., 2001). Individuals with fragile X syndrome are also known to have impairments in visuospatial working memory and appear to be unable to modulate activation in the prefrontal and parietal cortex in response to an increasing working memory load. These deficits may be related to a lower level of FMRP expression in individuals with fragile X syndrome compared with typical subjects (Kwon et al., 2001).

Visuospatial Recognition and Recall Memory

In addition to the frontoparietal network implicated in spatial processing and working memory, medial temporal lobe structures, particularly in the right hemisphere, have been implicated in visuospatial memory in adults. The question of whether a similar hemispheric bias exists in children has been investigated in neuropsychological studies of children with unilateral temporal lobe epilepsy. In one study, children who had either early (0 to 5 years) or later (5 to 10 years) onset of seizures were tested with visual and verbal tasks; children with early-onset epilepsy performed generally poorly, whereas children with later onset showed a material-specific pattern of deficit (Lespinet, Bresson, N'Kaoua, Rougier, & Claverie, 2002). Two other studies investigating children following temporal lobectomy noted that visuospatial deficits were both pronounced and persistent (Hepworth

& Smith, 2002; Mabbott & Smith, 2003). These results suggest that hemispheric biases (left verbal, right visuospatial) develop at some point after 5 years of age.

Spatial Navigation

The ability to remember locations and routes in the visual environment relies on both body-centered (e.g., egocentric) and environment-centered (allocentric) spatial information. In adults, the hippocampus appears to be involved in spatial memory (Astur, Taylor, Mamalak, Philpott, & Sutherland, 2002; Nunn, Polkey, & Morris, 1998), particularly with respect to allocentric spatial memory (Abrahams, Pickering, Polkey, & Morris, 1997; Holdstock et al., 2000; Incisa della Rocchetta et al., 2004). It has been suggested that the hippocampus is involved in the consolidation of allocentric information into long-term memory, rather than the initial encoding of allocentric spatial information (Holdstock et al., 2000).

A case study of a patient with perinatal selective hippocampal damage also shows deficits in allocentric spatial processing. This patient was tested in a virtual reality town and showed a massive additional impairment when tested from a shifted viewpoint compared with a mild, list length-dependent impairment when tested from the original viewpoint (King, Burgess, Hartley, Vargha-Khadem, & O'Keefe, 2002). The same patient was impaired on all topographical tasks on a second virtual reality study and on his recall of the context-dependent questions. In contrast, he showed normal recognition of objects from the virtual town, and of topographical scenes (Spiers, Burgess, Hartley, Vargha-Khadem, & O'Keefe, 2001). These results suggest a relative lack of developmental plasticity following hippocampal lesions, at least with respect to allocentric spatial encoding.

OBJECT RECOGNITION

Face/Object Recognition

Among the numerous visual inputs that we receive each moment, the human face is perhaps one of the most salient. The importance of the many signals it conveys (e.g., emotion, identity, direction of eye gaze), together with the speed and ease with which adults typically process this information, are compelling reasons to suppose that there may exist brain circuits specialized for pro-

cessing faces. Neuropsychological studies provided the first evidence to support this view, with reports of double dissociation of face and object processing. That is, there are patients who show impaired face processing but relatively intact general vision and object processing (with the occasional exception of color vision; reviewed in Barton, 2003), and other patients who show the opposite pattern of deficit (e.g., Moscovitch, Winocur, & Behrmann, 1997). These studies also hinted that damage to the right hemisphere might be necessary for the face-processing impairments to be observed. More recently, ERP, MEG, and fMRI methods have been used to identify the pathways involved in face processing in the intact brain. These studies have confirmed and extended findings from brain-injured patients, indicating that a distributed network of regions in the brain mediate face processing: occipito-temporal regions are important for the early perceptual stages of face processing, with more anterior regions, including areas of the temporal and frontal cortices and the amygdala, involved in processing aspects such as identity and emotional expression (Adolphs, 2002; Haxby, Hoffman, & Gobbini, 2002). In this section, we focus mainly on the involvement of occipito-temporal cortex and the amygdala, as these are the areas for which the most developmental data are available.

Occipito-Temporal Cortex

In adults, a network including the inferior occipital gyrus, the fusiform gyrus, and the superior temporal sulcus is important for the early stages of face processing (Haxby et al., 2002). In this view, the inferior occipital gyrus is primarily responsible for early perception of facial features, while the fusiform gyrus and the superior temporal sulcus are involved in more specialized processing (Haxby et al., 2002). In particular, the fusiform gyrus is thought to be involved in the processing of invariant aspects of faces (such as the perception of unique identity), whereas the superior temporal sulcus is involved in the processing of changeable aspects (such as perception of eye gaze, expression, and lip movement; Haxby et al., 2002; Hoffman & Haxby, 2000).

Perhaps the most intensively studied of these regions is an area of fusiform gyrus labeled the fusiform *face area* (Kanwisher, McDermott, & Chun, 1997; Puce, Allison, Asgari, Gore, & McCarthy, 1996). This region is more activated to faces compared with other objects or body parts (Kanwisher et al., 1997; Puce et al., 1996).

Although some investigators have argued against the view of face-specific patches of cortex and have instead emphasized the distributed nature of the representation of object feature information over the ventral posterior cortex (Haxby et al., 2001), even these authors acknowledge that the response to faces appears unique in certain ways (e.g., extent of activation, modulation by attention; Ishai, Ungerleider, Martin, & Haxby, 2000).

Although these studies appear to suggest that particular regions of cortex are devoted specifically to face processing, this interpretation has been questioned. In particular, it has been argued that the supposed face-specific cortical areas are not specific to faces per se, but instead are recruited for expert-level discrimination of complex visual patterns, whether faces or other classes of objects (R. Diamond & Carey, 1986; Gauthier et al., 1999). In this view, the mechanisms active during development of face processing could be the same as those observed in adults learning an equally challenging visual perceptual task. In support of this view, studies have shown that the fusiform face area is also activated by nonface objects (e.g., cars) if the subjects are experts with that category (Gauthier, Skudlarski, Gore, & Anderson, 2000), and activation in the fusiform face areas increases following training of expertise with a category of visual forms (Gauthier et al., 1999).

Developmental studies can provide important information to constrain the claims of the different sides of this debate. For example, by studying when and how face-specific brain responses emerge, developmental studies can provide some hints as to whether and how much experience might be needed for these responses to emerge. Behavioral studies provide a suggestion that face-processing pathways may be functional from very early in life: newborn babies move their eyes, and sometimes their heads, longer to keep a moving facelike pattern in view than several other comparison patterns (Johnson, Dzurawiec, Ellis, & Morton, 1991). While there is a debate as to whether this reflects a specific response to facelike configurations or a lower-level visual preference (e.g., for patterns with higher density of elements in the upper visual field, see Turati, Simion, Milani, & Umiltà, 2002; see also Banks & Ginsburg, 1985; Banks & Salapatek, 1981), there is some agreement among the divergent views that the ultimate result is that facelike patterns are preferred to other arrangements from the first hours to days of life.

While this might seem to support the notion that face-specific cortical areas are active from birth, the prevailing view is that this early preferential orienting to

faces is likely mediated by subcortical mechanisms (e.g., superior colliculus; for a review of the evidence, see Johnson & Morton, 1991), and that cortical mechanisms do not begin to emerge until 2 to 3 months of age. At this early age, cortical areas are thought to be relatively unspecialized (Johnson & Morton, 1991; Nelson, 2001). One possible role of the earlier-developing subcortical system is to provide a “face-biased” input to the slower-developing occipito-temporal cortical system, and to provide one mechanism whereby an initially more broadly tuned processing system becomes increasingly specialized to respond to faces during development (Johnson & Morton, 1991; Nelson, 2001).

The only functional neuroimaging study to investigate face processing in human infants confirms that occipito-temporal cortical pathways are involved by 2 to 3 months of age. In this study, 2-month-olds’ positron emission tomography (PET) activation in the inferior occipital gyrus and the fusiform gyrus, but not the superior temporal sulcus, was greater in response to a human face than to a set of three light diodes (Tzourio-Mazoyer et al., 2002). These results demonstrate that areas involved in face processing in adults can also be activated in infants by 2 months of age, although they do not address the question of whether these areas are specifically activated by faces rather than by other visual stimuli. It is interesting that the superior temporal sulcus, suggested to be involved in the processing of information relevant to social communication, was not activated in this study. One possible explanation is that the stimuli (static and neutral) were not optimal for activating processing in the superior temporal sulcus. However, the observation that activation in the superior temporal sulcus has been found in adults even in response to static, neutral faces (e.g., Kesler-West et al., 2001) argues against this interpretation. It is possible that the superior temporal sulcus plays a different role in the face-processing network in infants than in adults, since in primates its connectivity with other visual areas is known to differ in infants compared with adult monkeys (Kennedy, Bullier, & Dehay, 1989).

Event-related potential studies support the idea that cortical mechanisms are involved in face processing from at least 3 months of age. However, these studies also suggest that when cortical mechanisms become involved in infants’ processing of faces, they are less “tuned in” to faces than is the mature system. Two studies have shown that face-responsive ERP components are more specific to human faces in adults than in infants (de Haan, Pascalis, & Johnson, 2002; Halit, de

Haan & Johnson, 2003). In adults, the N170, a negative deflection over occipito-temporal electrodes that peaks approximately 170 ms after stimulus onset, is thought to reflect the initial stage of the structural encoding of the face. Although the location in the brain of the generator(s) of the N170 remains a matter of debate, it is generally believed that regions of the fusiform gyrus (Shibata et al., 2002), the posterior inferior temporal gyrus (Bentin et al., 1996; Shibata et al., 2002), lateral occipito-temporal cortex (Schweinberger, Pickering, Jentzsch, Burton, & Kaufman, 2002), and the superior temporal sulcus (Henson et al., 2003) are involved. The N170 is typically of larger amplitude and/or has a longer latency for inverted than upright faces (Bentin et al., 1996; de Haan et al., 2002; Eimer, 2000; Itier & Taylor, 2002; Rossion et al., 2000), a pattern that parallels behavioral studies showing that adults are slower at recognizing inverted than upright faces (Carey & Diamond, 1994). In adults, the effect of inversion on the N170 is specific for human faces and does not occur for inverted compared with upright exemplars of nonface object categories (Bentin et al., 1996; Rebai, Poiroux, Bernard, & Lalonde, 2001; Rossion et al., 2000), even animal (monkey) faces (de Haan et al., 2002).

Developmental studies have identified two components, the N290 and the P400, believed to be precursors of the N170. Both components are maximal over posterior cortex, with the N290 peaking at about 290 ms after stimulus onset and the P400 about 100 ms later. The N290 shows an adultlike modulation of amplitude by stimulus inversion by 12 months of age: inversion increases the amplitude of the N290 for human but not monkey faces (Halit et al., 2003). The P400 has a quicker latency for faces compared with objects by 6 months of age (de Haan & Nelson, 1999) and shows an adultlike effect of stimulus inversion on peak latency by 12 months of age: it is of longer latency for inverted than upright human faces but does not differ for inverted compared with upright monkey faces (Halit et al., 2003). At 3 and 6 months, the N290 is unaffected by inversion; and the P400, while modulated by inversion, does not show effects specific to human faces (de Haan et al., 2002; Halit et al., 2003). Overall, these findings suggest that there is a gradual emergence of face-selective response over the first year of life (and beyond). This finding is consistent with results of a behavioral study showing a decrease in discrimination abilities for nonhuman faces with age; 6-month-olds can discriminate between individual humans and monkeys, whereas 9-month-olds and adults tested with the same

procedure discriminate only between individual human faces (Pascalis, de Haan, & Nelson, 2002). The results also suggest that the structural encoding of faces may be dispersed over a longer time in infants than in adults. It is possible that, as the processes become more automated, they are carried out more quickly and/or in parallel rather than in serial fashion.

Interestingly, the spatial distribution of the N170 and P400 both change from 3 to 12 months, with maxima shifting laterally for both components (de Haan et al., 2002; Halit et al., 2003). In addition, the maxima of these components appear more superior than in adults, a result consistent with studies in children finding a shift from superior to inferior maximum of the N170 with age (Taylor, Edmonds, McCarthy, & Allison, 2001). This might reflect a change in the configuration of generators underlying these components with age.

Investigations with older children also support the view of a gradual specialization of face processing. ERP studies suggest that there are gradual, quantitative improvements in face processing from 4 to 15 years of age rather than stagelike shifts (Taylor, McCarthy, Saliba, & Degiovanni, 1999). The ERP studies also provide evidence that there is a slower maturation of configural than featural processing: Responses to eyes presented alone matured more slowly than responses to eyes presented in the configuration of the face (Taylor et al., 2001). There have not been many functional imaging studies of face processing during childhood, but one study examining facial identity processing suggests that changes in the network are activated in 10- to 12-year-olds compared with adults (Passarotti et al., 2003). Children showed a more distributed pattern of activation compared with adults. Within the fusiform gyrus, children tended to show more activation in lateral areas of the right hemisphere than did adults: In the left hemisphere, children showed greater lateral than medial activation, whereas adults showed no difference for the two areas. In addition, children showed twice as much activation of the middle temporal gyrus as adults. The authors interpret these results as suggesting that increased skill is associated with a more focal pattern of activation.

Studies of children with autistic spectrum disorders support the view that atypical activation of occipito-temporal cortex is related to impairments in face processing. Autistic spectrum disorders are characterized by impairments in processing of social information, including faces. Functional imaging studies indicate that when individuals with autism or Asperger syndrome

view faces, they show a diminished response in the fusiform gyrus compared with controls (Hubl et al., 2003; Pierce, Muller, Ambrose, Allen, & Courchesne, 2001; Schultz et al., 2000) and show an increased activation of object-processing areas in the inferior temporal cortex (Hubl et al., 2003; Schultz et al., 2000). It is possible that this reflects a different processing strategy in which individuals with autism focus more on featural rather than configural information in the face. In other words, individuals with autism may rely more on general purpose object-processing pathways rather than specialized face-processing pathways when viewing faces.

Amygdala

The amygdala is a heterogeneous collection of nuclei located in the anterior temporal lobe. Several studies in adults have shown that lesions to the amygdala impair emotion recognition, even when they leave other aspects of face processing intact (e.g., identity recognition; Adolphs, Tranel, Damasio, & Damasio, 1994). Lesion studies also indicate that recognition of fearful expressions is particularly vulnerable to such damage (Adolphs et al., 1994, 1999; Broks et al., 1998; Calder et al., 1996). Functional imaging studies in healthy adults and school-age children complement these findings, with some studies showing that the amygdala responds to a variety of positive, negative, or neutral expressions (Thomas et al., 2001; Yang et al., 2002), and other studies suggesting that the amygdala is particularly responsive to fearful expressions (Morris et al., 1996; Whalen et al., 2001).

There is indirect evidence that the amygdala plays a role in processing facial expressions in infants. Balaban (1995) used the eye-blink startle response (a reflex blink initiated involuntarily by sudden bursts of loud noise) to examine the psychophysiology of infants' responses to facial expressions. In adults, these reflex blinks are augmented by viewing slides of unpleasant pictures and scenes, and they are inhibited by viewing slides of pleasant or arousing pictures and scenes (Lang, Bradley, & Cuthbert, 1990, 1992). Consistent with the adult findings, Balaban found that 5-month-old infants' blinks were augmented when they viewed angry expressions and were reduced when they viewed happy expressions, relative to when they viewed neutral expressions. As animal studies indicate that the fear potentiation of the startle response is mediated by the amygdala (Davis,

1989; Holstege, van Ham, & Tan, 1986), these results suggest that by 5 months of age, portions of the amygdala circuitry underlying the response to facial expressions may be functional.

Interestingly, there is evidence that early damage to the amygdala may have a more pronounced effect on recognition of facial expression than damage sustained later in life. For example, in one study of emotion recognition in patients who had undergone temporal lobectomy as treatment for intractable epilepsy, emotion recognition in patients with early, right mesial temporal sclerosis, but not those with left-sided damage or extratemporal damage, showed impairments on tests of recognition of facial expressions of emotion but not on comparison tasks of face processing (Meletti et al., 2003). This deficit was most pronounced for fearful expressions, and the degree of deficit was related to the age of first seizure and epilepsy onset.

Role of Experience

The preceding studies suggest that the cortical system involved in face processing becomes increasingly specialized for faces throughout the course of development. Several developmental theories propose that experience is necessary for this process of specialization to occur (e.g., Nelson, 2001). Only a few studies have directly examined the role of experience in development of face processing. In one series of studies, the face-processing abilities of patients with congenital cataracts who were deprived of patterned visual input for the first months of life were tested years after this period of deprivation. These patients show normal processing of featural information (e.g., subtle differences in the shape of the eyes and mouth), but show impairments in processing configural information (i.e., the spacing of features within the face; Le Grand et al., 2001; Geldart, Mondloch, Maurer, de Schonen, & Brent, 2002). This pattern was specific to faces in that both featural and configural aspects of geometric patterns were processed normally (Le Grand et al., 2001). Moreover, when patients were examined whose visual input had been restricted mainly to one hemisphere during infancy, it was found that visual input to the right hemisphere, but not the left hemisphere, was critical for an expert level of face processing to develop (Le Grand, Mondloch, Maurer, & Brent, 2003). These studies suggest that visual input during early infancy is necessary for the normal development of at least some aspects of face processing.

Another way in which the role of experience has been investigated is by studying children who experience atypical early emotional environments. For example, Pollak and colleagues have found that perception of the facial expression of anger, but not other expressions, is altered in children who are abused by their parents. Specifically, they report that, compared with nonabused children, abused children show a response bias for anger (Pollak, Cicchetti, Hornung, & Reed, 2000), identify anger based on less perceptual input (Pollak & Sinha, 2002), and show altered category boundaries for anger (Pollak & Kistler, 2002). These results suggest that atypical frequency and content of their emotional interactions with their caregivers result in a change in the basic perception of emotional expressions in abused children.

Is There a Visuospatial Module?

There are different perspectives regarding whether visuospatial processing is mediated by a specific module in the brain. According to the innate modularity view, the cognitive modules observed in adults are genetically specified and are already present from the beginnings of development. This view predicts that, even early in development, one or more modules can be impaired without affecting other modules. Williams syndrome, together with another developmental disorder called Specific Language Impairment (SLI), provides support for this view. In Williams syndrome, language is a strength despite lowered intellect; in SLI, language is impaired despite normal intellect. The double dissociation of language and general intellect across the two developmental disorders is taken by some to support the view that there is a language module that can be selectively spared or impaired. Also consistent with this view is the finding that LIMK1 hemizygosity in Williams syndrome is related to impaired visuospatial constructive cognition (Frangiskakis et al., 1996).

An opposing view is that the brain is not initially organized into distinct modules and only becomes so during development as an emergent property of both biological maturation and experience in the environment. One piece of evidence in support of this view is that the cognitive profile of Williams syndrome is not constant over development. Whereas adults and older children with Williams syndrome show a strength in verbal skills and weakness in number skills, infants show the opposite pattern (Paterson, Brown, Gsodl, Johnson, & Karmiloff-Smith, 1999). This finding is incompatible

with the innate modularity view that certain modules are impaired or intact from the start, since it shows that early abilities do not necessarily predict later ones.

Advocates of the innate modularity view might argue that there could still be innate modules, because face processing has been noted as a strength even from early in life in Williams syndrome. Moreover, adults with Williams syndrome can achieve near normal performance on standardized tests of face recognition. Could this be an intact innate module? Proponents of the interactive specialization view suggest that, if so, face recognition should be accomplished by the same cognitive mechanisms as in typically developing individuals. However, several studies show this is not the case. Individuals with Williams syndrome appear to rely less than typically developing children on cues from the configuration of features in the face to recognize identity (Deruelle, Mancini, Livet, Casse-Perrot, & de Schonen, 1999). In addition, their ERPs show atypical patterns within the first several hundred milliseconds of processing (Grice et al., 2001.). Together, these results argue against the view that the cognitive strengths in Williams syndrome reflect the operation of intact, specific modules.

EXECUTIVE FUNCTIONS

Most high-level cognitive functions involve executive processes, or cognitive control functions, such as attention, planning, problem solving, and decision making. These processes are largely voluntary (as opposed to automatic) and are highly effortful. Such functions, including selective and executive attention, inhibition, and working memory, are hypothesized to improve with age and practice, and to vary with individual differences in motivation or intelligence. These cognitive control processes have been described as providing a “supervisory attention system” (Shallice, 1988)—a system for inhibiting or overriding routine or reflexive behaviors in favor of more controlled or situationally appropriate or adaptive behaviors. Desimone and Duncan (1995) describe this system as an attentional bias that provides a mechanism for attending to relevant information by simultaneously inhibiting irrelevant information (Casey, Durston, & Fossella, 2001). The ability to override a dominant response or ignore irrelevant information is critical in everyday life, as evidenced by the functional

impairments associated with chronic inattention, behavioral impulsivity, or poor planning and decision making.

Classic lesion cases, such as the famous case of Phineas Gage, indicate that injury to the prefrontal cortex can result in difficulties in behavioral regulation, such as impulsivity and socially inappropriate behavior (Fuster, 1997), as well as disruptions in planning, working memory, and focused attention. Cognitive developmentalists will recognize these same functions as showing relatively protracted behavioral maturation, often not reaching adult levels of performance until late adolescence (Anderson, Anderson, Northam, Jacobs, & Catroppa, 2001). It is therefore not surprising that prefrontal cortex shows one of the longest periods of development of any brain region (A. Diamond, 2002; Luciana, 2003, for reviews). In fact, the relations between prefrontal cortex development and the development of executive functions is probably one of the clearest relations in the developmental cognitive neuroscience literature. However, this does not imply that we fully understand the instantiation of attention, working memory, or inhibition in the brain. Instead, we have significant evidence from lesion and neuroimaging methods to relate subregions of prefrontal cortex to specific aspects of cognitive control in adulthood, as well as a growing body of literature addressing the normative and atypical function of these regions, and their connected networks of structures, in the development of cognitive control. For reasons of space, only illustrative examples from normative behavioral development, animal models, adult and pediatric neuroimaging studies, and atypical developmental populations are provided here (Casey, Durston, et al., 2001; A. Diamond, 2002; Luciana, 2003).

Domains of Executive Function

Many researchers have identified working memory and behavioral inhibition as the primary functions of prefrontal cortex, and by extension, the basic components of executive function (e.g., A. Diamond, 2001). Working memory has typically been associated with dorsolateral prefrontal cortex (DLPFC; J. Cohen et al., 1994; Fuster, 1997; Levy & Goldman-Rakic, 2000), while more ventral regions have been implicated in inhibition of a prepotent behavioral response (Casey, Trainor, Orendi, et al., 1997; Kawashima et al., 1996; Konishi et al., 1999). Other investigators have parsed their definition of executive functions somewhat differently in an effort to include the voluntary and effortful aspects of attentional control as well as response inhibition. Whatever scheme is used, it is apparent that the classic executive function tasks involve more than one of the preceding aspects of voluntary control or regulation. In the following sections, we provide examples of behavioral tasks thought to tap various aspects of executive function across development, as well as provide select examples that evidence the role of specific regions of prefrontal cortex in supporting cognitive control. Of course, prefrontal cortex does not act in isolation. Other brain regions are assumed to be integral to the executive function system, providing input and feedback, as well as receiving inputs from prefrontal cortex. Developmental improvements in executive function may arise as much from the development of such functional integration as from the architectural and physiological development of prefrontal cortex (Anderson et al., 2001; Anderson, Levin, & Jacobs, 2002).

Working Memory Revisited

Perhaps the task most clearly associated with both child development and prefrontal cortex is the classic A-not-B task. In this paradigm (or its close cousin, the delayed response task), an infant or animal watches an object being hidden at one of two identical locations, and after some delay is rewarded for retrieving the object. This task requires both holding information in mind across a delay and, on subsequent trials when the hiding location changes, inhibiting a prepotent tendency to return to a previously correct response location (A. Diamond, 1985). Animal lesion studies support the importance of DLPFC in successful performance on the A-not-B and delayed response tasks (A. Diamond & Goldman-Rakic, 1989; Fuster & Alexander, 1970; Goldman & Rosvold, 1970). In addition, electrophysiological studies indicate that cells in this region actively respond during the delay interval, suggesting that DLPFC is involved in the maintenance of information in working memory (Funahashi, Bruce, & Goldman-Rakic, 1989; Fuster & Alexander, 1971). Further investigation demonstrates that lesions to this region impair performance only under delay conditions and not during immediate object retrieval (A. Diamond & Goldman-Rakic, 1989). Functional imaging studies suggest that developmental differences in working memory function, at least in middle childhood, may be reflected in less efficient or less focal activation of DLPFC. That is, pediatric fMRI studies have demonstrated that children activate similar

regions of DLPFC compared with adults during both verbal and spatial working memory tasks, but also may activate additional areas of prefrontal cortex, including ventral lateral regions (VLPFC; Casey et al., 1995; Nelson, Lin, et al., 2000; Thomas et al., 1999).

Inhibitory Control

Although working memory has been associated with dorsolateral regions of the prefrontal cortex, the ability to inhibit inappropriate behaviors has typically been associated with ventral medial or orbital frontal cortex (Casey, Trainor, Orendi, et al., 1997; Konishi et al., 1999). In adults, lesions to ventral prefrontal cortex lead to impulsive and socially inappropriate behavior (Barash, Tranel, & Anderson, 1994; Damasio, Grabowski, Frank, Galaburda, & Damasio, 1994). One common developmental measure of response inhibition is the go/no-go paradigm. In this task, children are asked to respond to every stimulus *except* one (e.g., all letters except X). The task is designed such that the majority of trials are “go” trials, building up a compelling behavioral response tendency. The child’s ability to refrain from making the response at the occurrence of the “no-go” stimulus is used as an index of inhibitory control. Performance on such tasks has been shown to improve across the preschool and school-age years (Casey, Durston, et al., 2001; Ridderinkhof, van der Molen, Band, & Bashore, 1997). Neuroimaging studies using the go/no-go paradigm have demonstrated signal increases in ventral PFC during periods high in inhibitory demand (Casey, Forman, et al., 2001; Casey, Trainor, Orendi, et al., 1997), with correspondingly lower levels of activity during periods of low inhibitory demand. Konishi et al. (1999) observed increased ventral PFC activation during no-go trials in an event-related fMRI paradigm. Recent pediatric neuroimaging studies have demonstrated both developmental differences in activation of ventral prefrontal cortex (Bunge, Dudukovic, Thomason, Vaidya, & Gabrieli, 2002), with children showing reduced signal compared with adults, and increasing activation of ventral lateral PFC with increasing inhibitory load (Durston, Thomas, & Yang, 2002). Durston and colleagues (2002) showed that behavioral performance on the go/no-go task was significantly correlated with activity in inferior frontal cortex, as well as other prefrontal regions, including the anterior cingulate gyrus (ACC).

Importantly, these same studies highlight the importance of regions beyond the prefrontal cortex. In particular, basal ganglia structures have also been shown to be involved in response inhibition (e.g., Luna et al., 2001), perhaps particularly so for children (Bunge et al., 2002; Casey, Trainor, Orendi, et al., 1997; Durston et al., 2002). Children with ADHD show significantly lower activity in basal ganglia regions during performance of a go/no-go task than typically developing children (Durston et al., 2003; Vaidya et al., 1998) and show high rates of false alarms on the task. In a recent study, children with ADHD showed additional recruitment of dorsolateral PFC not observed for the control group who performed at a high rate of accuracy (Durston et al., 2003). Interestingly, when taking medication to treat their inattention and impulsivity, children with ADHD show basal ganglia activity equivalent to the typically developing group along with parallel improvements in behavioral performance (Vaidya et al., 1998). Other developmental disorders, such as Tourette syndrome, obsessive-compulsive disorder, and childhood-onset schizophrenia also have been associated with disruption of frontal-striatal circuitry (connections between basal ganglia and frontal cortex) and impaired performance on tasks involving attentional control.

Attentional Control

Beyond the general processes of working memory or inhibition, many real-world and experimental tasks require selectively focusing attention on relevant task information while simultaneously suppressing interference from salient but irrelevant or misleading information (Casey, Durston, et al., 2001). Perhaps the most studied adult task of this type is the color-word Stroop paradigm, in which participants are asked to identify the color of ink in which a word is written but, in the case of a color word, have to inhibit a natural tendency to read the word instead (e.g., the word “BLUE” presented in red ink). Neuroimaging data from the Stroop paradigm identify medial prefrontal cortex, specifically the anterior cingulate cortex, as particularly important in detecting (e.g., Botvinick, Braver, Barch, Carter, & Cohen, 2001; Bush et al., 1999; Bush, Luu, & Posner, 2000; Duncan & Owen, 2000; Fan, Flombaum, McCandliss, Thomas, & Posner, 2003; MacDonald, Cohen, Stenger, & Carter, 2000; Posner & Petersen, 1990) and perhaps even resolving this type of attentional conflict.

DLPFC and other regions of prefrontal cortex may also be activated during cognitive conflict depending on demands of the specific task. In the Simon task, a spatial conflict is created between the location of a stimulus (left or right side of the screen) and the required response (left or right button; Gerardi-Caulton, 2000). In a study by Fan et al. (2003), this conflict was associated with activation of superior frontal gyrus as well as anterior cingulate cortex, while conflict in the Stroop task was associated with activity in ventral lateral prefrontal cortex. When the same adult participants performed the Eriksen flanker task, which requires focusing attention on a central stimulus and actively ignoring competing flanking stimuli, these authors observed attention-related activity in premotor cortex. Despite these task-related differences in MR signal, further analyses demonstrated overlapping regions of activity in the anterior cingulate gyrus and the left prefrontal cortex across all three tasks, suggesting some common activity related to cognitive control or management of cognitive conflict (Fan et al., 2003). Other neuroimaging studies of the Eriksen flanker task have indicated that prefrontal cortex is differentially activated based on the degree of cognitive conflict within the same task (Casey et al., 2000; Durston et al., 2003). Recently, Durston and colleagues (2003) found that parametric manipulations of conflict on the flanker task were associated with monotonic increases in both DLPFC and ACC. Of course, additional brain regions are activated beyond the prefrontal cortex, such as the superior parietal cortex, perhaps related to the spatial nature of the task. Applying the concept of a “spotlight of attention” (Posner & Raichle, 1997), the flanker task requires narrowing the spatial distribution of attentional focus to reduce interference or conflict from the irrelevant flanking stimuli. Activation of superior parietal cortex may be related to this spatial feature of the task (also see Orienting, later in this chapter).

Behaviorally, the cognitive control tasks previously described show significant developmental changes across early and middle childhood, and in some cases, even into adolescence. Casey, Durston, and Fossella (2001) provide developmental data demonstrating that, for tasks such as the Eriksen flanker and Stroop, adultlike performance is not achieved until early adolescence. A. Diamond (2002) has shown similar trajectories for Stroop-like tasks including the Simon task, with evidence of protracted development. Rueda and colleagues (2004) showed evidence of increased cognitive conflict in 6- and 7-year-olds com-

pared with 8- to 10-year-olds and adults. Despite a significant literature demonstrating developmental improvements in cognitive control across early and middle childhood, fewer studies have addressed the brain bases of this development. A. Diamond (2001) has shown that children with presumed functional disruptions of prefrontal cortex (children treated for phenylketonuria or PKU) are impaired on their performance of Stroop-like and inhibitory control tasks like the go/no-go task, suggesting that typical developmental function is relying on this brain region that is continuing to develop across childhood. Similar effects on other executive function tasks have also been observed in this population (Luciana, Sullivan, & Nelson, 2001). Likewise Casey, Tottenham, and Fossella (2002) have demonstrated that children with psychiatric disorders associated with frontal-striatal circuitry show specific impairments on tests of cognitive conflict. Children with obsessive-compulsive symptomatology showed deficits when required to inhibit a well-learned response set, but no impairment in a Stroop-like task. In contrast, children with diagnoses of childhood onset schizophrenia were impaired on the Stroop-like task but not on the response selection task or on a go/no-go inhibition task, suggesting potential differences within prefrontal cortex.

A related aspect of cognitive control arises when the individual is required not only to ignore irrelevant information, but also to shift among multiple rules for responding. The classic adult task of this type is the Wisconsin Card Sorting Task (WCST), in which participants must discover the sorting rule simply on the basis of binary feedback received during card-sorting performance. Healthy adults show rapid acquisition of the initial sorting rule and quickly alter their behavior if and when the rule is changed. Lesions to the left DLPFC but not other regions of prefrontal cortex impair performance on switching tasks, resulting in perseverative errors (Keele & Rafal, 2000; Owen et al., 1993; Shallice & Burgess, 1991). Neuroimaging studies provide convergent evidence for the role of DLPFC and basal ganglia circuits in task switching and reversal learning (Cools, Clark, & Robbins, 2004; Cools, Clark, Owen, & Robbins, 2004).

Perhaps not surprisingly, typically developing 3-year-old children perform very similarly to adults with frontal lobe lesions. Zelazo et al. (1996) have described a dramatic developmental shift in set-switching performance in the preschool years using the dimensional card sorting task. This task requires the child to first sort cards by one criterion (e.g., shape), and then to shift and

sort the cards by another criterion (e.g., color). While 3-year-olds have no trouble sorting by the first criterion, whether it is shape or color, they frequently fail to shift their sorting behavior when the criterion changes despite being able to verbalize the rule, reminiscent of some patients with prefrontal cortex damage (REF). However, 5-year-olds generally have no difficulty with this task. Kirkham and colleagues have suggested that this developmental shift is predominantly the result of improved inhibitory control (A. Diamond, Kirkham, & Amso, 2002).

The developmental neuroimaging data in this domain are still sparse, although a number of groups are working in this direction. Additional work will be needed to assess developmental changes in the recruitment and efficiency of prefrontal cortex in such cognitive conflict or cognitive control tasks. It remains to be seen whether the normal developmental pattern of functional brain activity engages the same circuits known to be disrupted in adult lesion populations with executive dysfunctions.

NONEXECUTIVE ASPECTS OF ATTENTION

The previously discussed concepts of attentional control and cognitive conflict, while well-studied in adult populations, are more difficult to apply to the earliest periods of development. Although tasks such as the A-not-B or delayed response fall under the broad rubric of executive functions, the majority of research on infants' attention involves more basic processes, such as maintaining an alert state, and orienting to stimuli in the environment. While these functions can involve voluntary or controlled processes (Posner & Raichle, 1997), often they reflect automatic or obligatory responses. Not unlike the memory literature discussed previously, the various forms of attention have been associated with somewhat separable brain systems (Posner & Raichle, 1997).

Alerting, Vigilance, or Arousal

One major function of the attentional system is to maintain alertness or vigilance (also called arousal). Vigilance processes allow the brain to prepare for upcoming stimuli that may require decision making and/or a behavioral response. Alertness or arousal is associated with improved behavioral performance in a nonspecific or unfocused way (Posner & Raichle, 1997). Although researchers have proposed various neural mechanisms

subserving arousal, one common view of arousal is Posner's alerting model, identifying regions of right frontal and parietal cortices and the norepinephrine system as critical players in vigilance (Lewin et al., 1996). In this model, alertness leads to quieting of other activity in the brain through the release of norepinephrine (NE) from the locus coeruleus. The presence of NE is hypothesized to bring on the state of alertness by enhancing the signal-to-noise ratio in regions where it is acting. As alerting-related activity in right frontal cortex increases, activity in the anterior cingulate cortex, a region associated with target detection decreases. Posner suggests that this decrease in activity is important for the brain to reduce potential sources of interference during the waiting period prior to the appearance of a target stimulus (Posner & Raichle, 1997). Arousal or sustained attention is associated with decreases in heart rate, both in adults and in infants, reflecting activity of cardioinhibitory centers in the brain, particularly in orbitofrontal cortex (Richards, 2001). Using heart rate measures as an index of the brain's arousal system, Richards and colleagues have demonstrated developmental improvements in sustained attention over the first 6 months of life (Casey & Richards, 1988; Richards, 1994). Likewise, certain components of the ERP in infancy are thought to reflect automatic alerting responses, particularly in response to novel stimuli (Courchesne, 1978). ERP studies of the response to familiar and novel events in 6-month-olds show that the early negative component (Nc) typically elicited by stimulus novelty is enhanced during periods of sustained attention (as indexed by heart rate deceleration), compared with periods of attention termination (Richards, 1998). However, Richards found that, during sustained attention, the Nc component did not differentiate among familiar and novel stimuli. Instead, a later component, the positive slow wave (PSW), was enhanced to familiar but infrequently occurring stimuli (Richards, 1998), suggesting that this basic alerting function may modulate the brain response to stimulus novelty, as might be expected behaviorally.

Orienting

The third arm of the Posner model of attentional networks is the orienting network. Posner describes both overt and covert forms of orienting, or attentional shifting in adults (Posner & Raichle, 1997; Posner, Walker, Friedrich, & Rafal, 1984). When a cue stimulus flashes

in the periphery, adults tend to automatically shift eye gaze to the periphery (overt attention shift). In contrast, a centrally presented stimulus can cue the individual to either overtly orient (by shifting eye gaze to fixate) or covertly orient (by shifting attention without shifting eye gaze). Therefore, in adults, centrally presented cues allow the individual to choose to orient in a controlled manner, whereas peripheral cues tend to elicit automatic orienting responses. An extensive neuropsychological literature implicates parietal cortex in the ability to orient attention (e.g., Posner et al., 1984). Adults with parietal lesions show a deficit in the ability to disengage attention from one stimulus in order to shift attention elsewhere. Single cell recordings in animals suggest that cells in the thalamus and parietal cortex show increased activity during covert shifts of attention (D. Robinson, Bowman, & Kertzman, 1995). Lesions in other brain regions can mimic the unilateral behavioral neglect observed with parietal lesions, but do not appear to disrupt covert orienting (Posner et al., 1984). Functional imaging studies of covert orienting in adults show activity in superior parietal cortices, particularly contralateral to the direction of attention (Corbetta, Kincade, Ollinger, McAvoy, & Shulman, 2000). However, in contrast to the inability to disengage observed with parietal lesions, damage to the midbrain visual system (superior colliculus) involved in saccadic eye movements leads to difficulty in moving between stimuli, a separate step in visual orienting (Rafal, Posner, Friedman, Inhoff, & Bernstein, 1988). Finally, damage to the pulvinar (part of the thalamus) yields difficulties in reengaging attention or amplifying the target location once a movement has been made (Danziger, Ward, Owen, & Rafal, 2001).

Several major developments occur in visual orienting behavior that are assumed to reflect development of the brain systems supporting orienting in adults. Around 1 month of age, once infants are able to voluntarily fixate on a stimulus, infants experience a period of obligatory looking, during which they stare fixedly at objects and may have difficulty disengaging their fixation. This obligatory looking can be distressing when a baby becomes fixated on strong visual stimuli, such as high-contrast checkerboard patterns, but is very adaptive for forming social bonds when the baby is fixated on the caregiver's face. Obligatory looking disappears around 4 months of age when infants develop more voluntary control of their orienting (Posner & Raichle, 1997), presumably reflecting development of the orienting net-

work of brain regions. The developmental trajectory of orienting behavior has been examined most often using the inhibition of return paradigm. Inhibition of return refers to the tendency to avoid returning attention to a location just previously attended. Adult studies by Rafal, Calabresi, Brennan, and Scioloto (1989) indicate that inhibition of return occurs only in situations in which an eye movement is prepared, even if the actual movement is never made. Studies of infants 3, 4, 6, 12, and 18 months of age showed that, although 6- to 18-month-olds showed inhibition of return equivalent to adults, 3- and 4-month-olds showed no evidence of inhibition of return (Clohessy, Posner, Rothbart, & Vecera, 1991; Johnson, Posner, & Rothbart, 1994). This age coincides with behavioral evidence of the development of saccadic eye movements, as well as PET evidence of the age at which parietal metabolism reaches adult levels (Chugani, Phelps, & Mazziotta, 1987). Hood et al. (1998) have demonstrated that 4-month-olds can show evidence of covert orienting, however. When a cue is too short in duration to elicit an eye movement, 4-month-olds show improved performance for targets presented at the cued location (Hood, Atkinson, & Braddick, 1998). The importance of the development of the abilities to disengage, shift, and reengage attention is probably obvious to developmental psychologists. These abilities are critical for learning new information from our environments—perceptual, cognitive, social, and emotional—and impairments in this system result in significant problems in everyday life.

THE FUTURE OF DEVELOPMENTAL COGNITIVE NEUROSCIENCE

Based on our extensive review of the literature, the field of developmental cognitive neuroscience has clearly advanced since the fifth edition of the *Handbook* was published. We know a considerable amount about the neural bases of a variety of cognitive abilities, although our knowledge base is uneven both between and within developmental periods. We know more about the neural bases of memory in infancy than we do in childhood, and we know more about some executive functions than others (e.g., working memory versus planning).

What does the future hold for those interested in this area? For starters, as our knowledge of brain development improves, our ability to ground behavior in the

brain should similarly improve. This, in turn, should permit establishing more biologically plausible models of behavioral development (connectionist models, in particular, should benefit from this advance). Second, as our knowledge of neural plasticity and molecular biology increases, we will do a better job of designing studies that shed light on which behaviors are derived from experience-dependent versus experience-independent processes. This, in turn, should lead us away from strongly held nativist beliefs, at least in the context of higher-level cognitive functions. Third, we anticipate a judicious increase in the study of clinical populations, as such study has the potential to provide converging information on typical development. Fourth, given increased interest in using neuroimaging tools to study affective development, we anticipate increased interest in linking cognitive and emotional development in the context of brain development. Fifth, increased attention will be paid to the coregistration of imaging modalities, particularly ERPs with fMRI and optical imaging. Sixth, as investigators gain more experience in conducting fMRI studies with children, and as physicists and engineers improve MR scanning parameters, the field should experience a downward shift in the age at which such studies can be performed. Scanning infants will always prove difficult, but scanning preschool-age children may prove less challenging.

These are just a few of the areas of growth we anticipate in the coming decade—others will surface as the field evolves. But, we remain optimistic that interest in linking brain with behavior in the context of development is now firmly entrenched in developmental psychology.

The Infant's Auditory World	94
REFERENCES	95

The auditory world provides a rich source of information to be acquired by the developing infant. We are born with well-developed auditory systems, capable of gathering a wealth of knowledge even prior to birth. Audi-

We thank Dick Aslin, Suzanne Curtin, LouAnn Gerken, Lincoln Gray, Jim Morgan, and Erik Thiessen for their helpful comments on a previous draft. Support for the preparation of this chapter was provided by grants from NIH (R01 HD37466) and NSF (BCS-9983630) to J. R. S., from the Natural Science and Engineering Research Council of Canada, Social Sciences and Humanities Research Council of Canada, The Canada Research Chair Program, and the Human Frontiers Science Program to J. F. W., and from NIH (R01 DC00396, P30 DC04661) to L. A. W.

This chapter is dedicated to the memory of Peter Jusczyk.

tion provides a channel for many important sources of inputs, including a variety of critical environmental sounds such as music and spoken language. For these reasons alone, it has long been of great interest to characterize the nature of this system as it develops.

But studying how infants use their auditory environments can tell us more than just how these developmental processes unfold. In the past decade, studies of infant audition, speech, and the beginnings of language have increasingly begun to bear on central debates in developmental cognitive science and cognitive neuroscience. We are moving beyond such classic questions such as whether speech is special (i.e., subserved by a dedicated neural system that is not shared by other aspects of perception) to begin to study the actual learn-

ing mechanisms underlying infants' precocious acquisition of the speech sounds of their native language. Similarly, studies of the origins of infants' linguistic knowledge have moved beyond descriptions of *when* infants know about various features of their native language to studies that ask *how* that learning occurred. Increasingly, such behavioral studies are paired with research using psychophysiological methods to study the neural underpinnings of the behavior, experiments using nonhuman animals to probe the species-specificity of the behavior, and studies using materials drawn from other domains to assess the domain-specificity of the behavior.

In this chapter, we review the state of the art in our field, using the ever-increasing interdisciplinarity of research on infant audition, speech perception, and early language acquisition to highlight several themes. One broad theme is the cause of developmental change. Are changes due to maturation of central and/or peripheral neural structures? Or are they due to learning mechanisms, which are continually discovering complex structure in the environment? A related broad theme concerns the nature of these perceptual and learning processes, and the extent to which they are specifically tailored for a single task (e.g., learning about speech) as opposed to available more generally for learning across domains. We will also consider constraints on perception and learning—arising from our perceptual systems, neural structures, species-specific limitations on learning, and domain-specific limitations on learning—that will help to inform our theories of how these processes are related to other aspects of infant development. Finally, we will point to many of the open questions that continue to drive research in this field, and which we hope to see answered in the subsequent edition of this *Handbook*.

INFANT AUDITION

Most infant auditory research has focused on infants' perception of speech. In subsequent sections of this chapter, we review many of these studies that demonstrate that even newborns are capable of making many phonetic and other speech distinctions. Clearly infants have the auditory capacity to represent some of the critical acoustic features of speech. Little is known, however, about the acoustic information that infants use to make these fine-grained distinctions. Immature

auditory processing will result in imprecise representations of speech as well as other sounds, and hence limit the information that is available to the infant. In this section, we consider whether limitations of auditory processing may serve to constrain early speech perception.

The auditory system is designed to locate and identify sound sources in the environment. Sounds entering the ear are shaped by the structures of the outer ear to optimize detection of relevant sounds and to allow determination of a sound's location in space. The sound is then analyzed into frequency bands by the inner ear. Periodicity, intensity and temporal fluctuations are represented within each band. This code provides the basis of all auditory perception, but the auditory system must calculate some sound characteristics from the basic code. For example, the shape of a sound's spectrum is extracted and differences between the ears are calculated in the auditory brainstem. Once all of this coding and calculation, referred to as primary processing, is completed, however, the system must still determine which frequency bands emanate from a common source, on the basis of commonalities in frequency, periodicity, intensity, temporal fluctuations, location, and spectral shape. The latter stage of processing is known as sound source segregation or auditory scene analysis (Bregman, 1990). Failure to segregate a sound source from the background makes a listener less sensitive to that sound; factors that promote sound source segregation tend to make listeners more sensitive to a sound. These processes are likely to undergo important developmental change during infancy. Finally, it is important to recognize that attention, motivation, memory and other cognitive processes influence auditory scene analysis, and in a very real way, hearing. These effects are described collectively as "processing efficiency," and they also contribute to auditory development.

Development of the Auditory Apparatus: Setting the Stage

In humans, the inner ear begins to function during the second trimester of gestation. If humans are like other mammals, neural responses to sound are possible as soon as the inner ear begins to transduce sound. The consensus is that scalp-recorded auditory evoked potentials and behavioral responses can be observed in fetuses and in preterm infants as young as 28 weeks gestational age. The

possibility of prenatal hearing has important implications for understanding the effects of early experience on neural development. Fetuses' experience with sound is severely limited by the sound transmission properties of maternal tissue and amniotic fluid, by the conduction of sound to the fetal inner ear, and by immaturities of the inner ear and auditory nervous system (Smith, Gerhardt, Griffiths, & Huang, 2003). Nonetheless, several studies have documented differential fetal responsiveness to sounds of different intensities and frequencies (e.g., Lecanuet, Gramer-Deferre, & Busnel, 1988; Shahidullah & Hepper, 1994). Further, several studies have demonstrated that prenatal experience with sound can influence later auditory responses, at least in the immediate postnatal period. This is most dramatically shown in the preference for mother's voice shown at birth (DeCasper & Fifer, 1980) and in the preference for a story and/or song heard prenatally (DeCasper & Spence, 1986). At the same time, little is known about the importance of prenatal experience with sound for auditory or other aspects of development.

At term, the neonate is believed to have a mature inner ear (but see Abdala, 2001; for example, Bargones & Burns, 1988; Bredberg, 1968). However, the conduction of sound through the external and middle ear to the inner ear is less efficient in neonates than in adults (Keefe, Bulen, Arehart, & Burns, 1993; Keefe, Burns, Bulen, & Campbell, 1994; Keefe et al., 2000). The transmission of information through the auditory neural pathway is slow and inefficient (e.g., Gorga, Kaminski, Beauchaine, Jesteadt, & Neely, 1989; Gorga, Reiland, Beauchaine, Worthington, & Jesteadt, 1987; Ponton, Moore, & Eggermont, 1996). The implications of this pattern of immaturities for postnatal auditory development are discussed in the sections that follow.

Approximately 2 to 3 in 1,000 infants are born with a hearing loss, 1 in 1,000 with a severe to profound hearing loss. However, 20% to 30% of hearing-impaired children develop hearing loss postnatally. These children can be identified, even as neonates, with appropriate hearing screening (Norton et al., 2000), although in the recent past, the average age of identification of hearing-impaired children was 2½ years. Disruption of nearly all aspects of development, but particularly of language development, is typical in hearing-impaired children. Recent evidence suggests, however, that early identification of hearing loss—with intervention beginning prior to 6 months of age—facilitates the development of language skills (signed and/or spoken) within the normal

range in childhood (Yoshinaga-Itano, Sedey, Coulter, & Mehl, 1998).

Measuring Auditory Development

Sounds differ in three basic dimensions—frequency, intensity, and changes in frequency and intensity over time. The auditory system encodes the frequency and intensity of sound and extracts information about temporal variation. In addition, the auditory system calculates additional information about differences between sounds arriving at the two ears, or interaural differences. In psychoacoustics, auditory capacities are approached from two directions. One is to describe the accuracy with which a dimension is coded, or resolution. The other is to describe the function relating the acoustic dimension to its perception. Both approaches have been taken in characterizing hearing during infancy, although the former is more straightforward in a nonverbal subject.

Except as noted, the studies described in this section used one of three varieties of discrimination learning procedures to estimate infants' thresholds for detecting or discriminating between sounds. Each depends upon teaching the infant that when a sound occurs or when a sound changes in some way, a response will be reinforced by the presentation of an interesting audiovisual event. The common reinforcers are mechanical toys and video displays. Two of the procedures teach infants to make a head turn when the appropriate sound occurs. In one variant, infants learn to turn toward the reinforcer (e.g., Berg & Smith, 1983; Nozza & Wilson, 1984). In the other variant, sounds are presented from one of two loudspeakers on a random schedule. The infant learns to turn toward the speaker producing the sound (e.g., Trehab, Schneider, & Edman, 1980). Infants older than about 6 months of age can be successfully tested using either of these procedures. However, younger infants do not make the crisp directional head turns that older infants do. To get around this difficulty, observer-based conditioning procedures capitalize on whatever response the infant makes to the sound (e.g., Tharpe & Ashmead, 2001; Werner, 1995). In this method, which was originally developed to study infants' visual acuity (Teller, 1979), an observer watching the infant knows when a sound may be presented but not whether it was in fact presented. On the basis of the infant's response, the observer must judge whether or not the sound was presented. The infant is reinforced for producing a response that leads to a correct observer judgment. Infants as

young as 1 month of age have been successfully tested using this technique.

Once children are 3 or 4 years old, they can be tested using a variant of adult psychophysical procedures (e.g., Wightman, Allen, Dolan, Kistler, & Jamieson, 1989). Commonly, three intervals are presented to the child, only one of which randomly contains the signal to be processed. The child is asked to choose the interval containing the different sound. The intervals can be presented with cartoon indicators, making the whole procedure more like a video game.

Frequency Coding

Frequency is coded in the auditory system by two mechanisms. The basilar membrane in the inner ear vibrates in response to incoming sound, and because the stiffness of the membrane varies along its length, each position along the membrane responds maximally to a particular frequency. Hair cells are positioned along the length of the basilar membrane. Outer hair cells provide mechanical feedback that results in higher amplitude and more restricted, or sharper, basilar membrane responses to a given frequency. Each inner hair cell transduces basilar membrane motion into a neural response in the auditory nerve fibers that exclusively contact it. Thus activity in a particular auditory nerve fiber indicates the presence of frequencies within a band about a third of an octave wide. The frequency content of any sound, then, is represented in the pattern of activity across auditory nerve fibers innervating different positions along the basilar membrane. This neural representation of sound is referred to as the place code. Because the basilar membrane vibrates at the frequency of stimulation, the action potentials in auditory nerve fibers tend to occur at the frequency of stimulation. Thus, for frequencies below 5,000 Hz, the intervals between action potentials provide another code for frequency.¹ This phenomenon is known as phase locking, and it provides the basis for the temporal code for frequency. The bulk of evidence from adults indicates that both frequency codes are involved

in determining pitch, the perceptual dimension correlated with sound frequency. Further, in adults, it is the processing of sound in the inner ear that limits the representation of complex sounds.

Frequency Resolution

The most common way to assess the resolution of the place code of frequency is to determine the frequencies of competing sounds that interfere with a listener's ability to detect a frequency-specific sound. The phenomenon of one sound's increasing the difficulty of detecting another is called masking. The interfering sound is the masker; the sound to be detected is called the signal or probe. When masking occurs, the threshold ratio of probe to masker intensity required to detect the probe is higher. It has long been known that one sound will only mask another if their frequencies are separated by less than about a third of an octave (there are exceptions to this rule which are discussed below). It is fairly easy to understand, then, that masking occurs when the masker evokes activity in the same auditory nerve fibers that respond to the probe, and that masking provides a method for assessing the quality of the place code for frequency.

Both behavioral and electrophysiological measures indicate that frequency resolution measured using masking is immature at birth, but is mature by about 6 months of age. For example, Spetner and Olsho (1990) showed that a 4,000 or 8,000 Hz tone was masked by a broader range of frequencies for 3-month-olds than for 6-month-olds and adults. Three-month-olds' frequency resolution was mature only at 1,000 Hz, and 6-month-olds demonstrated mature frequency resolution at all frequencies. Studies by Schneider, Morrongiello, and Trehub (1990) and Olsho (1985) confirmed that frequency resolution was mature at 6 months of age. Although a few studies purported to show immature frequency resolution at 4 years of age (Allen, Wightman, Kistler, & Dolan, 1989; Irwin, Stillman, & Schade, 1986), Hall and Grose (1991) subsequently showed that children of this age had mature frequency resolution when thresholds were appropriately measured. Thus, frequency resolution at low frequencies appears to be mature by birth. At high frequencies, frequency resolution becomes adultlike some time between 3 and 6 months.

Lack of development of the auditory nervous system appears to be responsible for early immaturity of frequency resolution. The consensus is that the inner ear mechanisms responsible for frequency resolution are mature at birth (but see Abdala, 2001; for example, Barganes & Burns, 1988; Bredberg, 1968). However, the

¹ Single auditory nerve fibers do not fire on every cycle of a continuing periodic sound; at frequencies above about 1,000 Hz, single nerve fibers cannot fire fast enough to provide a temporal code for frequency. However, each nerve fiber responds at the same phase of the sound and different nerve fibers randomly respond on different cycles. By combining the responses of many auditory nerve fibers responding to the same frequency, a code for frequency can be derived up to 5,000 Hz.

mature frequency resolution established in the inner ear is not faithfully transmitted through the auditory nervous system. Like the studies based on behavioral measures, several studies based on brainstem evoked-potential measures of frequency resolution report maturity at low frequencies, but not at high frequencies for 3-month-old infants (Abdala & Folsom, 1995a, 1995b; Folsom & Wynne, 1987). By 6 months, these measures indicate mature resolution across the frequency range. The parallels between behavioral and neural evoked potentials results suggest a neural basis for the immaturities observed early in infancy.

Frequency Discrimination

Frequency resolution is a measure of the precision of the place code for frequency. Discrimination between sounds on the basis of frequency, however, is accomplished via both the place code and the temporal code for frequency. Despite the fact that 6-month-olds have mature frequency resolution, frequency discrimination remains immature, at least at low frequencies. Olsho (1984) first reported that 6-month-olds needed about twice the frequency change that adults did to detect a change in frequencies below 2,000 Hz. At 1,000 Hz, several studies have estimated that 6-month-old infants can detect a 1.5% to 3% change in frequency, while adults can detect a change of 1% or less (Aslin, 1989; Olsho, 1984; Olsho, Koch, & Halpin, 1987; Olsho, Schoon, Sakai, Turpin, & Sperduto, 1982; Sinnott & Aslin, 1985). At higher frequencies, Olsho (1984) reported that 6-month-olds detected frequency changes as well as adults did. Sinnott and Aslin (1985) and Olsho et al. (1987) reported results generally consistent with that pattern. Olsho et al. also tested 3-month-old infants and found that they performed similarly to 6-month-olds at low frequencies, but that they had higher frequency discrimination thresholds at high frequencies.

Several studies of preschool and school-age children show that pure-tone frequency discrimination is not adultlike until 10 years of age (Jensen & Neff, 1993; Maxon & Hochberg, 1982; Thompson, Cranford, & Hoyer, 1999). Maxon and Hochberg reported that the discrimination of low frequencies was more immature than that of high frequencies at 4 years, consistent with the results of the infant studies. However, these investigators did report some improvement in discrimination of high frequencies between 4 and 12 years. Nonetheless, the greatest changes in high-frequency discrimination appear to occur during the first 6 months of life, while

the greatest changes in low-frequency discrimination appear to occur between 4 and 6 years of age.

The change in high-frequency discrimination between 3 and 6 months is consistent with the improvement in frequency resolution observed at this age. The nature of the prolonged developmental course for low frequency discrimination is less obvious. It has been suggested that adults use the temporal code to represent low frequency tones and the place code to represent high frequency tones (B. C. J. Moore, 1973). One possible explanation for poor low-frequency discrimination by infants and children is that they do not use the temporal code in pure-tone frequency discrimination or that they use the temporal code inefficiently. However, Allen, Jones, and Slaney (1998) reported that, compared to adults, 4-year-olds' detection is more dependent on the periodicity, or "pitchiness" of a tone. The temporal code is the basis of that sound quality (B. C. J. Moore, 1996). In addition 7-year-olds' pure tone frequency discrimination is more affected by decreases in tone duration than is that of adults', which would suggest that children are more dependent on the temporal code (Thompson et al., 1999). However, by 7 years of age, children are also good at low-frequency discrimination (Maxon & Hochberg, 1982). The other possible explanation for poor low-frequency discrimination is that it takes longer to learn to discriminate between low frequencies than high (Demany, 1985; Olsho, Koch, & Carter, 1988). If infants and young children generally take longer to learn a task than adults do, then they might be at a particular disadvantage in learning to discriminate between low frequencies. An analysis of infant frequency discrimination by Olsho, Koch, and Carter (1988) suggests that training effects might account for some, but not all, of the difference between infants and adults in low-frequency discrimination.

Perception of Pitch

The relative importance of the temporal and place codes has been debated extensively in the literature on complex pitch perception. A complex tone consists of multiple frequency components, a fundamental frequency and harmonics. The perception of complex pitch is said to be unitary. That is, although the pitch of a complex tone generally matches the pitch of its fundamental, the complex is perceived as having a single pitch, and the higher harmonics contribute to that percept (B. C. J. Moore, 1996). Clarkson and her colleagues have carried out an impressive series of studies of infants' perception of

complex pitch. In many respects, complex pitch perception in 7- to 8-month-olds appears to be adultlike: Infants are able to categorize complexes on the basis of fundamental frequency, even when the fundamental frequency component is missing from the complex (Clarkson & Clifton, 1985; Montgomery & Clarkson, 1997). Infants have difficulty categorizing inharmonic complexes on the basis of pitch, as do adults (Clarkson & Clifton, 1995). However, when only high-frequency harmonics are present, adults are still able to hear the pitch of the missing fundamental, while infants are not (Clarkson & Rogers, 1995). Because periodicity in the waveform of combined high-frequency harmonics provides the basis of this percept in adults, Clarkson and Rogers' result suggests, again, that infants have difficulty using the temporal code in pitch perception.

Intensity Coding

The primary code for intensity in the auditory system is the firing rate of auditory nerve fibers. There are several studies of developing nonhumans that suggest that immature neurons cannot sustain a response over time and that the maximum firing rate achieved by auditory nerve fibers increases with development (Sanes & Walsh, 1998). In humans, evoked potential amplitude increases more slowly with increasing intensity in infants than in adults (Durieux-Smith, Edwards, Picton, & McMurray, 1985; Jiang, Wu, & Zhang, 1990). Further, because the external and middle ear grow during infancy and childhood, the conduction of sound to the inner would be expected to improve with age. Thus, there is reason to believe that intensity processing would undergo postnatal developmental change in humans.

Intensity Resolution

Some sensory processes can be measured by comparing thresholds across masking conditions. In the studies of infant frequency resolution described earlier (Olsho, 1985; Schneider et al., 1990; Spetner & Olsho, 1990), 6-month-olds' thresholds for detecting a tone were always higher than those of adults, but their thresholds changed as the frequency or bandwidth of the masker changed exactly as adults' thresholds did. It is the pattern of change in threshold that indicates resolution. Making it difficult to judge intensity resolution to be immature is the fact that measures of intensity resolution tend to be absolute measures; they do not depend on a comparison of performance across conditions, but on the absolute

level of performance. It is difficult to distinguish intensity coding effects from processing efficiency effects on an absolute measure. Few experiments have been carried out that allow for this distinction, and a major question in this area is the relative contributions of auditory capacities and processing efficiency to age-related changes in thresholds.

Intensity resolution is typically measured psychophysically by finding the smallest intensity change that a listener can detect. When the change detected is from "no sound" to "sound," we say we are measuring absolute sensitivity. When change is detected in an audible sound, we say we are measuring intensity discrimination, increment detection or masking. In the classic intensity discrimination paradigm, a listener hears two or more sounds, and responds to the more intense. In increment detection, the background sound is continuous; the listener responds when the intensity of the background increases. Simultaneous masking is a special case of intensity discrimination or increment detection in that the addition of a signal to the masker is detected as an increase in the intensity of the stimulus. All of these measures largely depend on the same underlying processes, so the expectation is that they will develop along a similar course, with one exception: The "noise" that limits absolute sensitivity is neural and physiological noise. It is not conducted through the external and middle ear. Immaturity of the conductive apparatus will affect the level of a signal played into the ear, but not the level of the background when absolute threshold is measured. In masking, intensity discrimination and increment detection, the conductive apparatus affects both the signal and the background, leaving the signal-to-noise ratio unchanged. Thus, conductive immaturity will be reflected in absolute thresholds, but not the other measures of intensity resolution.

The most commonly measured aspect of intensity processing is the absolute threshold, the intensity of sound that is just detectable in a quiet environment. Some studies have measured absolute thresholds in infants 3 months and younger. Weir (1976, 1979) estimated the behavioral threshold of neonates, based on their spontaneous responses to tones. The thresholds she measured ranged from 68 dB SPL at 250 Hz to 82 dB SPL at 2,000 Hz, approximately 30 and 70 dB higher than adult thresholds at these frequencies, respectively. Ruth, Horner, McCoy, and Chandler (1983) and Kaga and Tanaka (1980) reported behavioral observation audiometry thresholds for 1-month-olds that are similar to

those reported by Weir for neonates. However, thresholds measured at 1 to 2 months of age using observer-based procedures are quite a bit lower, about 40 to 55 dB SPL, 35 to 45 dB higher than adults' thresholds (Tharpe & Ashmead, 2001; Trehub, Schneider, Thorpe, & Judge, 1991; Werner & Gillenwater, 1990; Werner & Mancl, 1993). The difference between 1-month-olds' and adults' threshold is about 10 dB greater at 500 Hz than at 4,000 Hz (Werner & Gillenwater, 1990). Whether infants' sensitivity actually improves by 25 dB between birth and 1 month is not clear, given the differences in the procedures used to assess threshold.

By 3 months, thresholds appear to improve by about 10 dB at 500 Hz and by nearly 20 dB at 4,000 Hz (Olsho, Koch, Carter, Halpin, & Spetner, 1988). Compared to adults, 3-month-olds are still about 5 dB less sensitive at the higher frequency. A longitudinal, observer-based study of infants' detection thresholds for a broad noise band confirmed an improvement of about 15 dB between 1 and 3 months (Tharpe & Ashmead, 2001). Between 3 and 6 months, very little improvement is observed in the 500-Hz threshold, but a further 15 dB improvement is seen in the 4,000-Hz threshold (Olsho, Koch, Carter, et al., 1988). Tharpe and Ashmead observed about a 15 dB improvement in threshold for a noise band between 3 and 6 months. In the Olsho et al. study, the performance difference between 6-month-olds and adults at 4,000 Hz is about 15 dB, while at 500 Hz it is about 20 dB. There is general consensus that in the vicinity of 1,000 Hz, 6-month-olds are about 15 dB less sensitive than adults (Berg & Smith, 1983; Nozza & Wilson, 1984; Olsho, Koch, Carter, et al., 1988; Ruth et al., 1983; Sinnott, Pisoni, & Aslin, 1983; Tharpe & Ashmead, 2001; Trehub et al., 1980).

More extensive work has documented absolute sensitivity from 6 months to adulthood. Trehub, Schneider, Morrongiello, and Thorpe (1988) measured thresholds for noise bands centered at different frequencies for listeners ranging from 6 months of age through the school years to adulthood. They report that threshold improves by about 25 dB at 400 Hz, about 20 dB at 1,000 Hz, but only 10 dB at 10,000 Hz. Further, the higher the frequency, the earlier adult levels are achieved: 10 years or later at 1,000 Hz, but before 5 years of age at 4,000 and 10,000 Hz.

The ability to detect a change in the intensity of an audible sound is frequently measured by intensity discrimination, that is, by asking the listener to respond to an intensity difference between sounds. Several studies of infants indicate that they are poorer at intensity dis-

crimination than are adults. Few data are available for infants younger than 6 months of age, but there is evidence that newborns respond to an intensity change in a speech sound as small as 6 dB (Tarquinio, Zelazo, & Weiss, 1990). By 7 to 9 months, Sinnott and Aslin (1985) found that infants detected intensity differences of 6 dB between 1,000 Hz tones, while adults could detect differences of about 2 dB. Kopyar (1997) reported that infants of this age detected differences of 9 dB between tones or between broadband noises. Adults detected differences of about 4 dB between tones, but about 3 dB between noises.

Intensity discrimination has not been examined in children between 9 months and 4 years of age. Maxon and Hochberg (1982) tested intensity discrimination of tones in children older than 4 years. They found a steady improvement in the discrimination threshold from about 2 dB at age 4 years to about 1 dB at 12 years, when the level of tones was near 60 dB above the child's absolute threshold. Thus, by 4 years, intensity discrimination appears to be quite good. Only minor improvements occur thereafter, at least for tones well above absolute threshold.

Increment detection matures somewhat earlier than does discrimination between discrete sounds. Several studies have shown that 7- to 9-month-olds can detect 3 to 5 dB increments in a broad noise band (Berg & Boswell, 1998; Kopyar, 1997; Werner & Boike, 2001), under conditions in which adults detect increments of 1 to 2 dB. Schneider, Bull, and Trehub (1988) reported that 12-month-olds could detect 3 dB increments in a continuous broadband noise, while adults could detect increments less than 1 dB. Berg and Boswell (2000) measured increment detection thresholds in 1- and 3-year-old children, for a 2-octave wide noise band centered at 4,000 Hz. Their results for 1-year-olds are similar to those reported by Schneider et al.; 3-year-olds appeared to be adultlike in this task.

The only thresholds for detection of an increment in a tone were reported by Kopyar (1997). Infants do relatively worse in detecting tone increments than noise increments, requiring increments of 8 dB, compared to 2 dB for adults. A number of studies have examined the development of detection of a tone or narrow noise band masked by a noise, essentially the detection of an increment in an ongoing sound. Schneider, Trehub, Morrongiello, and Thorpe (1989) estimated masked thresholds for a 1-octave band noise, centered at frequencies ranging from 400 to 10,000 Hz, masked by a broadband noise, in children ranging from 6 months to

10 years of age and adults. At 6 months, the infants' detection threshold was equivalent to a 7 dB increment; adults detected a 1 dB increment.² The age difference was about the same across the frequency range. Relatively large improvements in performance were reported between 6 and 18 months and between 4 years and 8 years. There was little difference between 10-year-olds and adults. Other studies have examined infants' and children's detection of tones in noise (Allen & Wightman, 1994; Bargones, Werner, & Marean, 1995; Berg & Boswell, 1999; Nozza & Wilson, 1984). They report similar results, although it is clear that there is considerable variability across children in this task (e.g., Allen & Wightman, 1994).

Perception of Timbre

Timbre, or sound quality, is determined by the relative amplitudes of the components of a complex sound, and thus involves the comparison of intensities across frequency. The physical dimension associated with timbre is referred to as spectral shape. Vowel perception and sound localization depend on spectral shape processing. A few studies have examined the development of timbre perception. Seven-month-olds can discriminate between sounds of different timbres, complex tones with the same pitch that contain different harmonics (Clarkson, Clifton, & Perris, 1988). Trehub, Endman, and Thorpe (1990) also showed that infants could categorize tonal complexes on the basis of "spectral shape." The sharpness of infants' representation of spectral shape has not been assessed. Allen and Wightman (1992) used a complex sound with a sinusoidal spectral shape to measure children's threshold for detecting changes in spectral shape. They were unable to elicit discrimination between such complexes in 4-year-olds. Five and 7-year-olds performed the task, but only 9-year-olds performed as well as adults. These results suggest that spectral shape, or timbre, discrimination follows a long developmental course. It is not clear that performance on this task generalizes to vowel perception.

Perception of Loudness

A final measure of intensity processing is loudness. In adults, loudness is measured by having listeners match sounds in loudness or by having them rate loudness by

some means. Children as young as 5 years of age are able to rate the loudness of tones numerically and with line length. Moreover, loudness appears to grow with increasing intensity in the same way for children and adults (Bond & Stevens, 1969; Collins & Gescheider, 1989). The evidence on loudness growth in infants is sparse. Leibold and Werner (2002) examined the relationship between intensity and reaction time in 7- to 9-month-olds and adults. Reaction time decreased with increasing sound intensity in both age groups, but the rate of decrease was greater for infants than for adults. This finding suggests that loudness grows more rapidly with increasing intensity in infants, but again, the implications of this finding for early audition are not clear.

In summary, absolute threshold, intensity discrimination, detection of tones masked by noise and spectral shape discrimination all undergo relatively large age-related improvements during infancy and the preschool years. However, adult levels of performance are not reached until 8 or 10 years of age. Interestingly, increment detection in broadband sounds appears to mature earlier, around 3 years of age. Nozza (1995; Nozza & Hensen, 1999) showed that the level at which a noise would just start to mask a tone was 8 dB more intense for infants than for adults. This clever experiment demonstrates that immature thresholds of 8- to 11-month-olds are due largely to changes in sensitivity, rather than performance factors. Several factors are known to contribute to age-related improvements in intensity processing. For example, the frequency response of the infant ear canal changes during infancy. While the adult ear canal conducts sounds best in the range between 2,000 and 5,000 Hz, the infant ear canal conducts higher frequency sounds better (Keefe et al., 1994). Further, the efficiency with which the middle ear conducts sound into the inner ear has been shown to increase over a long age period, from birth to perhaps 10 years of age (Keefe et al., 1993, 2000; Keefe & Levi, 1996; Okabe, Tanaka, Hamada, Miura, & Funai, 1988). The largest improvements occur during the 1st year of life, especially for frequencies over about 1,000 Hz. It has been estimated that the efficiency of the conductive apparatus improves by as much as 20 dB at 3,000 Hz between birth and adulthood, with about half of that improvement occurring during infancy. Age-related improvement in conductive efficiency is smaller at lower frequencies, with about a 5 dB improvement between birth and adulthood (Keefe et al., 1993). Thus, one factor in the development of absolute sensitivity is the development of the conductive apparatus. It is likely that

²If the threshold is expressed as the sound pressure level of the signal added to the masker, 6-month-olds' threshold for detecting a noise band or a tone in noise is 8 to 10 dB higher than adults'.

much, but not all, of the improvement in high-frequency absolute thresholds during the first 6 months of life is due to improvements in conductive efficiency. The conductive improvement is also reflected in thresholds for evoked neural responses (e.g., Lary, Briassoulis, de Vries, Dubowitz, & Dubowitz, 1985; Sininger & Abdala, 1996; Sininger, Abdala, & Cone-Wesson, 1997).

Development of the inner ear is probably not a contributing factor to postnatal auditory development. Most indications are that the inner ear is adultlike in structure by term birth (Bredberg, 1968; Fujimoto, Yamamoto, Hayabuchi, & Yoshizuka, 1981; Hoshino, 1990; Igarashi & Ishii, 1979, 1980; Igarashi, Yamazaki, & Mitsui, 1978; Lavigne-Rebillard & Bagger-Sjöback, 1992; Lavigne-Rebillard & Pujol, 1987, 1988, 1990; Nakai, 1970; Pujol & Lavigne-Rebillard, 1992). Otoacoustic emissions³ may have a higher amplitude in infants and a higher stimulus level may be required to elicit emissions, but they are qualitatively adultlike (Bonfils, Avan, Francois, Trotoux, & Narcy, 1992; Bonfils, Francois, et al., 1992; Brown, Sheppard, & Russell, 1994; Burns, Campbell, & Arehart, 1994). Abdala and her colleagues (Abdala, 1998, 2001; Abdala & Chatterjee, 2003) have presented data on otoacoustic emissions from young infants that differ somewhat from that seen in adults. However, at this point it is not clear that these differences could not be accounted for by the reduction in input to the cochlea because of middle ear immaturity.

Werner and her colleagues (Werner, Folsom, & Mancl, 1993, 1994) have reported that the time that it takes for the neural response to sound to travel through the brainstem predicts a 3-month-old's absolute threshold at 4,000 and 8,000 Hz. Thus, another factor in the early development of intensity processing is maturation of the primary auditory nervous system. Anatomical and electrophysiological studies suggest that the auditory brainstem continues to develop throughout infancy (Gorga et al., 1989; J. K. Moore, Guan, & Shi, 1997; J. K. Moore, Perazzo, & Braun, 1995; J. K. Moore, Ponton, Eggermont, Wu, & Huang, 1996; Ponton, Eggermont, Coupland, & Winkelhaar, 1992; Ponton et al., 1996). Ponton et al. (1996) provide evidence that age-related change in evoked potentials during infancy results largely from increases in synaptic efficiency. Primary

auditory cortex takes much longer to reach maturity, with anatomical and physiological changes occurring to adolescence (J. K. Moore, 2002; J. K. Moore & Guan, 2001; Ponton et al., 2000). The extent to which these changes in the auditory nervous system are reflected in intensity processing beyond infancy is not known.

Finally, higher-level processes also contribute to age-related improvements in intensity processing. Such processes fall into the category of efficiency, as opposed to resolution, but nonetheless influence sensitivity. Several investigators have examined the age differences in intensity processing, and concluded that only a small portion of the difference in thresholds between infants and adults can be accounted for by simple lapses of attention (Viemeister & Schlauch, 1992; Werner, 1992; Wightman & Allen, 1992). Recall, however, that infants and children tend to do quite well in detecting increments in a broadband noise. Werner and Boike (2001) showed that 7- to 9-month-old infants were more adult-like in their detection of an increment in a broadband noise than they were in detecting a tone masked by a broadband noise. Werner and Boike argued that because infants ultimately achieve the same asymptotic performance in detecting tones and noise, the difference cannot be accounted for by differences in attentiveness to narrow-band and broadband sounds. Bargones and Werner (1994) showed that adults tended to listen selectively for a tone at an expected frequency, with the result that they did not hear tones at unexpected frequencies. Infants, in contrast, detected expected and unexpected frequencies equally well. This suggests that infants listen over a broad band of frequencies, even when they are detecting a narrow-band sound. As a result, more of the background noise will interfere with their detection and their thresholds will be higher (Bargones et al., 1995; Dai, Scharf, & Buus, 1991). Because infants and adults both listen over a broad frequency range when detecting broadband sounds, infants will detect broadband sounds better, relative to adults. There is evidence that 6-year-olds detect expected frequencies better than unexpected frequencies (Greenberg, Bray, & Beasley, 1970). The age at which this ability is acquired has not been established.

To summarize, maturation of the conductive apparatus, of primary auditory pathways, and of listening strategies are important factors in the development of intensity processing. Infants' failure to distribute their attention to the features of complex sound as adults do may have additional implications. Given that infants

³Otoacoustic emissions are sounds that are produced in the ear and transmitted back out into the ear canal. The presence of otoacoustic emissions is a good indicator of normal cochlear function.

have relatively little experience with complex sounds and don't know which features are most important, their broadband approach seems sensible. An interesting question is how this broadband listening strategy influences what infants hear in a natural environment.

Temporal Coding

As Viemeister and Plack (1993) noted "the temporal pattern of spectral changes is, essentially, the information substrate" of speech and other communication signals (p. 116). Temporal resolution is defined as the precision with which a listener can follow rapid changes in the intensity or frequency of sound over time. Adult listeners process sounds through a running temporal window, which averages the input over about 8 ms (B. C. J. Moore, Glasberg, Plack, & Biswas, 1988). However, adults also demonstrate temporal integration: They can integrate or otherwise combine a series of these 8-ms "looks" at a sound over 200 to 300 ms while maintaining the temporal detail with 8 ms resolution (Viemeister, 1996; Viemeister & Wakefield, 1991). As noted, early in development auditory neurons often do not maintain their response to ongoing sound, at least in nonhuman species (Sanes & Walsh, 1998). Moreover, it is well established that auditory evoked responses from infants and children are more susceptible to adaptation, or the effects of prior stimulation, than responses from adults. (Fujikawa & Weber, 1977; Fujita, Hyde, & Alberti, 1991; Jiang et al., 1990, 1991; Klein, Alvarez, & Cowburn, 1992; Lasky, 1984, 1991, 1993, 1997; Lasky & Rupert, 1982; Mora, Exposito, Solis, & Barajas, 1990; Plessinger & Woods, 1987). Adaptation effects decline with age, but may be seen in the auditory brain-stem response as late as 3 years of age (Jiang et al., 1991). More centrally generated evoked potentials may exhibit even more dramatic adaptation effects in infants and children (e.g., Mora et al., 1990). Such effects may be reflected in a reduced ability to follow rapidly changing stimuli. How temporal integration might be affected is unclear.

Conclusions about the development of temporal resolution depend strongly on the measure chosen to describe it. Further, the interpretation of age effects that have been demonstrated is not always obvious. A good example is the development of duration discrimination. At least two studies indicated that infants as young as 2 months of age could discriminate a change in the duration of a repeated 200- or 300-ms-long sound of about

20 ms (Jusczyk, Pisoni, Reed, Fernald, & Myers, 1983; Morrongoillo & Trehub, 1987), a change on the order of 10%. Morrongoillo and Trehub also found that 5- to 6-year-olds could discriminate 15 ms changes, while adults discriminated 10 ms changes in the same conditions. At the same time, two studies of children 4- to 10-years-old, using an oddity task ("Which of these three sounds is different?"), report that 4-year-olds may need at least a 50% change in the duration of a 300 or 400 ms sound to detect the change (Elfenbein, Small, & Davis, 1993; Jensen & Neff, 1993). Elfenbein et al. found that duration discrimination did not reach adult levels of performance until 10 years of age. There are many differences among these studies, most notably in the methods used to estimate a threshold, making it extremely difficult to decide how good duration discrimination really is at a given age.

The earliest studies of temporal resolution examined gap detection in infants and in children. In a gap detection task, the duration of an interruption, or "gap," in a sound is manipulated to find the shortest gap duration that can be detected. Werner et al. (1992) reported that the gap detection thresholds in a continuous noise for 3-, 6-, and 12-month-old infants were an order of magnitude worse than those of adults, around 50 compared to 5 ms. Trehub, Schneider, and Henderson (1995) reported better performance for 6- and 12-month-olds when the gap to be detected was between two short tone pips. However, infants' gap detection thresholds were still around 30 ms. Six-month-olds barely achieved 70% correct for gap durations of 28 and 40 ms. Wightman and his colleagues (1989) reported that gap detection thresholds remained immature at 3.5 years, with the threshold for detecting a gap in a noise band centered at 2,000 Hz at about 10 ms. Trehub et al. and Wightman et al. both reported that gap detection thresholds were mature by 5 years of age. In adults, gap detection performance tends to be better for high-frequency sounds than for low (Eddins & Green, 1995). Both infants and children demonstrate adultlike frequency effects on gap detection (Werner et al., 1992; Wightman et al., 1989).

Trehub et al. (1995) suggested that the reason that infants had somewhat better thresholds for detecting a gap between two short sounds than they did for detecting a gap in a continuous sound was that the continuous sound created excess adaptation in the immature auditory system. If the neural response is low at the onset of the gap, because of adaptation, it will be more difficult to detect the gap. Further, if the immature system takes longer to

recover from adaptation, the response at the offset of the gap will be reduced. A psychophysical paradigm for measuring adaptation is forward masking: a relatively intense sound, the masker, is presented, quickly followed by a probe sound. If the interval between the initial and following sound is less than about 100 ms, the audibility of the probe is reduced relative to the unmasked condition. The development of forward masked thresholds has been examined in infants and in children. Werner (1999) measured forward masked thresholds for a 1-kHz tone in 3- and 6-month-old infants at masker-probe intervals ranging from 5 to 100 ms. Her results showed that the amount of forward masking decreased as the interval increased, and in the same way, for each age group. The audibility of the probe tone was affected more for the 3-month-olds than it was for older listeners. However, 6-month-olds were more or less adultlike in the amount of forward masking demonstrated at all intervals. Thus, by this measure of temporal resolution, 3-month-olds are immature, but 6-month-olds are not. This conclusion argues against the idea that adaptation effects are responsible for variation in gap detection thresholds of 6-month-olds. Buss, Hall, Grose, and Dev (1999) also report that the amount of forward masking demonstrated by 5- to 11-year-old children is adultlike.

A measure of temporal resolution that has received considerable attention from developmentalists in recent years is backward masking, in which a probe tone is masked by a relatively intense masker that follows it by a short interval (0 to 50 ms). Tallal and her colleagues (Tallal, Miller, Jenkins, & Merzenich, 1997; Tallal & Piercy, 1973, 1974) have long argued that a deficit in auditory temporal resolution is the underlying cause of specific language impairment. Wright et al. (1997) collected psychophysical data from children with language impairment and typically developing children. They found that children with language impairment did not differ from typically developing children in simultaneous masked thresholds. Their thresholds were a little higher in forward masking, but their thresholds were considerably higher in backward masking. This finding was taken to support Tallal's position and has spurred research in this area. It has also spurred an interest in the development of backward masking, which had heretofore not been examined. For example, Hartley, Wright, Hogan, and Moore (2000) reported 6-year-olds' backward masked threshold for a 1,000-Hz tone to be 34 dB higher than adults'. At 10 years, backward masked thresholds were nearly 20 dB higher than those of adults. Even if the absolute threshold of 6-year-olds are

5 dB or so higher than those of adults, that still means that they are exhibiting 30 dB more masking than adults. Other studies confirm that children at this age are more susceptible to backward masking than adults (Buss et al., 1999; Rosen, van der Lely, Adlard, & Manganari, 2000). Werner (2003) has also reported that 7- and 11-month-olds have higher backward masked thresholds than adults, although the age difference in amount of masking is not clear. A recent study, however, suggests that at least among children, the apparent susceptibility to backward masking may not reflect immaturity of temporal resolution. Hartley and Moore (2002) showed that a listener with normal temporal resolution, but poor processing efficiency, will be relatively more susceptible to backward masking than to forward or simultaneous masking. It should be noted that a similar conclusion could be drawn about the nature of the perceptual deficit associated with language impairment.

The gold standard of temporal resolution measures is the temporal modulation transfer function (TMTF, Viemeister, 1979). Listeners are asked to detect amplitude modulation (AM) in a sound. The depth, or amount, of modulation is manipulated to define the threshold for AM detection. AM detection threshold is estimated over a range of modulation frequencies. For adults, the result is a function, the TMTF, with a "low-pass characteristic": AM detection threshold is fairly constant from a 4-Hz modulation rate to about 50 Hz. Beyond 50 Hz modulation rate, the AM detection threshold grows poorer at rate of about 3 dB per doubling of modulation frequency. The modulation frequency at which AM detection begins to deteriorate is taken as the measure of temporal resolution. Hall and Grose (1994) described the TMTF of 4- to 10-year-old children. The AM detection threshold of 4- to 7-year-olds was poorer than that of adults across the range of modulation rates; 9- to 10-year-olds were adultlike in this respect. However, the shape of the TMTF was the same for all ages; AM detection began to deteriorate at about 50 to 60 Hz in all age groups. When the TMTF becomes mature is uncertain. Levi and Werner (1996) reported AM detection thresholds of 3-month-olds, 6-month-olds and adults at two modulation rates, 4 and 64 Hz. The difference between thresholds at the two modulation rates for 3- and 6-month-olds was 3 dB. This difference suggests that infants have an adultlike TMTF and mature temporal resolution.

The development of temporal integration has also been of recent interest. In adults, increasing the duration of a sound by a factor of 10 leads to a little less than 10-

dB decrease in the absolute threshold for that sound. This means that adults are integrating information about the sound over time nearly perfectly. Sound energy cannot be integrated, however, over intervals longer than 200 to 300 ms. Several studies of infants have reported that the maximum interval over which infants integrate sound energy in detection is similar to the adult value (e.g., Berg & Boswell, 1995; Thorpe & Schneider, 1987). However, it was also reported that increasing the duration of sound had a much greater than expected effect on infants' absolute threshold. For example, Thorpe and Schneider found that increasing the duration of a noise band by a factor of 6.3 leads to a 20-dB decrease in 6- to 7-month-olds' absolute threshold. Berg and Boswell argued that infants' temporal integration was mature, but that infants had difficulty detecting short duration sounds (see also Bargones et al., 1995). Maxon and Hochberg (1982) reported temporal integration data for 4- to 10-year-olds. For durations of 50 ms and longer, thresholds decreased with increasing duration at an adultlike rate, and thresholds leveled off between 200 and 400 ms duration. The only difference between children and adults was at quite short durations: increasing the duration from 25 to 50 ms leads to a 7-dB decrease in threshold at 4 years. By 12 years, the decrease is only 5 dB, but still greater than expected in adults. Thus, as children get older they appear to be able to deal with progressively shorter sounds. The nature of the immaturity is not clear; Berg and Boswell suggest that it actually could result from immaturity in the growth of neural response with intensity (Fay & Coombs, 1983) or that the immature auditory system is less able to process onset responses and hence, transient stimuli.

Spatial Resolution

Locating sound sources in space involves several processes including evaluation of spectral shape and intensity, as well as binaural comparisons. Under normal circumstances, spectral shape is the primary cue to position in elevation, while binaural time and intensity differences are the primary cues to position in azimuth (the plane that runs through your ears parallel to the ground).

Development of the ability to use these cues has been well studied in infants via measurements of the minimum audible angle (MAA), the threshold for detecting a change in the position of a sound source. The MAA in azimuth has been shown to decrease from about 27° at 1 month to less than 5° at 18 months (Ashmead, Clifton, & Perris, 1987; Clifton, Morrongiello, Kulig, & Dowd,

1981; Morrongiello, 1988; Morrongiello, Fenwick, & Chance, 1990; Morrongiello, Fenwick, Hillier, & Chance, 1994; Morrongiello & Rocca, 1987a, 1990). The MAA is adultlike, 1° to 2°, in 5-year-olds. The MAA in elevation decreases from a value greater than 16° at 6 to 8 months to about 4° at 18 months, which is comparable to the adult MAA in elevation (Morrongiello & Rocca, 1987b, 1987c). In adults, the MAA in azimuth is generally smaller than that in elevation, because additional, binaural, cues can be used to localize sounds in azimuth. Interestingly, during infancy the MAA in azimuth is similar to that in elevation (Morrongiello & Rocca, 1987b, 1987c). That the MAA is similar in the two dimensions suggests that infants may rely more heavily on spectral shape in sound localization than on binaural differences. Finally, several studies have suggested that infants are sensitive to the changes in sound intensity that signal a change in sound source distance (Clifton, Perris, & Bullinger, 1991; Morrongiello, Hewitt, & Gotowiec, 1991). The accuracy with which infants can judge sound source distance has not been examined.

Humans and other mammals base their judgments of a sound source's location on information that first reaches their ears; they are able to suppress information carried in echoes of the original sound. This effect is known as the precedence effect. It is known that infants also demonstrate this effect (Clifton, Morrongiello, & Dowd, 1984). Interestingly, Litovsky (1997) found that while sound localization is influenced to some degree by the presence of echoes in adults, 5-year-olds are more affected. This difference suggests that while the traditional MAA is mature by 5 years, sound localization in real environments may continue to be refined beyond that age.

The mechanisms underlying the development of sound localization are not completely understood. One obvious change that will influence this ability is the growth of the head and external ear. As the head grows, the size of interaural differences increases (Clifton, Gwiazda, Bauer, Clarkson, & Held, 1988), and discrimination of interaural time differences has been shown to improve during infancy (Ashmead, Davis, Whalen, & Odom, 1991). Ashmead et al. (1991), however, showed that immaturity of interaural discrimination does not appear to be great enough to account for early immaturity of sound localization. One possible explanation for early sound localization immaturity is that infants are more dependent on spectral shape than interaural differences in determining a sound source location. Infants'

ability to use spectral shape cues will also improve as the external ear grows. Another explanation is that infants can process the cues to sound location adequately, but that they have not yet developed the ability to translate a set of acoustic cues into a precise location in space (Gray, 1992). In other animals, it has been shown that multimodal experience is required to grow such a map of sensory space (e.g., Binns, Withington, & Keating, 1995; King, Hutchings, Moore, & Blakemore, 1988). Further, humans who have only monaural hearing early in life may be able to discriminate interaural differences normally when hearing is restored to the previously deprived ear, but still be unable to locate sounds in space (Wilmington, Gray, & Jahrsdorfer, 1994).

Besides allowing us to localize sounds with precision, interaural differences improve our sensitivity to sound. In the laboratory this improvement in sensitivity is called the masking level difference (MLD): Threshold for a tone presented to both ears is lower if there are interaural differences in the masker presented to the two ears. It appears that infants derive less benefit from interaural differences than adults do, and that by 5 years of age the MLD is adultlike (Hall & Grose, 1990; Nozza, 1987). However, 5-year-olds may still derive less benefit from listening with two ears when the listening situation is complex (Hall & Grose, 1990).

Development of Auditory Scene Analysis

Once the auditory system has analyzed incoming sound and extracted information about its spectral shape, temporal fluctuations and location, it remains to resynthesize the auditory scene. Information in different frequency bands must be grouped according to source on the basis of the initial analysis. Moreover, once the scene has been reconstructed, the listener may choose to attend to one sound source, while ignoring others. The development of these processes has not been studied extensively. A few studies suggest that the process of grouping components on the basis of source, called sound source segregation, is functional in infancy, but it is not clear how accurately or efficiently it operates.

Demany (1982), for example, used repeating tone sequences to study source segregation. In one sequence, three of four tones were close in frequency while the fourth was somewhat higher in frequency. Adult listeners perceived this sequence as coming from two sources, one producing three different low frequencies, the other producing the single higher frequency tone. If the order

of the tones in this sequence was reversed, adults had no trouble reporting the change. In another sequence, two pairs of near-frequency tones were repeated. Adults heard this sequence as coming from two sources, each of which produced two alternating tones. When the order of this sequence was reversed, adults had difficulty hearing the change. Demany tested 2- to 4-month-olds' ability to discriminate an order change in these two sequences, using a habituation/dishabituation task wherein looking time was the dependent variable. Infants appeared to discriminate the order change in the first sequence, but not in the other sequence, paralleling adults' perception. This result suggests that infants can organize sounds on the basis of frequency.

Demany's (1982) study has been criticized on methodological grounds. It is possible to discriminate some of the sequences he used from their reversed version on the basis of the frequency contour, even if the sequence is not perceived as two parallel streams. Fassbender (1993) corrected this problem and tested 2- to 5-month-olds on sequences that adults organized on the basis of frequency, amplitude or timbre. Infants discriminated order changes in the sequences as adults did, supporting the idea that infants group sounds at least qualitatively like adults. In addition, McAdams and Bertoncini (1997) tested 3- to 4-day-old infants on sequences that adults segregated on the basis of both location and timbre. Again, infants discriminated order reversals as adults did, although it is not clear whether the sequences were organized by location, by timbre, or by both location and timbre. In this test paradigm, note, listeners are never asked to segregate simultaneously occurring sounds, as most frequently occurs in natural environments. Thus, the conclusions that can be drawn about infants' sound source segregation are currently limited.

Only one study has been conducted bearing on the issue of sound source segregation in children. Sound in different frequency bands that fluctuate over time in the same way tend to be grouped together by adults. In fact, an adult will detect a signal at a lower level if the masker consists of multiple frequency bands with common amplitude modulation than when the masker is a single frequency band centered on the signal or if the masker noise bands have different amplitude fluctuations. This effect is known as comodulation masking release (CMR). Grose, Hall, and Gibbs (1993) first showed that 4-year-old children derived the same benefit from adding off-frequency, comodulated frequency bands as

do adults. Hall, Grose, and Dev (1997) subsequently confirmed this finding in slightly older children. However, Hall et al. also reported that when the masker band centered on the signal frequency and the off-frequency comodulated bands were slightly asynchronous, adults' CMR was reduced, but children's CMR was eliminated or became negative. Thus, it would appear that the basic process of grouping frequency bands on the basis of common temporal fluctuations is functional early in life, but the process is more easily disrupted in children than it is in adults. These findings may have considerable relevance to children's listening in modern, complex sound environments.

Finally, to process sound emanating from one among several sources, listeners must be able to ignore irrelevant sounds. Consider that under normal circumstances, the irrelevant sounds in the environment may vary from moment to moment in unpredictable ways. One of the most intriguing findings in psychoacoustics is that uncertainty about the sounds to be ignored makes it much more difficult for listeners to detect a known sound (e.g., Kidd, Mason, & Arbogast, 2002; Neff & Callaghan, 1988; Neff & Green, 1987; Oh & Lutfi, 1999), even when the sounds to be ignored are distant in frequency from the sound to be detected. Reduction in the audibility of one sound due to the introduction of a second sound that does not interfere with the peripheral processing of the signal sound is called informational masking (Pollack, 1975).

In some respects, infants act as if they are uncertain about an irrelevant sound, even when the irrelevant sound does not change over time. Werner and Bargones (1991) showed that 7- to 9-month-olds' thresholds for detecting a tone increased when a noise band distant in frequency was presented simultaneously. Adults did not demonstrate masking under the same condition. If competing distant-frequency tones of varying frequency are presented with the tone to be detected, infants exhibit the same increase in threshold as adults do relative to the condition in which the competing tones are constant in frequency (Leibold & Werner, 2003). Thus, infants may be equally affected by increased uncertainty, even though they are more uncertain than adults under non-variable conditions.

By contrast, additional uncertainty appears to have more dramatic effects on older children than it does on adults. Allen and Wightman (1995), for example, found that half of 4- to 8-year-olds could not detect a tone at all when two competing tones varying in frequency were

presented. The average threshold of the children who could perform the task was much higher than that of adults. Oh, Wightman, and Lutfi (2001) reported that preschool children demonstrated about 50 dB more masking than adults on average when a varying distant-frequency, two-tone masker was presented with the tone to be detected. Moreover, Wightman, Callahan, Lutfi, Kistler, and Oh (2003) found that while presenting the varying masker tones to the ear contralateral to the signal ear eliminated such informational masking in adults, this manipulation did little to reduce informational masking in preschool children. Since acoustic factors that increase the listener's ability to perceptually segregate the signal and masker typically reduce informational masking in adults, this finding suggests that children's ability to segregate sound sources is not as robust as that of adults. Stellmack, Willihnganz, Wightman, and Lutfi (1997) quantified the extent to which irrelevant information entered into children's perceptual decisions about intensity, finding that preschool children tended to weight information at different frequencies equally, even when they were asked to attend to a single frequency.

Implications for the Development of Speech Perception

The preceding review of infant audition has several implications for their perception of the complex sounds of human language. In the first 6 months of postnatal life, it is likely that the neural representation of sounds is not as sharp or detailed as it is in adulthood. This representational limitation may in turn limit infants' ability to extract information from those sounds. By 6 months of age, infants probably have adultlike representations of speech and other complex sounds. However, this is not to say that their *perception* of complex sounds is adultlike. It is clear that infants do not attend to the information within complex sounds in the same way that adults do. They do not appear to focus on the spectral or temporal details that are most informative. They identify the spatial location of a sound source rather grossly, and they may also have difficulty segregating speech from competing sounds. Adult caregivers may compensate for these immature processing abilities by exaggerating important details and by speaking to infants in a way that makes their speech stand out from background sounds, as indicated at various points in the following sections. We return to the possible links between early auditory

processing and resulting effects on speech and language learning at the end of this chapter.

INFANT SPEECH PERCEPTION AND WORD LEARNING: BEGINNINGS OF LANGUAGE

Emergence of the Field: Phonetic Perception

When the first studies of infant speech perception were launched in 1971, a number of studies had been published revealing that adults show categorical perception of speech, but not nonspeech sounds. For example, adults presented with an equal step-size continuum of stimuli spanning two phonetic categories (e.g., a voicing difference between /b/ and /p/ or a place of articulation difference between /b/ and /d/) categorically labeled the first several steps along the continuum as one phoneme (e.g., /b/), and the next several steps as the other (e.g., /p/), with a very sharp boundary in between. Moreover, their labeling performance predicted discrimination. When presented with pairs of stimuli of equal sized differences, adults reliably discriminated only those differences to which they were able to assign different phonetic category labels. This perceptual skill is very important to language processing. There are tremendous variations in the way each individual phoneme is pronounced as a function of the other phonemes around it (/b/ is somewhat different in "bat" than in "boot" due to the coarticulation from the following vowel), as a function of speaking rate, and as a function of the voice quality of the individual speaking. Categorical perception allows listeners to treat these differences as equivalent, and thus to recover the word (and hence the meaning) rapidly when listening to others speak. On the basis of the studies published until 1970, it was believed that categorical perception, and perceptual normalization for speaking rate, vowel context, and so on, was unique to humans and unique to speech versus other types of acoustic signals (see Liberman, Cooper, & Shankweiler, 1967; Repp, 1984).

To explore the ontogeny of this capacity, Eimas and his colleagues (Eimas, Siqueland, Jusczyk, & Vigorito, 1971) published a classic study using the high amplitude sucking method, in which infant habituation and dishabituation are measured via rate of sucking on a nonnutritive pacifier (see also Moffit, 1971). Their results demonstrated that 1- and 4-month-old infants, like English-speaking adults, are better able to dis-

criminate stimuli from the /ba-/pa/ continuum that constitute between, rather than within, category differences (according to adult perceptual performance). Given the difficulty of obtaining labeling data from infants, these findings showing better between than within category discrimination, were taken as evidence that infants also show categorical perception. A year later, Morse (1972) extended this work to show that 2-month-old infants can categorically discriminate /ba/ versus /ga/, but fail on nonspeech counterparts to these syllabic forms. Similarly, Eimas (1974) showed that infants, like adults, only discriminate between stimuli that adults label as instances of different categories, holding acoustical distinctiveness constant. A number of additional studies extended this work to other consonant types (e.g., Eimas, 1975a; Hillenbrand, 1984), to consonants in medial as well as initial position (Jusczyk, Copan, & Thompson, 1978), and even to newborn infants (Bertoni, Bijeljac-Babic, Blumstein, & Mehler, 1987). Subsequent studies demonstrated that phonetic categories in young infants show many other properties observed in adults. The boundaries between categories are not absolute values, as would be indicated by auditory models. Instead, they are influenced by other articulatory variables, such as speaking rate (Miller, 1987). Infants (Eimas & Miller, 1992), like adults (Whalen & Liberman, 1987) show a phenomenon called "duplex perception" wherein the exact same stimulus can be simultaneously heard as both speech and nonspeech with categorical perception of the speech percept and continuous (no sharp category boundaries) perception of the nonspeech percept.

Similar results were found with vowels. Infants, like adults, show categorical perception of brief (Swoboda, Morse, & Leavitt, 1976; Trehub, 1973) but not more extended, isolated vowels (Swoboda, Kass, Morris, & Leavitt, 1978), and categorize vowels as equivalent even across variations in speaker and gender (Kuhl, 1979). In more recent work, Kuhl and colleagues provided data suggesting that vowel categories are organized around prototypes, with "best" central instances (see Grieser & Kuhl, 1989). These central instances have been described as "magnets" which warp the vowel space (Kuhl, 1991; though see Lotto, Kluender, & Holt, 1998, for an alternative account). A comprehensive review of this sizeable early work on consonants and vowels can be found in Eimas, Miller, and Jusczyk (1987). Taken together, these studies led to the claim that speech perception is special in infants just as it is in adults, and

must therefore reflect the operation of a domain-specific ability.

A number of studies examining cross-language speech perception complement the above studies of native-language speech perception. Languages differ in many properties, including their phoneme inventories. English, for example, contains a contrast between /r/ and /l/ which is lacking in Japanese, but English lacks the retroflex /D/ versus dental /d/ distinction that is used in Hindi and other South Asian languages. A series of cross-language speech perception studies in the 1970s revealed that adults have difficulty perceiving acoustically similar nonnative contrasts, and are constrained to distinguishing only those differences that are used phonemically in the native language (e.g., Lisker & Abramson, 1971; Strange & Jenkins, 1978) whereas young infants discriminate phonetic contrasts whether or not they are used in the language they are learning (Aslin, Pisoni, Hennessy, & Percy, 1981; Lasky, Syrdal-Lasky, & Klein, 1975; Streeter, 1976; Trehub, 1976). To capture this pattern of results, Eimas (1975b) proposed that babies are born with broad-based, universal sensitivities and that lack of listening experience leads to loss of unused initial sensitivities. Aslin and Pisoni (1980) formalized this view in their “universal theory” of speech perception, drawing on the notion of “maintenance” as the perceptual mechanism accounting for cross-linguistic differences (Gottlieb, 1976; Tees, 1976).

However, these comparisons of infants and adults relied on different testing procedures for the two populations, and in most cases, tests in different labs on different contrasts. Werker, Gilbert, Humphrey, and Tees (1981) addressed this problem by comparing English infants aged 6 to 8 months, English adults, and Hindi adults on their ability to discriminate both an English and two (non-English) Hindi consonant contrasts, using precisely the same methodology—the conditioned head-turn procedure—with the three groups. Their results confirmed the developmental change. All three groups discriminated the English /ba/-/da/ contrast, but only the Hindi adults and the English infants discriminated the two Hindi distinctions.

Werker and her colleagues subsequently completed a series of studies designed to identify the age at which the change from “universal” to language-specific phonetic perception might occur (Werker & Tees, 1983), and found important changes occurring across the 1st year of life. At 6 to 8 months of age, English-learning infants

successfully discriminate the Hindi retroflex-dental distinction and another non-English (Interior Salish, Ntlakampx glottalized velar versus uvular) distinction, but by 10 to 12 months of age English infants were no longer discriminating non-English distinctions (Werker & Tees, 1984). Confirming that the change was one of maintenance via language-specific listening exposure, and not simply a general decline at 10 to 12 months for all difficult phonetic contrasts, Werker and Tees (1984) showed that infants of the same age (10 to 12 months) raised with Hindi or Ntlakampx did successfully discriminate the contrasts from their native languages.

In the years since this initial work, there have been a number of replications and extensions of this finding. Several studies have confirmed an effect of listening experience on the phonetic differences infants can discriminate by the end of the 1st year of life. A decline in performance on nonnative contrasts was the common pattern in the first wave of studies (Best, McRoberts, Lafleur, & Silver-Isenstadt, 1995; Pegg & Werker, 1997; Tsushima et al., 1994; Werker & Lalonde, 1988; Werker & Tees, 1984). Moreover, the basic pattern of findings from these behavioral studies has been replicated by recording event-related potentials (Cheour et al., 1998; Rivera-Gaxiola, Silva-Pereyra, & Kuhl, 2005). Werker showed in her earliest work that this decline likely involves a reorganization of attention rather than a loss of basic discriminatory capacity (Werker & Logan, 1985).

In the past several years, some revealing exceptions to this pattern of findings have appeared. It is now known that vowel perception likely reorganizes at a somewhat younger age than consonant perception (Kuhl, Williams, Lacerda, Stevens, & Lindblom, 1992; Polka & Werker, 1994), and that acoustically quite distinct contrasts that lie outside the phonological space of the native language (e.g., click contrasts) may remain discriminable even without listening experience (Best, McRoberts, & Sithole, 1988). Indeed, there are differences across nonnative contrasts, with some showing the pattern of decline noted above, and others remaining discriminable (e.g., Best & McRoberts, 2003; Polka & Bohn, 1996), with one influential model suggesting that the assimilability to the native language phonology is the best predictor of maintenance versus decline (Best, 1994). Moreover, experience not only maintains native distinctions, but also seems to improve the sharpness of the native categories (Kuhl, Tsao, Liu, Zhang, & de Boer, 2001; Polka, Colantonio, & Sundara, 2001). This

observation has led to a reanalysis of the original Eimas (1974) claim of universal phonetic sensitivities from birth, with experience playing primarily a maintenance role. Now it appears that although substantial organization may be evident from birth, learning also plays a role (Kuhl, 2000; Werker & Curtin, 2005). As we will later address further, an exciting new development is attempting to ascertain just how powerful learning might be.

In addition to the empirical evidence suggesting innate biases in phonetic perception, considerable research supported the notion that speech might be special. Early studies suggested that while speech is perceived categorically, listeners typically perceive nonspeech analogues in a more continuous fashion (e.g., Mattingly, Liberman, Syrdal, & Halwes, 1971) and utilize specialized areas or structures in the left hemisphere when engaged in phonetic discrimination tasks (Phillips, Pellathy, & Marantz, 1999; Studdert-Kennedy & Shankweiler, 1970). Similar types of findings were revealed in infant studies (e.g., Eimas et al., 1971). Dichotic tasks with infants showed a significant right ear (LH) advantage in phonetic discrimination tasks by 3 months of age (Glanville, Levenson, & Best, 1977) and possibly earlier (Bertoni et al., 1989). Even in these initial reports, however, some results did not support the notion of a right-ear/left-hemisphere advantage for phonetic discrimination in young infants (see Best, Hoffman, & Glanville, 1982; Vargha-Khadem & Corballis, 1979, for contradictory studies).

The use of electrophysiology, with the event related potential (ERP) as the dependent variable, has helped clarify the early neuropsychological work. For example, Dehaene-Lambertz and Baillet (1998), using ERP, found brain areas that show activation to a change in phonetic category, but not to an equal sized change within a phonetic category in 3-month-old infants. More recently, they have shown the same pattern of findings when multiple voices are used, showing that the infant brain can extract phonetic categories across variations in speakers (Dehaene-Lambertz & Peña, 2001). ERP studies also consistently reveal asymmetries in phonetic discrimination tasks, but the pattern of asymmetries appears to vary with stimulus type and infant age. Some studies reveal a left hemisphere (LH) advantage for stop consonant discrimination (Dehaene-Lambertz & Baillet, 1998; Dehaene-Lambertz & Dehaene, 1994; Molfese & Molfese, 1979, 1980, 1985) whereas others indicate bilateral responses at birth, with the emergence of right hemisphere (RH) dominance at 3 months of age

(e.g., Novak, Kurtzberg, Kreuzer, & Vaughan, 1989). Molfese consistently found the LH advantage for place-of-articulation differences reported above, but a stronger RH ERP response to a change in voicing (Molfese, Burger-Judish, & Hans, 1991; Molfese & Molfese, 1979). The pattern seen with vowels also suggests asymmetrical processing, in this case favoring the RH (Cheour-Luhtanen et al., 1995). The findings of early sensitivity to potential phonetic distinctions and the possibility of specialized neural systems subserving this discrimination strengthened the notion that "speech is special" and computed by dedicated neural systems.

As is the case with any complex research endeavor, not all the data fit the pattern so nicely. Shortly after the first studies were published revealing categorical-like perception for speech sounds, similar studies were published showing that both adults (Pisoni, 1977) and infants (Jusczyk, Pisoni, Walley, & Murray, 1980) perceive some nonspeech sounds categorically. Moreover, nonhuman animals seem to show similar category boundaries to human infants. Chinchillas (Kuhl & Miller, 1978; Kuhl & Paden, 1983) show categorical perception for both voicing (e.g., /pa/-/ba/) and place (e.g., /ba/-/da/) continua, and several other animal species can also discriminate between consonants (Morse & Snowdon, 1975; Waters & Wilson, 1976). Japanese quail show perceptual constancy of consonant categories across variations in vowels (Kluender, Diehl, & Kileen, 1987), and budgies similarly discriminate consonants (Dooling, Best, & Brown, 1995). Similar findings have been reported for vowels. Monkeys and even cats discriminate /i/ from /u/ (Dewson, 1964), and studies with Old World monkeys suggest the same pattern of vowel perception as seen in humans, with excellent discrimination of distinct vowels and more confusion of close vowels such as /E/ (as in bet) and /ae/ (as in bat; Sinnott, 1989). It was initially thought that only humans (adults and infants) show the prototype magnet effect (see Kuhl, 1991), but even rats and birds show a warping of their perceptual space to reveal a prototype organization following brief exposures to vowel categories (Kluender, Lotto, Holt, & Bloedel, 1998; Pons, in press). The animal work raises the strong possibility that speech perception is not necessarily a specialized human capacity, but perhaps instead reflects perceptual biases that are common at least across primates, and perhaps beyond.

To summarize, the first generation of infant speech perception work took as its starting point the work on

phonetic perception in adults, and was designed to assess whether infants showed the same types of responses to phonetic differences as do adults, and if so, whether they used the same underlying neural mechanisms. This research led to increasingly sophisticated methods and techniques, and to studies with both human and nonhuman animals. The findings greatly enriched our understanding of the development of speech perception, and the explanations offered to explain these findings provided rich theoretical fodder for subsequent work. However, one of the insights guiding research for the past several years has been the realization that there is much more to speech than just phonetic categories, and that infants may be sensitive to many other characteristics of the speech around them.

A Preference for Speech

One of the first questions one might ask is whether infants' perceptual systems help them to separate speech from other types of acoustic signals in the environment. An early appearing preference for speech would help infants orient to just those signals in the environment which are essential for language acquisition. Although it is widely believed that infants prefer to listen to speech over other sounds from the first moments of life, there are actually very few data that specifically address this question. Indeed, until very recently the studies upon which this widely held belief was founded were not actually designed to test infants' preference for speech over nonspeech. For example, one study that is widely cited as showing a neonatal preference for speech over nonspeech showed that 4- to 5-month-old infants look longer to a target when it is paired with continuous female speech than when it is paired with white noise (Colombo & Bundy, 1981). Today no one would accept the aversive sound of white noise as an appropriate control for human speech, but in fact Colombo and Bundy had not designed the experiment to test for a preference for speech. Rather, they were attempting to develop a method for assessing infants' responsiveness to different types of speech sounds. Moreover, what is not noted is that 2-month-old infants in Colombo and Bundy's (1981) study, in contrast to older infants, did not respond differently to speech and white noise. The only other early study directly assessing a listening preference for speech was one by Glenn, Cunningham, and Joyce (1981) in which 9-month-old infants pulled a lever more frequently to listen to a female singing a song in

comparison with three solo musical instruments playing the same tune.

More recently, a set of studies has examined infants' preference for acoustic stimuli that have the structural properties of isolated syllables of human speech in comparison to carefully matched nonspeech tokens. Vouloumanos, Kiehl, Werker, and Liddle (2001) used complex nonspeech analogues modeled on sine-wave analogues of speech (Remez, Rubin, Pisoni, & Carrell, 1981). The speech stimuli consisted of the syllable "lif" repeated several times in the high pitch, highly modulated speech that parents use when speaking to their infants. The nonspeech counterparts replaced the fundamental frequency and three most intense higher order frequency components (formants) with a sine wave that tracked their changes across time. Thus, in contrast to the earlier studies investigating preference for speech over nonspeech, these stimuli were carefully matched for duration, timing, fundamental frequency, and area in the spectrum in which information was presented. However, human vocal tracts cannot produce the sine wave nonspeech stimuli.

In the first set of studies, Vouloumanos and Werker (2004) used a sequential preferential looking procedure (e.g., Cooper & Aslin, 1990) to test the listening preferences of 2- to 6-month-old infants. The infants preferred the speech over the complex nonspeech analogues, listening longer on the alternating trials during which speech versus nonspeech was presented. In the second set of studies, newborn infants were tested with these same stimuli, with HAS (high amplitude sucking) as the dependent variable. Like their older counterparts, the newborn infants chose to deliver more HA sucks on the alternating minutes in which speech versus complex nonspeech was presented (Vouloumanos & Werker, 2002). To attempt to rule out a role of experience in eliciting this preference, Vouloumanos created stimuli that would sound like those available to the fetus by filtering them using the filtering characteristics of the uterine wall. Neonates treated the filtered speech and nonspeech as equivalent, even though they discriminate the nonfiltered counterparts. This strengthens the possibility that the preference seen in the newborn is not a direct result of prenatal listening experience with human speech, and argues instead for an evolutionarily given perceptual predisposition for sounds that have the structural characteristics of those which could be produced by a human vocal tract. Moreover, the preference for communicative signals extends beyond spoken language.

In a recent study, Krentz and Corrina (2005) have shown that hearing infants show a preference for watching sign language over carefully matched nonlinguistic gestures. Taken together, these studies suggest a broad-based perceptual bias for communicative signals.

These results are corroborated by studies using neuroimaging techniques. In an event-related fMRI study completed with adults, Vouloumanos et al. (2001) found that the typical speech areas in the left hemisphere of the temporal cortex are more activated by a change to the speech than a change to the complex nonspeech stimuli described above. This finding complements many other studies with adults showing greater activation of specialized brain areas in the left hemisphere in response to speech than to other types of sounds (e.g., Benson et al., 2001; Binder et al., 1997; Fiez et al., 1995; Price et al., 1996; Zatorre, Evans, Meyer, & Gjedde, 1992; but see also Binder et al., 2000; Zatorre, Meyer, Gjedde, & Evans, 1996).

To date, only two studies have used imaging techniques to determine if the infant brain responds differently to speech versus nonspeech. Both of these studies have contrasted the perception of forward versus backwards speech (for related adult studies, see, Dehaene et al., 1997; Wong, Mihamoti, Pisoni, Sehgal, & Hutchins, 1999). Using both optical topography (Peña et al., 2003), and fMRI (Dehaene-Lambertz, Dehaene, & Hertz-Pannier, 2002), speech stimuli elicited greater activation in the infants' LH than the RH. In the Peña et al. (2003) study neonates were tested, and the increased activation was in the classic language areas over the temporal lobe. The Dehaene, Dehaene, and Hertz-Pannier (2002) study tested 3-month-olds, eliciting bilateral activation to both the forwards and backwards speech over the temporal lobes, with greater LH activation more posteriorly. Further experimentation with nonhuman primates is necessary to determine whether these early perceptual and neural markers of human speech perception are specific to humans or are instead part of our shared evolutionary history.

Perception of the Visible Information in Speech

Speech perception involves not only the acoustic signal, but also visible articulatory information. The best known example of this is the McGurk effect (McGurk & MacDonald, 1976). When watching a speaker produce the syllable /ga/ while listening to /ba/, adults typically report perceiving an unambiguous /da/ or /tha/, a syllable

that combines features of both the heard and seen stimuli. This effect is robust across many testing conditions and languages (see Green, 1998 for a review) and has been interpreted as part of our endowment for phonetic perception. Yet, there is also evidence of learning. The McGurk effect is stronger in adults than in children (Hockley & Polka, 1994; MacDonald & McGurk, 1978; Massaro, Thompson, Barron, & Laren, 1986), is reduced further in children who have difficulty articulating (Desjardins, Rogers, & Werker, 1997), and shows the same kind of language-specific influences as is seen in the perception of audible speech with nonnative "visemes" assimilated to those used in the native language (Massaro, Cohen, & Smeele, 1995; Werker, Frost, & McGurk, 1992).

Two kinds of studies have explored whether the visible information in speech is available prior to learning. In one, infants are presented with side-by-side displays of two faces articulating two different syllables. An acoustic syllable that matches the syllable being articulated by one of the faces is then presented at mid-line, and the amount of time the infant looks at each face is recorded. Using this method, Kuhl and Meltzoff (1982) showed that infants of 4.5 months look preferentially at the face articulating the heard vowel sound (/a/ versus /i/). This finding has since been replicated with other vowels (Kuhl & Meltzoff, 1988), with male as well as female faces and voices (Patterson & Werker, 1999), with disyllables (e.g., "mama," "lulu"; MacKain, Studert-Kennedy, Speiker, & Stern, 1983), and with a high amplitude sucking method (Walton & Bower, 1993). Moreover, these young infants often display mouth movements themselves that correspond to the concordant bimodal display (Kuhl & Meltzoff, 1988; Patterson & Werker, 1999; 2002), suggesting connections including not only the visual and auditory perceptual modalities, but also articulatory processes. More recently it has been shown that the matching effect is equally robust in 2-month-old infants (Patterson & Werker, 2003). The precocity of this matching ability is particularly striking when compared to other types of biologically important information. Infants do not match gender in the face and voice until 7 to 9 months of age (Walker-Andrews, Bahrick, Raglioni, & Diaz, 1991) even when they are tested using precisely the same stimuli for which they show vowel matching (Patterson & Werker, 2002).

Evidence for the McGurk effect itself is less convincing in the infancy period. Although there are reports of infants' percepts showing the same kind of

“fusion” or “visual capture” as seen by adults when mismatched auditory and visual stimuli are presented (Burnham & Dodd, 2004; Desjardins & Werker, 2004; Rosenblum, Schmuckler, & Johnson, 1997), the effect is not nearly as strong or as consistent as that seen in adults. Taken together, these studies suggest that the infant may be endowed from an early age with a perceptual system which is sensitive to both heard and seen features of phonetic segments, but that this system is perfected and tuned through experience listening to and articulating speech. A recent study suggests that we are not the only primate species to use both heard and seen information in perceiving communicative stimuli (Ghazanfar & Logothetis, 2003), suggesting that the intermodality of speech might be deeply ingrained in our evolutionary heritage.

Perception of Prosodic Attributes of the Speech Signal

One of the fundamental characteristics of human languages is their prosody—the musical aspects of speech, including their rhythm and intonation. Languages have classically been categorized according to their predominant rhythmic properties into three major types: stress-timed, syllable-timed, and mora-timed (Abercrombie, 1967; Pike, 1945). Stress-timed languages, like English and Dutch, tend to alternate between strong and weak syllables, and the strong syllables are roughly equally spaced in time, thus the term *stress-timed*. Languages like Spanish and Italian, however, use the syllable as the basic unit of timing; syllables are similarly stressed and roughly equally spaced in time. Finally, languages like Japanese are timed-based on the mora, a rhythmic unit roughly corresponding (in English) to a consonant followed by a short vowel (“the” contains one mora, while “thee” contains two). This nomenclature has been refined and quantified by two key properties: percent vowel per syllable and the variability in the consonants (Ramus, Nespor, & Mehler, 1999). These rhythmical properties of the language influence adults’ processing of speech; speakers of different languages employ different units as their primary unit of segmentation. Speakers of syllable-timed languages (e.g., French, Spanish, Catalan, & Portuguese) show a processing advantage for the syllable (e.g., Mehler, Dommergues, Frauenfelder, & Segui, 1981; Morais, Content, Cary, Mehler, & Segui, 1989; Sebastián-Gallés, Dupoux, Segui, & Mehler, 1992), speakers of stress-timed languages such as En-

glish and Dutch show greater access to the phoneme (Cutler, Mehler, Norris, & Segui, 1986; Cutler & Norris, 1988; Vroomen, van Zon, & de Gelder, 1996), and Japanese adults use the mora as the primary unit of segmentation (Otake, Hatano, Cutler, & Mehler, 1993). These differences not only describe the surface properties of languages, but may also provide cues to the underlying syntactic structure, that is, the head direction, of the language (Nespor, Guasti, & Christophe, 1996).

Human infants are sensitive to rhythmical differences from birth. Since the classic study by Demany, McKenzie, and Vurpilot (1977) showing that 2- to 3-month-old infants can discriminate tones based on their rhythmical sequences, there is growing evidence that young infants can use rhythm to detect the timing characteristics of speech (Fowler, Smith, & Tassinary, 1986). Indeed, there is now considerable evidence that infants utilize rhythmical characteristics to discriminate one language from another at birth. In a seminal experiment, Mehler et al. (1988) demonstrated that newborns can discriminate French from Russian produced by a single bilingual speaker—as long as one of these languages is the infant’s native language. Interestingly, at least part of this discrimination is based on prosodic characteristics of speech. The same results were obtained using low-pass filtered speech, in which the phonetic characteristics were removed while retaining the prosodic rhythm of the speech samples. Given that these are the same speech characteristics maintained in the uterine environment, an initial interpretation of these data was that newborn speech capacities are influenced by prenatal maternal exposure. A subsequent reanalysis of the initial data, however, revealed that discrimination was not limited to the native versus an unfamiliar language, but instead was evident as well when the French infants listened to English versus Italian, two unfamiliar languages (Mehler & Christophe, 1995). This weakened the interpretation that it is prenatal experience that leads to language discrimination.

Indeed, there is now abundant evidence that infants use such rhythmical differences to discriminate among a wide variety of languages, suggesting that rhythm may be prioritized in infants’ early speech representations. Consistent with this hypothesis, infants’ discriminations are predictable based on languages’ membership in rhythmic classes. For example, newborns and 2-month-olds can discriminate between two languages from two different classes, but not two languages from the same class (Mehler et al., 1988; Moon, Cooper, & Fifer, 1993;

Nazzi, Bertoni, & Mehler, 1998). This discrimination ability is present for forward speech but not backwards speech, which disrupts rhythmic cues. Nonhuman primates show this same pattern of performance, suggesting that processing of the rhythmic characteristics of speech is not specific to humans (Ramus, Hauser, Miller, Morris, & Mehler, 2000). Only by 5 months of age does experience with one's native language allow infants to discriminate it from other languages in the same class (e.g., Nazzi, Jusczyk, & Johnson, 2000). There is thus an interplay between an inherent bias to attend to rhythmic distinctions in languages and the learning processes required to distinguish one's own language from others. Even by 5 months of age, infants can't distinguish between two unfamiliar languages from the same rhythmic class.

Languages from different rhythmical classes differ not only in their timing characteristics, but also in their intonation contours. And, in some cases, this information is also adequate to discriminate two languages that have been low-pass filtered at 400 Hz (which removes phonetic content while preserving intonation cues), including English versus Japanese (Ramus & Mehler, 1999). As indicated earlier, young infants are highly sensitive to differences in pitch. Moreover, they are able to use intonation to discriminate vowels (Bull, Eilers, & Oller, 1984; Karzon & Nicholas, 1989), and even to distinguish lists of words differing in pitch contour (Nazzi, Floccia, & Bertoni, 1998). The preference for infant directed speech (Cooper & Aslin, 1990; Fernald, 1984; Werker & McLeod, 1989) may be explained, at least in part, by this exquisite sensitivity to fundamental frequency (see Colombo & Horowitz, 1986).

It is thus of interest to determine whether infants' ability to discriminate languages is a function of their perception of rhythm, intonation, or both cues in tandem. To do so, Ramus and Mehler (1999) resynthesized natural speech, preserving the rhythm while holding intonation constant. With these stimuli, French newborns were still able to discriminate languages from two different rhythmic classes (Ramus, 2002; Ramus et al., 2000), although levels of discrimination were somewhat attenuated. These results confirm that while infants may be using intonation to boost performance, rhythm alone is sufficient to distinguish one family of languages from another.

These early language discrimination abilities may be particularly useful in bilingual environments. Infants exposed to multiple languages may use these rhythmic distinctions to segregate the input into the different lan-

guages they hear. Such a process would likely facilitate successful bilingual language acquisition by alerting infants to the fact that their input is drawn not from one but two language systems. In the absence of this information, infants may not have a way to determine that they are hearing multiple languages, leading to potential confusions during the learning process.

To begin to address these issues, Bosch and Sebastián-Gallés (2001) assessed the language recognition abilities of 4-month-olds learning both Spanish and Catalan. Importantly, these two Romance languages belong to the same rhythmic category, which should make them quite difficult to discriminate. Nevertheless, these bilingual-to-be infants were able to discriminate between the two languages present in their home environments. These results suggest the availability of an early capacity to distinguish languages given simultaneous bilingual exposure, potentially based on the presence of vowel reduction (since rhythmic cues do not distinguish the two languages). More recently, it has been shown that bilingual-exposed infants process languages differently even from birth (see Werker, Weikum, & Yoshida, *in press*). When tested on their preference for English over a rhythmically distinct language, Tagalog, English-exposed newborns showed a robust preference for filtered English speech over filtered Tagalog speech. However, newborns exposed to both English and Tagalog prenatally did not show this preference, and indeed, chose to listen equally to filtered English and Tagalog. Contrary to hypotheses suggesting that lexical knowledge is needed to engage in language differentiation (e.g., Genesee, 1989), the basic capacities for language differentiation may be in place well prior to the onset of spoken language. However, these results leave open the question of whether infants actually represent the two languages as separate systems, as opposed to discriminable components of a single system.

Perception of Other Aspects of the Speech Signal

In addition to their sensitivity to speech itself, to phonetic segments, to visual speech, and to rhythm and intonation, even the youngest infants also show impressive sensitivities to many other types of information carried by the speech signal. They are sensitive to some kinds of within phonetic category variation. At 3 to 4 months, infants show graded perception of VOT (Miller & Eimas, 1996), and at 6 months can discriminate within-category differences from along the VOT continuum if tested in sufficiently sensitive tasks (McMurray &

Aslin, 2005). Moreover, infants of 6 to 8 months (but not 10 to 12 months) can even treat multiple instances of the voiced, unaspirated [d] versus voiceless, unaspirated [t] (created by removing the “s” from /sta/) as two separate categories, even though adult English speakers treat both of these syllables as equivalently acceptable instances of the phoneme /d/ (Pegg & Werker, 1997).

Sensitivity to within category phonetic variation is necessary in some language processing tasks (see Werker & Curtin, 2005). One illustration comes from the work on allophone discrimination. Allophones are different phonetic realizations of the same phoneme with precise phonetic characteristics that vary depending on their position in words. By 2 months of age, infants can detect the allophonic difference between the unaspirated, unreleased /t/ in “*night rate*” from the aspirated, released, partially retroflex /t/ in “*nitrate*” (Hohne & Jusczyk, 1994), a sensitivity which will ultimately be useful in word segmentation, as discussed next.

Infants are also sensitive to syllable form. Newborn French infants can “count” syllables, discriminating lists of bi- versus trisyllabic words even when the words are modified to have the same overall duration (Bijeljac-Babic, Bertoncini, & Mehler, 1993). They show better discrimination of stimuli that correspond to “good” syllable forms—those with a vocalic nucleus (/tap/ versus /pat/), in comparison to /tsp/ versus /pst/ (Bertoncini & Mehler, 1981). Sensitivity to rhyme (Hayes, Slater, & Brown, 2000), alliteration (Jusczyk, Goodman, & Baumann, 1999), and full syllable repetition (Jusczyk, Goodman, et al., 1999) have all also been demonstrated in infants from 7 to 9 months of age.

One such auditory sensitivity may be of use in the acquisition of grammatically relevant knowledge. Infants are astonishingly sensitive to the acoustic and phonological cues that distinguish grammatical classes. Just as languages differ in their phoneme inventories and in their rhythmical characteristics, they also differ in the number and kinds of grammatical categories words might belong to. For example, while English has prepositions, Chinese has postpositions. The languages of the world seem to all share a fundamental distinction between open-class (lexical words, such as nouns, verbs, adjectives, etc.) and closed-class (grammatical words, such as determiners, prepositions, etc.) categories. These classes of words can be distinguished on the basis of acoustic and phonological cues such as syllable complexity, syllable number, duration, loudness, and presence of reduced vowels (see Kelly, 1992). These differences are magnified in the speech directed to infants,

and are evident in maternal speech across typologically distinct languages (Morgan, Shi, & Allopenna, 1996; Shi, Morgan, & Allopenna, 1998).

In a recent series of studies, Shi and colleagues showed that infants become increasingly able to use these cues across development. Newborn infants categorically discriminate content from function words, even when the words are equated for volume and number of syllables (Shi, Werker, & Morgan, 1999). Specific prenatal listening experience cannot account for this discrimination capacity; the same pattern of results emerges when the items are drawn from an unfamiliar language. By 6 months of age, infants prefer to listen to the content words (Shi & Werker, 2001). This preference cannot be accounted for by specific knowledge of highly familiar items because, again, it is seen even when infants are tested on words from an unfamiliar language (Shi & Werker, 2003). Thus the phenomenon must be based on a developing preference for items with the acoustic and phonological patterns seen in content words. These findings do not necessarily suggest that infants are born with knowledge of important grammatical categories. They do, however, show that infants’ perceptual biases facilitate dividing words into two fundamental categories. Subsequently, as infants approach the age of learning word meanings, they selectively focus on the louder and generally more salient content word category.

When they first begin to speak, infants typically omit function morphemes (e.g., *the*, *-ed*, *-s*), raising the question of whether infants simply do not perceive them or whether there are other reasons for the omissions, such as constraints on speech production (e.g., Gerken & McIntosh, 1993). Several lines of evidence suggest that infants do in fact perceive these weak items. For example, 11-month-olds, but not 10-month-olds, show a different pattern of scalp-recorded ERPs to stories that contained either correct or modified English function morphemes (Shafer, Shucard, Shucard, & Gerken, 1998). Similar results using the head-turn preference procedure with German infants suggest that 7- to 9-month-olds, but not 6-month-olds, can recognize previously familiarized closed class items (Höhle & Weissenborn, 2003). By 11 months of age, infants prefer nonsense words preceded by a familiar high frequency function word over that same nonsense word preceded by a mispronunciation of the function word (e.g., English infants listen longer to “*the brink*” over “*ke brink*”), and do so even for low frequency function words such as “*its*” or “*her*” by 13 months of age (Shi, Werker, & Cutler, 2003). Indeed, by 11 months of age it

appears that familiar high frequency function words such as “the” facilitate segmentation and learning of new words. Infants show better recognition of nonce word forms if they are first presented in a phrase with a familiar closed class item such as “the” (Shi, Werker, Cutler, & Cruickshank, 2004).

The importance of familiar function words becomes more pronounced when children are at the peak of learning new words, and then shows an apparent decline. In a preferential looking task (side by side pictures) infants of 18 months were most accurate when the labels for the objects were preceded by a correctly pronounced function word and least accurate when the function word was mispronounced. Their performance was intermediate for labels with missing function words. Infants of 24 months showed a similar, but less pronounced pattern, and by 36 months of age children were able to ignore the function word information (Zangl & Fernald, 2003). The role of function words extends beyond segmentation and identification. By 2 years of age infants are able to use function words as cues to new versus old information in a sentence context (Shady & Gerken, 1999).

Speech also carries paralinguistic (sometimes called “indexical”) information—cues that convey emotion, speaker identity, and emphasis—to which infants are sensitive. They show a preference for infant-directed over adult-directed speech (Cooper & Aslin, 1994; Fernald, 1984). They discriminate individual voices (DeCasper & Prescott, 1984; Floccia, Nazzi, & Bertoncini, 2000) and show a robust preference for their mother’s voice (DeCasper & Fifer, 1980) from birth, indicating prenatal learning. Indexical cues may also aid in the perception of specifically linguistic information. Phonetic discrimination, for example, is facilitated when the contrasting syllable is produced at the pitch peak in motherese, as shown by Karzon (1985) in infants’ discrimination of /marana/ versus /malana/. This may be in part because the distinctiveness of segments may be clarified in motherese, as shown in the acoustic exaggeration of voicing (Ratner & Luberoff, 1984) and of the vowel space (Kuhl et al., 1997; Ratner, 1984) in infant-directed speech. Indeed, research shows that maternal clarification of the vowel space is correlated with superior speech discrimination in 6- to 12-month-old infants (Liu, Kuhl, & Tsao, 2003). Of interest, although speech directed to pets has many of the characteristics of infant-directed speech, the exaggeration of acoustic cues distinguishing vowels is evident only in speech directed to human infants (Burnham, Kitamura, &

Vollmer-Conna, 2003). This fact raises the possibility that the interplay between paralinguistic and linguistic factors may be part of, and exclusive to, within-species communication.

IMPLICIT DISCOVERY OF CUES IN THE INPUT: A DRIVE TO MAKE SENSE OF THE ENVIRONMENT

During the second half of the first year, an explosion occurs in infants’ knowledge of detailed aspects of the sound structure of their native language(s), as noted in the earlier discussion of age related changes in phonetic perception. In this section, we document developmental changes in perception of other properties of language. The following section addresses the mechanisms that may be responsible for these learning trajectories.

Stress and Phonotactic Cues

Languages differ greatly in their internal prosodic regularities. By adulthood, speakers use these regularities to generate predictions about possible word structures. For example, English-speaking adults expect words to be trochaic—to begin with stressed syllables—mirroring the distribution of stress in their native language (e.g., Cutler & Carter, 1987; Cutler & Norris, 1998). This “trochaic bias” emerges early in the process of language acquisition, well before infants are producing words. For example, 9-month-olds prefer to listen to words that exemplify their native language’s stress pattern (Jusczyk, Cutler, & Redanz, 1993), and are even sensitive to heavy versus light syllables (e.g., syllables with a long vowel and/or final consonant versus syllables with only a short vowel and no final consonant; Turk, Jusczyk, & Gerken, 1995). These results cannot be explained by recourse to inherent preferences for particular stress patterns, because 6-month-olds fail to show native-language stress preferences. This is an example of a potent learning process; somehow, English-learning infants must have discovered a probabilistic prosodic regularity in the input.

Infants’ sensitivities are not confined to syllable-level patterns. By 9 months of age, infants have learned a great deal about the probabilistic phonotactic patterns of their native language: the rates with which certain phoneme sequences occur in particular orders in particular positions in syllables and words. For example, the

sequence /ds/ can end, but cannot begin, syllables in English. Phonotactics are not a simple function of pronounability; sequences that are legal in some languages are illegal in others. Effects of phonotactic structure are observed in studies of adult word recognition (e.g., Vitevitch & Luce, 1999; Vitevitch, Luce, Charles-Luce, & Kemmerer, 1997). Similarly, children are affected by phonotactic probabilities when learning novel object names (e.g., Storkel, 2001) and nonword repetition tasks (Coady & Aslin, *in press*). By 9 months of age, infants prefer to listen to phonotactically legal sequences, whereas 6-month-olds do not (Friederici & Wessels, 1993; Jusczyk, Friederici, Wessels, Svenkerud, & Jusczyk, 1993), with frequent phonotactic structures preferred over infrequent structures (Jusczyk, Luce, & Charles-Luce, 1994). Interestingly, infants in bilingual environments exhibit similar knowledge of phonotactic structure (Sebastián-Gallés & Bosch, 2002). Differences were obtained as a function of language dominance: infants were most sensitive to phonotactic patterns in their to-be-dominant language, suggesting that infants may be limited in the number of phonotactic systems they can acquire in parallel.

Some types of subsyllabic regularities appear to be more salient to infants than others. For example, Jusczyk, Goodman, et al. (1999) demonstrated that 9-month-olds were sensitive to sound patterns that recurred at the beginnings of words, but not the ends of words (for related findings, see Vihman, Nakai, dePois, & Hallé, 2004). These results suggest that certain parts of words may be privileged relative to others in infants' early speech representations, such that onsets may contain more detail than codas. Such findings are particularly interesting in light of the conventional wisdom that infants are highly attuned to rhyming, as well as data suggesting that the ends of words may be privileged in young children's lexical representations (Echols & Newport, 1992; Slobin, 1973).

Higher-Level Units

Infants' representations of the sound structure of their language also encompass larger prosodic patterns, spanning multiple words. Beginning in the 1980s, researchers have been interested in how such prosodic patterns might provide cues to infants to allow them to break into the syntax of their native language. Such prosodic bootstrapping accounts, beginning with Gleitman and Wanner's (1982) proposal for the use of weak

syllable function words as cues to grammar, have generally supported the claim that infants are attuned to the kinds of prosodic variables that are correlated with syntactic structure (for review, see Morgan & Demuth, 1996). One such prosodic cue is changes in pitch and duration at the ends of clauses in infant-directed speech (Fisher & Tokura, 1996; Jusczyk et al., 1992). In a classic study, Hirsh-Pasek et al. (1987) found that 7-month-olds listened longer to speech samples with pauses inserted at clause boundaries than sentences with pauses inserted clause-medially, suggesting that infants detected the disruptions in the latter case. Similar results emerge for musical stimuli as well, suggesting that detection of prosodic markers serving as unit boundaries is not limited to language learners (Jusczyk & Krumhansl, 1993; Krumhansl & Jusczyk, 1990). More recent evidence suggests a similar process for phrase units, at least under some circumstances (Soderstrom, Seidl, Kemler Nelson, & Jusczyk, 2003), despite less clear prosodic markers of phrases (Fisher & Tokura, 1996). Indeed, even newborns have been shown to be sensitive to cues correlated with prosodic boundaries (Christophe, Mehler, & Sebastián-Gallés, 2001).

Of course, this evidence doesn't demonstrate that infants "know" that these prosodic cues point to syntactic boundaries. And the prosodic phrases to which infants are sensitive correlate only imperfectly with syntactic boundaries (Gerken, Jusczyk, & Mandel, 1994). Nonetheless, this sensitivity is a prerequisite for the use of prosodic cues to discover syntactic structure. There is evidence from adult studies using artificial languages that such grouping cues do assist learners in breaking into syntax (e.g., Morgan, Meier, & Newport, 1987; Morgan & Newport, 1981). Other evidence suggests that prosodic structure helps infants as young as 2 months of age to organize and group word sequences in memory (e.g., Mandel, Jusczyk, & Kemler Nelson, 1994). However, the degree to which prosodic structure facilitates infants' discovery of syntactic structure remains unknown.

LEARNING MECHANISMS

It is of paramount importance to understand *how* the myriad information in the linguistic environment becomes part of the infant's native language knowledge base. Until the advent of new testing techniques, this question was only addressable via analyses of production

from older children, or via logical arguments regarding the structure of the problems facing the child and the possible solutions that might be part and parcel of the child's linguistic endowment (e.g., Pinker, 1984, 1989). Research with computational models also suggested possible ways to structure a learning system that might be compatible with some of the facts of language acquisition (Elman, 1990; Rumelhart & McClelland, 1986).

In the past decade, researchers have developed experimental methods that help to identify potential learning processes. Saffran, Aslin, and Newport (1996) used one such task to determine whether infants could track statistical properties of speech. Eight-month-old infants listened to a 2 minute continuous sequence of syllables containing multisyllabic words: for example, *golabupabikututibabupugolabu...* They subsequently tested infants' ability to discriminate the words of this "language" from syllable sequences spanning word boundaries. Infants' success at this task, as evidenced by different listening times to the two types of sequences, indicated that they were able to detect and use the statistical properties of the speech stream.

Similar methods can be used to test specific hypotheses about the types of learning mechanisms used by infants. For example, infants could have succeeded in the preceding task using two quite different types of statistics: the probabilities of co-occurrence of syllables (e.g., the transitional probability of "la" given "go"), or a simpler computation, frequencies of occurrence (test words occurred more often in the input than the other test sequences). Aslin, Saffran, and Newport (1998) teased apart these two possibilities, demonstrating that infants succeeded at this task even when the test items were matched for frequency of occurrence in the input. A recent computational analysis of infant directed speech confirms that probabilities of syllable co-occurrence predict word boundaries better than frequencies of syllable co-occurrences (Swingley, 2005).

We must still track frequencies to discover probabilities. And these frequencies are quite salient to infants in some linguistic domains. For example, infants represent the frequencies of phonotactic patterns in their native language (Jusczyk et al., 1994; Mattys, Jusczyk, Luce, & Morgan, 1999). Moreover, infants learn about frequent properties of the input before they learn about infrequent ones. Anderson, Morgan, and White (2003) showed that English infants show a decline at a younger age in their perception of the non-English retroflex-dental /da/-/Da/ distinction than the non-English velar-

uvular /k/-/q/ distinction, presumably because "d's" are more frequent in the input than are "k's," giving infants a better opportunity to learn the native language category structure. Similarly, Shi et al. (2004) found that infants recognize and utilize high frequency function words earlier than infrequent ones.

Infant learning mechanisms are also sensitive to the statistical *distribution* of elements in the input. Maye, Werker, and Gerken (2002) presented 6- and 8-month-old infants with stimuli that simulated one of two types of languages. Materials in the unimodal condition collapsed a continuum of phonemes into a single category, such as English does with the two Hindi /d/ sounds, by presenting more instances of stimuli from the center of the continuum. Materials in the bimodal condition divided the continuum into two categories, such as Hindi does with the dental versus retroflex /d/, by including more instances of stimuli drawn from closer to the two ends of the continuum. The results suggested that infants were extremely sensitive to the distributions of the exemplars presented during exposure, with different test discrimination exhibited as a function of presentation of the unimodal versus bimodal materials. Distributional statistics can affect category structure, raising the possibility that sensitivity to the distributional information in the native language may contribute to the establishment of native language phonetic categories in the 1st year of life.

Infants also appear to be sensitive to nonstatistical regularities in the input. Marcus, Vijayan, Rao, and Vishton (1999) exposed infants to 3-syllable sentences following a particular pattern (e.g., *ga ti ga, li fa li*). Infants were then tested on novel sentences that either exemplified or violated the exposure pattern (e.g., *wo fe wo* versus *wo fe fe*). Successful discrimination suggested that the infants acquired abstract information, reflecting knowledge beyond just the specific syllable patterns observed in the input. Marcus et al. (1999) interpreted their results as evidence for a rule-based learning mechanism that detected algebraic rules (operating over variables). This claim has been controversial, as others have suggested that infants could have performed this task without rule-like representations (e.g., Altmann & Dienes, 1999; Christiansen & Curtin, 1999; Seidenberg & Elman, 1999). Investigators studying adults have similarly argued that the evidence supports a distinction between rule-based and statistical knowledge (Peña et al., 2003). However, it remains difficult to clearly distinguish between the two types of learning systems empiri-

ically (for discussion, see Seidenberg, MacDonald, & Saffran, 2003).

Units for Computations

In order to specify the processes that go into the operation of any learning mechanism, it is necessary not just to note the structure of the learning mechanism (e.g., what computations are performed?) but also to determine the primitives over which those computations are performed. Consider the simplest possible mechanism, a frequency counter that tracks how often some event occurs. Depending on the event in question, the output of the learning mechanism could be vastly different. For example, if the mechanism is applied to a flock of birds, does it compute the total number of birds, or the number of birds' feet, or the number of swallows versus doves? Each of these primitives, serving as input to the learning process, renders a different answer.

The issue of primitives has been prominent in the study of speech representations. Artificial speech recognition systems intended to simulate early language development have largely focused on the phoneme as the relevant unit for modeling (e.g., Brent & Cartwright, 1996; Christiansen, Allen, & Seidenberg, 1998; Jusczyk, 1997). Although some research supports this unit as important in infant speech perception, other work suggests that this idealization may be a mismatch to infants' capabilities.

Shortly after the field of infant speech perception emerged, researchers began to focus on what the unit of representation might be. One long-standing controversy concerns whether syllables or phonemes (or both) are psychologically real to infants. Studies using discrimination tasks in which either the syllable changes, or a phonetic feature in the segment changes, provided convincing evidence that both syllable-level and segment (phoneme) level features are accessed and used by 2- to 4-month-old infants (Eimas & Miller, 1981; Miller & Eimas, 1979). However, studies using similarity assessments (Bertoni, Bijeljac-Babic, Jusczyk, Kennedy, & Mehler, 1988; Jusczyk & Derrah, 1987) yielded a different pattern of results, suggesting that young infants are sensitive to changes in the number of syllables in a word, but not the number of phonemes (Bijeljac-Babic et al., 1993). Despite the contradictions in the studies with younger infants, older infants include some subsyllabic structures in their representations (Jusczyk, Goodman, et al., 1999). Moreover, with

development and/or literacy, adults represent both syllables and phonemes (Nygaard & Pisoni, 1995), and recent adult studies suggest that segmental representations may serve as the primitives for at least some kinds of language learning tasks (Newport & Aslin, 2004). Of additional interest, there may be differences across languages in which unit adults use for word segmentation, with French adults showing a pronounced syllable bias and English adults showing sensitivity to segmental information as well (Cutler, Mehler, Norris, & Segui, 1983, 1986).

One interpretation of this body of work is that the syllable is privileged as a unit of representation (Bertoni & Mehler, 1981), and may be used as the unit in computations across linguistic input. Another interpretation is that both syllables and phonemes are privileged, but for different types of tasks: the syllable is the primary unit for counting, but segmental detail plays a role in segmentation, at least in stress-timed languages (see Werker & Curtin, 2005). Further research will help distinguish between these possibilities.

BUILDING FROM THE INPUT DURING THE 1ST YEAR

The foregoing review provides some clues regarding the types of linguistic information infants acquire during the 1st year, as well as potential learning mechanisms that subserve this acquisition process. We can now turn to the burgeoning literature that puts these two pieces together: studies concerning the acquisition of particular linguistic structures. Some of these studies teach infants new information during a laboratory exposure session. Other studies ask how infants use what they've previously learned about their native language to discover structure in novel input.

Many of these studies use artificial nonsense languages, a methodology taken from the adult literature, in which specific cues can be isolated in a way that is impossible in natural speech (e.g., Gómez & Gerken, 2000; Morgan et al., 1987). Such languages are particularly useful in infant studies because they permit the development of brief exposure materials, fitting the task demands of infants with limited attention spans. On the other hand, artificial materials sacrifice ecological validity. An issue currently confronting researchers is the need to demonstrate that the learning abilities uncovered using artificial methods are the same as those infants use when acquiring their native language. While

ecological validity is always an issue in laboratory learning studies, it is particularly salient given exposure regimens that are so clearly unlike natural language input.

Learning Phonology and Phonotactics

Phonotactic knowledge is a prime candidate for learning studies, because it is so clearly tied to the structure of particular languages. Moreover, phonotactics is somewhat different from many of the other features of language that infants acquire. Phonotactic patterns are both general (they apply across the whole language, and are not specific to known words) and specific (they consist of segmental patterns, unlike the syllabic and prosodic patterns that often appear to be the focus of infants' attention). Studies of phonotactics in adults suggest a learning process in which mere exposure to phonotactic regularities influences expectations about possible word form regularities (Dell, Reed, Adams, & Meyer, 2000; Onishi, Chambers, & Fisher, 2002).

Chambers, Onishi, and Fisher (2003) extended their adult studies to include 16.5-month-old infants. The materials consisted of nonsense word sequences in which consonant positions were restricted; for example, /b/ could occur word-initially but not word-finally. Following exposure, infants listened longer to syllables that were phonotactically legal than those that violated the exposure patterns. Impressively, infants were also able to learn 2nd order phonotactic regularities, in which the presence of one element was conditioned on the presence of the other (e.g., that /k/ begins syllables if and only if the subsequent vowel is /ae/).

To determine whether certain phonotactic regularities are harder to learn than others, Saffran and Thiessen (2003) exposed infants to two different types of phonotactic patterns. One was consistent with the types of patterns found cross-linguistically, while the other was unlike natural language structure. Infants rapidly learned regularities of the first type, which involved generalizations across sets of acoustic/linguistic features (such as voicing, the feature that clumps /p/, /t/, and /k/ into a separate category from /b/, /d/, and /g/). However, infants failed to learn regularities that disregard such linguistic features (such as the grouping of /p/, /d/, and /k/ versus the grouping of /b/, /t/, and /g/), which are unlike natural language patterns. These results suggest a possible explanation for *why* languages show the types of patterning that they do. Sound structures that are hard for infants to learn may be less likely

to recur cross-linguistically. More generally, studies that uncover infants' failures may turn out to be as illuminating as those that display infants' considerable strengths at learning, by highlighting constraints on infant learning mechanisms.

The acquisition of phonological knowledge is also of great interest, given the rapidity with which infants acquire such knowledge in their native language. This learning process requires infants to integrate different types of information, an ability that likely emerges between 6 and 9 months of age (e.g., Morgan & Saffran, 1995). For example, consider the trochaic bias—the expectation that (at least for English-learning infants) words begin with stressed syllables. To learn this pattern, you must know something about the relationship between stressed syllables and their positions within words. If you have yet to discover any word boundaries, it would be impossible to know that stressed syllables fall in predictable places in words. Thus, to acquire a trochaic bias, infants must learn correspondences between stress and word position. This is only possible if infants first know some trochaic words, which may explain the lack of such a bias in 6-month-old infants. Indeed, 6½-month-old infants can be taught a rhythmic bias by briefly exposing them to word lists exemplifying the bias, and 9-month-olds' biases can be similarly altered (Thiessen & Saffran, 2004).

Other studies investigate how infants acquire more abstract phonological knowledge concerning the stress assignment patterns of their native language. Gerken (2004) presented infants with artificial language stimuli designed to exhibit particular patterns of metrical phonology—the structural principles for stress assignment in multisyllabic words. Following a brief exposure to a word list in which certain stress assignments were exemplified, infants were tested to determine whether they had inferred stress pattern structures that had not actually occurred in the input. The results suggest that 9-month-olds generalize to new words using abstract knowledge of possible stress patterns, opening the door to additional studies probing the extent to which infants are able to learn the types of abstract phonological structures that typify human languages.

Word Segmentation

The problem of how infants discover words in fluent speech, which lacks consistent physical cues to word boundaries (Cole & Jakimik, 1980) has played a promi-

inent role in studies of early language learning. While interest in this problem is a relatively recent development in the field of language acquisition, there are some notable exceptions. Roger Brown began his classic 1973 volume on language acquisition by describing his own problems with word segmentation while taking a Berlitz course in Japanese; later he described an early model of distributional learning in word segmentation by Olivier (1968). Gleitman and Wanner (1982) also treated the problem seriously, hypothesizing that stressed syllables may mark words for young learners. These two early discussions of the segmentation problem, invoking distributional and prosodic cues, were prescient, as these two sources of information are currently at the forefront of theories regarding infant word segmentation.

In a seminal study, Jusczyk and Aslin (1995) used the head-turn preference procedure to determine when infants begin to segment words. They first presented 7½-month-old infants with a word segmentation problem: sentences in fluent speech containing a particular target word (e.g., “Mommy’s cup is on the table. Do you see the cup over there?”). Following this familiarization period, infants were tested on the target words (e.g., “cup”) versus novel words (e.g., “bike”). Each item was played for as long as the infant maintained a head-turn in the direction of a speaker from which the word was played. Jusczyk and Aslin (1995) found a significant difference in listening times between the familiar and novel words, suggesting that the 7½-month-olds discovered the target words in fluent speech. Six-month-olds, however, failed to show any significant differences between the familiar and novel test items, suggesting either that the ability to segment word from fluent speech develops sometime between 6 and 7½ months of age, or that younger infants require additional exposure and/or cues to successfully perform the task. Support for the latter view comes from a study by Thiessen and Saffran (2003), in which 6½- to 7-month-olds successfully performed a word segmentation task in which they received more familiarization with the target words, and a study by Bortfeld, Morgan, Golinkoff, and Rathbun (2005) demonstrating word segmentation by 6-month-olds using additional cues.

How do infants solve such a complicated task? A growing body of evidence suggests that infants are attuned to a number of cues correlated with word boundaries. One such source of information was initially suggested in the linguistics literature in the mid-twentieth century (e.g., Harris, 1955), reflecting the observation that words consist of predictable sequences of

sounds. To see this statistical structure, consider the following example: because the syllable *pre* precedes a small set of syllables in English, the probability that *pre* is followed by *ty* is quite high. However, because the syllable *ty* occurs word-finally, it can be followed by any syllable that can begin an English word. Thus, the probability that *ty* is followed by *ba*, as in *pretty baby*, is extremely low. Indeed, infants are sensitive to such probabilistic cues, and use them for word segmentation (e.g., Aslin, Saffran, & Newport, 1998; Goodsitt, Morgan, & Kuhl, 1993; Saffran et al., 1996).

Several lines of research have converged to suggest that particular languages contain prosodic cues that facilitate word segmentation. For example, English-learning 7½-month-olds can make use of their knowledge that bisyllabic words tend to be trochaic to successfully segment strong-weak words (those stressed on their first syllable) such as “KINGdom” from fluent speech, while failing to segment weak-strong words (those stressed on their second syllable) like “guiTAR” (Jusczyk, Houston, & Newsome, 1999). In the latter case, infants treat the stressed syllable “TAR” as a word. Interestingly, they will combine TAR with a subsequent weak syllable if they are paired consistently, suggesting the integration of stress-based and statistically based strategies. Thus, infants use their expectations about word structure to assist in segmentation (for related results, see also Curtin, Mintz, & Christiansen, 2005; Houston, Jusczyk, Kuijpers, Coolen, & Cutler 2000; Houston, Santelmann, & Jusczyk, 2004; Nazzi, Dilley, Jusczyk, Shattuck-Hufnagel, & Jusczyk, in press).

Younger infants are unable to take advantage of stress-based segmentation cues, demonstrating that this knowledge must be learned (e.g., Echols, Crowhurst, & Childers, 1997; Jusczyk, Houston, et al., 1999; Thiessen & Saffran, 2003). Further evidence for a learning account comes from research on languages that incorporate different stress patterns, such as French (Polka, Sundara, & Blue, 2002). Artificial language studies also indicate that stress-based segmentation strategies are learnable (Thiessen & Saffran, 2004). Moreover, infants must learn not to overly focus on stress, which, like all individual cues to word boundaries, is fallible; only by 10½ months do infants successfully segment weak-strong words (Jusczyk, Houston, et al., 1999).

The fact that infants can use the distribution of stress cues as a cue to word boundaries raises a “chicken-and-egg” problem. If stress is a critical cue to word boundaries, how can infants have discovered the utility of this

cue prior to knowing words? One must know something about the words of one's native language to discover the correlation between stress position and word boundaries. One possibility is that infants learn the predominant stress pattern of words in their native language by hearing words spoken in isolation (e.g., Jusczyk, Houston, et al., 1999). This seems intuitively plausible, particularly given analyses of infant-directed speech suggesting that a nontrivial proportion of utterances consist of single words (e.g., Brent & Siskind, 2001). On this view, infants might learn words like "kitty" and "mommy" by hearing them spoken in isolation, and then use that nascent corpus to discover the stress patterns characteristic of their native language. However, a recent analysis suggests that this explanation is unlikely to be correct (Swingley, 2005). Only 14% of the bisyllabic utterances in English spoken to infants are trochaic; most bisyllables conform to a strong-strong pattern. Thus, infants must have some other means of discovering the predominant lexical stress pattern of their native language.

One possibility is that early access to sequential statistical segmentation cues provides infants with the beginnings of the corpus they need to subsequently discover prosodic regularities. Swingley's (2005) computational analysis suggests that words that are discoverable via statistical cues render the correct prosodic template, unlike words heard in isolation. A study by Thiessen and Saffran (2003) suggests a trajectory of cue usage over development consistent with this view. When 9-month-olds are confronted with continuous speech in which stress and statistical cues conflict, they follow the stress cues, as previously demonstrated by Johnson and Jusczyk (2001). However, 6- to 7-month-olds exhibit the opposite strategy, relying on statistical cues rather than stress cues, presumably because they do not yet know their native language's stress pattern. The stress strategy, then, is presumably bootstrapped from the regularities in the initial corpus acquired via sequential statistical cues (Thiessen & Saffran, 2004).

Other important cues to word boundaries become available to infants beginning around 9 or 10 months of age. For example, infants are able to use the distributions of allophones—the subtle differences in phonemes that are a function of the context in which the phoneme occurs—as word boundary cues. Certain sounds only occur in certain positions in words; the /t/ that begins English words differs from the /t/ that occurs word-medially or word-finally (Church, 1987). Young infants are sensitive to allophonic cues which might signal word boundaries, shown, for example, by their ability to dis-

criminate the bisyllable /mati/ when the /ma/ and the /ti/ are pulled from either a single word or from the final syllable in one word versus the first syllable in the next (Christophe, Dupoux, Bertoni, & Mehler, 1994). By 9 months of age, infants can detect word boundaries in contrasts such as *nitrates* versus *night rates*, which consist of the same sequence of phonemes but different allophones, suggesting the availability of allophonic cues for segmentation (Jusczyk, Hohne, & Baumann, 1999; Mattys & Jusczyk, 2001). Moreover, at this same age infants' phonetic categories reflect sensitivity to position-specific allophonic variants (Pegg & Werker, 1997). These findings raise the same sort of "chicken and egg" problem as the stress findings—one must first know something about words to discover cues correlated with internal word structures. It is thus likely not an accident that this ability emerges at roughly the same time for different types of cues. By 9 months of age, infants have likely segmented enough words using statistical cues and other types of information to have developed a sufficiently large corpus to discover these word-internal cues.

Phonotactic cues are also correlated with word boundaries (e.g., Brent & Cartwright, 1996; Cairns, Shillcock, Chater, & Levy, 1997; Vitevitch & Luce, 1998). For example, Mattys et al. (1999) demonstrated that infants use the likelihood that particular consonant clusters occur within or between words in their native language as a segmentation cue. Infants' ability to segment sequences such as *nongkuth* versus *nomkuth* was examined. Critically, while the consonant clusters in the middle of each sequence are equally likely in English, the former is more likely to occur within words (/ngk/) while the latter is more likely to span a word boundary (/mk/). Nine-month-olds used this subtle distinction as a segmentation cue, inferring word boundaries in the middle of *nomkuth* but not *nongkuth*. A segmentation strategy based on phonotactics requires the infant to already know enough words for these regularities to become apparent. Related segmentation cues may require no prior lexical experience. For example, 12-month-old infants follow the "Possible Word Constraint": they generate segmentations that only create possible words, while avoiding stranding sequences that are not possible words, such as sequences consisting of a single consonant (Johnson, Jusczyk, Cutler, & Norris, 2003). This constraint may help infants to segment speech appropriately and to avoid errors without requiring a lexicon from which to induce the constraint.

It should be clear at this point in the discussion that no single cue underlies word segmentation. This conclu-

sion is evident both from the empirical literature demonstrating that infants are sensitive to myriad cues and from the fact that each cue, in isolation, only solves part of the problem for infants. Studies using multiple cues have largely asked how infants weight conflicting cues. For example, 6- to 7-month-olds prioritize statistics over stress, while 9-month-olds prioritize stress over statistics (Johnson & Jusczyk, 2001; Thiessen & Saffran, 2003). Interestingly, Mattys et al. (1999) found that 9-month-olds also prioritize stress over phonotactic cues, supporting the hypothesis that, while imperfect, stress cues are relatively easy to detect and use (Thiessen & Saffran, 2003); Mattys et al. (1999) suggest that "prosody is an initial cue yielding a coarse first pass at word boundaries that is subsequently supplemented with additional cues such as phonotactic and allophonic constraints" (p. 482). However, it remains unknown how such cues are combined in infants' emerging segmentation strategies (see Morgan & Saffran, 1995, for an example of a study looking at additive effects of cue combinations).

One avenue of research that has effectively explored the use of cue combinations for the discovery of word boundaries is the computational literature (for an extensive review, see Batchelder, 1997). For example, Christiansen et al. (1998), building on the work of Aslin, Woodward, LaMendola, and Bever (1996), examined the efficacy of phonotactic cues that predict ends of utterances as a cue to word boundaries in a corpus of child-directed speech. While this cue worked only moderately well in isolation, inclusion of lexical stress cues markedly improved the performance of the network. A different approach to this problem was pursued by Curtin et al. (2005), who found that including stress information in a corpus enhanced performance by allowing the network to represent stressed and unstressed variants of the same syllable as distinct. One of the messages provided by the computational literature is that more cues are probably better than fewer cues, despite the paradoxical fact that this makes the input more complex. Awaiting future research is the determination of exactly which cues infants attend to, and whether these cues are weighted in the manner predicted by the computational models.

Throughout this section, we have been discussing word segmentation as though it is clear that infants are discovering words in the input, and subsequently representing these sound sequences as units, available for later mapping to meaning. However, it is certainly possible that infants are engaged in a simpler process. Return-

ing to the original Jusczyk and Aslin (1995) study, we earlier described the results as evidence that infants had segmented the word "cup" from the fluent speech. It is equally possible, though, that infants' test performance—discriminating "cup" from "bike"—rests on simply recognizing that the former set of sounds is more familiar than the latter. Doing so would not necessitate segmentation per se; instead, infants would be responding based on the familiarity of the sounds, without having represented "cup" as a distinct lexical representation. Indeed, one early study suggested that in segmentation tasks, infants pull out metrical feet (a rhythmical unit) rather than actual words (Myers et al., 1996). It is thus of great interest to ask what the output of word segmentation actually is. Saffran (2001) addressed this issue with respect to the statistical learning results. When infants respond to *golabu* during testing, after exposure to *golabupabikututipugolabu . . .*, are they treating *golabu* as a word, or as a familiar sound sequence? Based on results from a task in which infants are tested on words like *golabu* embedded in English sentences after exposure, Saffran (2001) suggested that infants treat these nonsensical patterns as primitive English words (i.e., whatever a word is to an 8-month-old, in the absence of mapping to meaning).

Recent studies by Curtin et al. (2005) with 7-month-old infants further suggest that stress cues are represented in these newly segmented proto-lexical representations. Curtin et al. used analyses of child-directed speech to argue that infant learners would be more successful if they represent stressed and unstressed syllables differently during word segmentation. In particular, the analyses suggest that incorporation of stress into infants' representational landscape would result in better distribution-based word segmentation, as well as an advantage for stress-initial syllable sequences. Results of a behavioral study corroborated these analyses. In particular, if items in the test phase were placed in a sentence context and the target was an exact match (*BEdoka*) as opposed to a sequence with the same segments but a different stress pattern (*beDOka*) or another type of nonmatching control sequences, infants demonstrated an overwhelming preference for the exact match. These results suggest that stress information in the ambient language not only shapes how statistics are calculated over the speech input, but that it is also encoded in the representations of parsed speech sequences.

Once some sequences have been segmented from the speech stream to become new lexical entries, can these

words assist in segmentation of subsequent fluent speech, helping infants to discover other adjacent words (e.g., Brent & Cartwright, 1996; Dahan & Brent, 1999)? A recent study by Bortfeld et al. (2005) provides evidence that 6-month-old infants can use known words to segment new words from fluent speech. Infants heard continuous speech in which the word to be segmented appeared adjacent to the infant's own name, which infants recognize early in the 1st year (Mandel, Jusczyk, & Pisoni, 1995). The familiar name served as a strong segmentation cue, providing the first positive evidence for word segmentation in infants as young as 6 months. By demonstrating that infants' prior knowledge alters the manner in which they process new input, the Bortfeld et al. (2005) results suggest a promising new tact for studies of word segmentation and infant learning more generally.

Beginnings of Word Recognition

Once infants have segmented words into discrete units, they are ready to begin recognizing familiar words, matching internal representations of words to their instantiation in subsequent input. This is no simple matter, because words are not static invariant patterns. The sounds of any given word are shaped by properties of the speaker (such as speaker's voice, sex, speaking rate, and affect) and by the context in which the words are produced (such as coarticulation effects).

What words might one expect infants to first recognize? Mandel et al. (1995) hypothesized that infants' names might be particularly salient. They occur frequently, are often presented in isolation, and likely carry affective prosody that attracts infants' attention. Using the preferential listening procedure, 4½-month-olds heard either their own name or an unfamiliar name. Infants preferred to listen to their own names, suggesting that they matched internal representations of these familiar sounds to the input played during the experiment. This does not mean that these infants knew the meanings of these sounds. However, by 6 months of age, infants can recognize highly familiar words based on their meanings. When presented with side-by-side video displays of their mother and father, infants look longer to the display that matches auditory presentations of "mommy" versus "daddy" (Tincoff & Jusczyk, 1999).

These results suggest that infants' developing lexical representations are not fleeting, but are built up incrementally and maintained over time, despite the variabil-

ity in the input. To explicitly investigate the time course of memory for new lexical representations, Jusczyk and Hohne (1997) exposed 8-month-olds to stories containing particular vocabulary items. After 10 days of exposure to the stories, a 2-week retention interval was introduced, during which infants did not hear the stories. Infants were then tested on their recognition of words from the stories versus similar words that had not occurred in the stories. Despite the 2-week retention interval, during which infants heard a vast array of potentially interfering speech, the infants listened longer to the words from the previously familiarized stories, suggesting that auditory representations that were garnered weeks before were sufficiently robust to support later word recognition.

How detailed are these early representations? Infants appear not to confuse similar sounding words, at least under certain circumstances. Infants in Jusczyk and Aslin's (1995) experiments did not incorrectly treat "zeet" as familiar after being exposed to "feet," suggesting that these early representations are fairly specific. Similarly, after repeated exposures to a word and object, 8-month-old infants show robust evidence of detecting a change to a new word that differs in only a single phonetic feature (Stager & Werker, 1997).

Early word representations also appear to include a level of acoustic detail that corresponds to the positions of syllables relative to structural boundaries in sentences, such as phonological phrases. Acoustic cues corresponding to phonological phrase boundaries are detected even by newborn infants (e.g., Christophe et al., 1994, 2001). By 13 months of age, infants can use this distinction in word recognition (Christophe, Gout, Peperkamp, & Morgan, 2003). For example, infants trained on the word "paper" were tested on sentences in which paper was either a word ("The college with the biggest *paper* forms is best") or in which paper spanned a phonological phrase boundary ("The butler with the highest *pay* performs the best"). Despite the fact that the syllable sequence was the same in both cases, with equivalent statistical and stress cues, the results suggested that the infants' representations included the subtle acoustic differences between "paper" and "pay per."

One source of information that may aid infants in speech processing is coarticulation. In order to produce speech as rapidly as we do, whenever we produce a segment, syllable, or word, we move the lips, tongue, and jaw in a way that maintains the positions required for that segment as well as for both the preceding and fol-

lowing consonants and vowels. For example, because of coarticulation, the phoneme /b/ is different in the word “beet” than in the word “boot.” Adults are sensitive to this coarticulatory information, but only under some listening conditions. For example, when words in a string are presegmented by the insertion of pauses, adult listeners show better recognition of those familiar syllables that maintain the same coarticulatory information as used during familiarization. However, when the pauses are omitted and adults must rely on only transitional information, their access to coarticulatory information is no longer evident (Curtin, Werker, & Ladhar, 2002). Seven-month-old infants are also sensitive to coarticulatory information, but under the opposite conditions as adults. When the syllables are presegmented by the insertion of pauses, infants’ recognition of familiar words is not enhanced by matching coarticulatory cues. However, in tasks that require the infant to segment syllables from a continuous stream of speech, matching coarticulatory information significantly improves performance (Curtin et al., 2002).

Infants also appear to represent indexical information that affects word recognition. For example, 7½-month-old infants readily recognize words previously heard produced by a speaker of the same sex, but show no evidence of word recognition when the target is produced by a speaker of the opposite sex (Houston & Jusczyk, 2000). It seems likely that infants’ representations include perceptual features of the speaker, such as components of pitch, that make cross-sex matching challenging. Similarly, 7½-month-olds represent the affective state of the speaker, showing word recognition only when the affective state of the familiarized words matched the targets (Singh, Morgan, & White, 2004). Related arguments are emerging in the field of infant music perception, where researchers are actively investigating the “grain” at which infants represent musical experiences in memory for subsequent recognition (e.g., Ilari & Polka, 2002; Palmer, Jungers, & Jusczyk, 2001; Saffran, Loman, & Robertson, 2001; Trainor, Wu, & Tsang, 2004).

Listening for Meaning

In contrast to the detailed, multiple levels of information available to prelinguistic infants in word recognition and segmentation tasks, infants who have begun to assemble a more sizeable lexicon seem to be more selective and more limited in which detail they use to recog-

nize words. For example, although 14-month-olds can learn to associate two different nonsense words with two different objects (Schafer & Plunkett, 1998; Werker, Cohen, Lloyd, Casasola, & Stager, 1998; Woodward, Markman, & Fitzsimmons, 1994), they fail at this same age if the two nonsense words are phonetically similar such as “bih” and “dih” (Stager & Werker, 1997) or “pin” and “din” (Pater, Stager, & Werker, 2004). Importantly, 14-month-old infants succeed in a virtually identical task when the word is paired with a visual display that is unlikely to evoke labeling (Stager & Werker, 1997). Moreover, when an easier variant of the task was used in which a single object was paired with a single word, the 14-month-olds still failed to notice the change to a phonetically similar word, whereas 8-month-olds succeeded in this same task. The failure to learn minimally contrastive words was shown to be short-lived. When tested in exactly the same task, 17- and 20-month-old infants succeeded at learning phonetically similar words (Werker, Fennell, Corcoran, & Stager, 2002), as did even infants of 14 months who had particularly sizeable vocabularies (Werker et al., 2002; see also Beckman & Edwards, 2000 for a discussion of the potential role of vocabulary size). An identical pattern of results was obtained using an ERP paradigm in which a higher amplitude deflection is seen to known versus unknown words (Mills et al., 2004).

Why might 14-month-old infants fail to distinguish phonetically similar words in a word-learning task when they could still discriminate these two words, and when both younger and slightly older (or even more advanced same-aged infants) succeed? Stager and Werker (1997) speculated that for the novice word learners, the computational demands of linking a word with an object are so great that attentional resources are not available to utilize all the word-level detail that is perceived (see Kahneman, 1973, for the original postulation of attention as a limited resource). However, other interpretations of these findings were that they revealed evidence of a discontinuity between the representations used in phonetic versus phonological (or lexical) representations. Indeed, there is a long-standing tradition in child phonology that posits such a representational discontinuity (see Brown & Matthews, 1997; Rice & Avery, 1995; Shvachkin, 1948). Empirical work by Hallé and de Boysson-Bardies (1994) provided potential support for this discontinuity hypothesis. They used a word recognition task requiring infants to listen to lists of highly familiar versus unknown words, and found that although infants of 7

and 11 months both showed a preference when the unknown words were phonetically dissimilar from the known words (Hallé & de Boysson-Bardies, 1994), if phonetically similar foils were used, only the 7-month-old infants succeeded.

A number of subsequent studies have now disconfirmed the discontinuity hypothesis. When tested in a simpler word recognition procedure wherein infants are shown two pictures and presented with a single word that either matches one of the objects or is a mispronunciation of the same name for that object (e.g., “baby” versus “vaby”), infants from 20 (Swingley & Aslin, 2000) down to 14 months (Swingley & Aslin, 2002) can detect the mispronunciation. Sometimes this detection is shown in longer looking to the correct object when the word is pronounced correctly (Swingley & Aslin, 2002), and sometimes it is evident in a shorter latency to look away from the mismatch (Swingley & Aslin, 2000), but it is consistently evident. This success is seen for well-known words in the associative task used by Stager and Werker (1997). If habituated to the word “ball” paired with the moving object “ball,” and the word “doll” paired with a visual display of a “doll,” 14-month-old infants detect a switch in the word object pairing in the test phase (Fennell & Werker, 2003). Thus, as suggested by both Stager and Werker (1997) and Swingley and Aslin (2000), it appears that an attentional resource limitation rather than a representational discontinuity accounts for the failure of 14-month-old infants under some circumstances.

An attentional resource limitation may not fully explain the preceding findings. It is still necessary to know why it is that phonetic detail is dropped. Is this the only detail that infants drop at 14 months, or is other detail also ignored? The word segmentation and recognition studies revealed that 7- to 9-month-old infants utilize many different kinds of information in the signal. This is evident, for example, in their failure to recognize words if there is a change in speaker gender (Houston & Jusczyk, 2000), or affect (Singh, Bortfeld, & Morgan, 2002). However, by 10½ months of age, infants successfully recognize words spoken by opposite-sex speakers (Houston & Jusczyk, 2000), and are able to ignore changes in affect and still show evidence of recognizing familiar words (Singh et al., 2002). One increasingly popular account, which is somewhat different from the traditional view in which indexical information is not part of lexical representations, is that a rich tapestry of

information—phonetic, indexical, coarticulatory—is included in the lexicon (e.g., Goldinger, 1992), but that not all of this information is used in every task situation (Werker & Curtin, 2005).

Evidence in support of this possibility is provided in recent work with 2.5- and 3-year-olds by Fisher, Church, and Chambers (2004). They demonstrated that children represent both abstract and detailed linguistic information pertaining to the specifics of pronunciation of familiar words. For example, their participants represented the distinction between a medial /t/ and a more /d/-like flap pronunciation of the same phoneme, despite the fact that both pronunciations are legal. Interestingly, the same pattern of results emerged in a related study using nonwords, suggesting that even new lexical representations—formed after just a few exposures to a word—are flexible, in that they are both abstract and specific (Fisher, Hunt, Chambers, & Church, 2001). These findings suggest that perceptual learning mechanisms used flexibly throughout life to adapt to new linguistic input may operate from the beginning of the word learning process (Fisher et al., 2004).

It may be that in the earliest stages of word learning, infants are less able to flexibly select which information to attend to. With the attentional resource demands of attaching meaning to words, infants at the cusp of word learning may be captured by that information which is most salient. To test this hypothesis, Curtin and Werker (cited in Werker & Curtin, 2005) recently tested the ability of 12-month-old infants to learn words that are similar in all respects except stress pattern. They found that these infants, a full 2 months younger than the infants who failed to learn phonetically similar words, could successfully learn to map words such as DObita versus doBIta (where capitals indicate stress) onto two different objects.

With these studies, the links between infant speech perception, word segmentation, word recognition, and word learning are being much more fully described. Moreover, the infant literature is beginning to interface much more richly with the large literature on adult lexical access. Infancy researchers are no longer restricted to asking questions like “what is the unit of representation”? Instead, the field is now poised to allow the asking of much more nuanced questions such as “what information is utilized, when, and why?”

The advent of new methodologies has allowed researchers to go beyond asking which words infants rec-

ognize to assess the time course of word recognition. Eye-tracking has become an important tool in assessing adults' lexical representations (e.g., Allopenna, Magnusson, & Tanenhaus, 1998; Tanenhaus, Spivey-Knowlton, Eberhard, & Sedivy, 1995). Adapting these methods to study infants, Fernald, Pinto, Swingley, Weinberg, and McRoberts (1998) assessed infants' speed and accuracy at word recognition over the course of the 2nd year. To do so, the experimenters measured infants' eye movements as they viewed computer-displayed pictures of familiar objects while listening to the names of these objects. Speed and reliability were correlated with age, suggesting that infants' lexical representations likely become more robust and the cognitive machinery underlying word recognition becomes more fluent during the 2nd year. Like adults, 24-month-olds do not need to hear an entire word to recognize it; instead, word recognition is incremental (Swingley, Pinto, & Fernald, 1999). For example, these infants rapidly distinguished *doggie* from *tree*, correctly fixating on the matching picture, but took 300 ms longer to distinguish *doggie* from *doll*, reflecting the increased phonetic overlap of the latter pair. Interestingly, infants recognize parts of words just as rapidly as whole words, supporting the view that infants, like adults, process words incrementally (Fernald, Swingley, & Pinto, 2001). This ability appears to be associated with infants' productive vocabularies, suggesting a link between lexical growth and the efficiency with which infants recognize words. These facts about how infants process words are consistent with corpus analyses suggesting that the words in infants' early vocabularies are sufficiently overlapping in phonological space to necessitate detailed lexical representations (e.g., Coady & Aslin, 2003).

Experience with particular words appears to enhance these nascent lexical representations. Church and Fisher (1998) observed long-term auditory priming in 2- to 3-year-olds very similar to that of adults, showing effects of experience with specific words on subsequent word identification and repetition. Similar effects emerged in a study with 18-month-olds using a preferential looking task, suggesting that just two repetitions of a word assisted infants in subsequently identifying the target word (Fisher et al., 2004). Similarly, neuroimaging tasks are broadening the range of questions that can be explored. For example, infants may fail to discriminate a nonnative contrast given the task demands of a behavioral task, yet still show evidence of a neurophysiologi-

cal response to the change, indicating that at some level in the brain the information is available (Rivera-Gaxiola et al., 2005).

Beginnings of Grammar

Since most infants do not begin combining words grammatically until the ripe old age of 18 to 24 months or beyond, is there any reason to suspect that the capacity to acquire grammatical structure is present earlier in life? Indeed, researchers have demonstrated early evidence for grammatical knowledge of the native language during infancy, as well as precocious abilities to learn new, simple, grammatical structures using artificial language methodologies (see Tomasello, Chapter 6, this *Handbook*, this volume, for a review of the literature on subsequent aspects of grammar learning). Comprehension studies suggest that infants have a sophisticated grasp of certain syntactic structures by the end of the 2nd year. For example, Naigles (1990) tested young 2-year-olds in a cross-modal matching task that required them to induce the meaning of a new verb. The infants heard either transitive structures, such as "The duck is kradding the bunny," or intransitive structures, such as "The duck and bunny are kradding." Infants looked longer at a video that matched the syntactic structure of the sentence they heard. These results suggest that infants can engage in what is known as "syntactic bootstrapping": using their prior knowledge of syntactic syntax (here, transitivity) to determine the meaning of *kradding*.

Infants' morphological knowledge is similarly advanced. For example, Santelmann and Jusczyk (1998) exposed infants to passages that contained either a grammatical English dependency between the auxiliary verb *is* and a main verb ending with *-ing*, or an ungrammatical combination of the modal auxiliary *can* and a main verb ending with *-ing*. Eighteen-month-olds, but not 15-month-olds, discriminated between the two types of passages. These results suggest that by the middle of the 2nd year, infants have learned how certain types of discontinuous grammatical dependencies operate in their native language.

A number of recent studies have employed artificial grammar methodologies to uncover the learning mechanisms underlying this process. When exposed to word sequences ordered by simple rules (e.g., Marcus et al., 1999) or finite state grammars (Gómez & Gerken, 1999), infants treat test items that violate those patterns

as novel, even if they are instantiated in new vocabulary. For example, Gómez and Gerken (1999) used the head-turn preference procedure to assess whether 12-month-olds could acquire a miniature artificial grammar. Infants discriminated new grammatical strings from ungrammatical strings after less than 2 minutes of training, with evidence that they acquired both specific information (e.g., legal beginnings and ends of sentences, and internal pair-wise combinations) and abstract information (e.g., grammatical structures produced using a new set of vocabulary). Ongoing research is probing the circumstances under which infants are more or less likely to generalize beyond the input given (e.g., Gómez, 2002; Gómez & Maye, 2005).

Saffran and Wilson (2003) extended this line of research to ask how infants might approach learning tasks consisting of multiple levels of information. Twelve-month-olds listened to a continuous speech stream in which the words were ordered via a finite-state grammar. The infants were thus presented concurrently with a word segmentation task and a syntax learning task. The results suggest that infants can first segment novel words and then discover syntactic regularities relating the new words—all within the same set of input. Studies of this type indicate that artificial learning situations can be scaled up to begin to represent some of the problems confronting learners faced with natural language input. For example, Gerken, Wilson, and Lewis (2005) performed a hybrid artificial/natural language learning study in which infants heard a small subset of Russian words marked with correct gender morphology. The results demonstrate that certain types of patterns that occur in natural language input (here, redundant cues) play an important role in learning, as indicated by performance in this lab-based learning task.

CONCLUSIONS AND FUTURE DIRECTIONS

As we hope has been reflected throughout this chapter, infants' accomplishments in the auditory domain are nothing short of extraordinary. In the absence of external guidance or reinforcement, our perceptual systems hone in on the dimensions of the auditory environment that are most relevant for the development of our communicative capacity, and we learn extremely complex and detailed information about how our auditory environment is structured, all during our 1st postnatal year. While much remains to be learned about how these

processes unfold, it is evident that they are heavily multidetermined, influenced by factors from the development of the peripheral auditory system to the nature of our learning mechanisms. We close by considering some limitations on these processes, which may be very important for future work aimed toward illuminating the nature of infants' accomplishments.

Relationship between Auditory Processing and Speech Perception

That even newborns can discriminate between speech sounds and recognize voices has led many to believe that hearing does not constrain speech perception or learning during infancy. It is clear, however, that several aspects of hearing remain immature early in infancy, and it is likely that these immaturities do constrain speech perception to some extent. There are suggestions in the literature that 2-month-olds, for example, represent speech with less detail than older infants do (Bertoni et al., 1988; Bijeljac-Babic et al., 1993). It is likely that some aspects of speech perception and language learning are delayed until 6 months, when representations of the acoustic characteristics of sound are adultlike. In any case, it should be possible to make predictions about young infants' speech discrimination abilities based on what is known about their hearing, and to test specifically to determine whether hearing immaturity has any bearing on early speech perception.

A related question is whether infants use the same information in speech as adults do when they are discriminating between speech sounds. Because there are multiple cues to phonetic identity, it is possible that infants use cues that they hear better, or that they attend to more salient cues and ignore others, or that they weight all cues equally. That infants do not attend to the components of a complex sound as adults do in a simple psychophysical task (Barganes et al., 1995; Barganes & Werner, 1994; Leibold & Werner, 2003; Werner & Boike, 2001) suggests that their approach to speech may differ from that of adults. Nittrouer's studies of speech discrimination in children suggest that preschool children do not, in fact, weight cues to phonetic identity as adults do (e.g., Nittrouer, Crowther, & Miller, 1998; Nittrouer & Miller, 1997; Nittrouer & Studdert-Kennedy, 1987). It would be surprising to find, then, that infants weight cues in an adultlike way. There are now correlational techniques that can be used to assess the weights that listeners place on various components

of a complex sound in making discriminations and these techniques have been successfully applied to young children (e.g., Stellmack et al., 1997). An interesting problem in the future will be to apply these techniques to infants, particularly in the realm of speech perception.

Constraints on Learning

Much of the previous discussion has focused on infants' remarkable capacity to glean structure from complex input. However, it is important to note that demonstrations of powerful learning mechanisms alone do not represent a satisfying solution to the problems facing young language learners. How do learners hone in on the right patterns and structures given the massive amount of data in the input? The "richness of the stimulus problem" is that there are an infinite number of patterns that an unbiased learner might detect. Clearly, human infants are not such learners, and it is incumbent upon researchers to show not just all the things that infants can learn, but also what infants find more difficult to learn, to elucidate the limits on learning. It is also possible to ask how the structure of the task itself affects the types of learning that occur, as some types of input may elicit different learning mechanisms than others (e.g., Peña et al., 2003; Saffran, Reeck, Niehbur, & Wilson, 2005).

Thus far, this research strategy has primarily been carried out with adult learners, with implications to be drawn for infant learners. For example, Newport and Aslin (2004) demonstrated that while adults readily track the dependencies between adjacent syllables (e.g., the probability that *pa* is followed by *bu*), they do not do so when the relevant dependency skips an intervening syllable. Such nonadjacent dependencies are apparently not automatically tracked by learners. Interestingly, however, adults do detect nonadjacent dependencies when the intervening material is different in kind. For example, adults can detect dependencies between two consonants with intervening vowels, or two vowels with intervening consonants (Newport & Aslin, 2004). Because these latter types of structures recur in human languages (in Semitic languages, and in languages like Turkish that use vowel harmony), while the former do not, Newport and Aslin (2004) suggest that languages may be constrained by the limits on human learning. That is, only those structures that are learnable by humans persist in our languages. Saffran (2002) makes a similar argument based on adult grammatical studies.

The extent to which similar findings emerge with young learners is the object of active research

Domain Specificity and Species Specificity

Much of the foregoing discussion has focused on learning from the input, and the types of information captured by infant learning mechanisms. A critical open question is the degree to which this learning is subserved by mechanisms tailored for speech and language. One possibility is that, perhaps due to the adaptive significance of human communication systems, we have evolved sophisticated learning machinery specifically tailored for language. Alternatively, these early learning processes may tap mechanisms that are available for more general tasks.

A growing body of results suggests that at least one of the learning mechanisms we have discussed, sequential statistical learning, is quite general. For example, infants can track sequences of musical tones, discovering "tone-word" boundaries via statistical cues (e.g., Saffran, 2003a; Saffran & Griepentrog, 2001; Saffran, Johnson, Aslin, & Newport, 1999), and can learn statistically defined visual patterns (e.g., Fiser & Aslin, 2002; Kirkham, Slemmer, & Johnson, 2002). These findings and others suggest that at least these basic learning processes are not tailored solely for language acquisition (e.g., Saffran, 2002, 2003b).

Another source of evidence bearing on this issue comes from studies of nonhuman primates. Hauser and his colleagues (Hauser, Newport, & Aslin, 2001; Hauser, Weiss, & Marcus, 2002) have tested cotton-top tamarins, a new world monkey species, on the linguistic tasks used by Saffran et al. (1996) and Marcus et al. (1999). Intriguingly, the monkeys showed the same pattern of performance as human infants, despite their presumed lack of evolved abilities to acquire human language (Hauser et al., 2001, 2002). Even rats detect some language-relevant patterns (Toro & Trobalan, 2004)! These findings reinforce the view that at least some of the learning mechanisms that subserve the beginnings of language learning are not evolutionary adaptations specialized for the linguistic domain.

Results like these lead immediately to the question of why, if monkeys share our learning machinery, language is uniquely human. That is, if monkeys learn like us, shouldn't they be as linguistically sophisticated as we are? Several avenues of explanation are currently being

explored. One, of course, is the traditional view that humans possess innate linguistic knowledge that other species lack (e.g., Pinker, 1984). Other investigators are focusing on the degree to which human learning mechanisms may in fact diverge from those possessed by other species. For example, tamarins and human adults do not show the same pattern of learning of nonadjacencies discussed in the previous section, suggesting that the constraints on human learning mechanisms may diverge from those seen in other species (Newport, Hauser, Spaepen, & Aslin, 2004). Similarly, Hauser, Chomsky, and Fitch (2002) have suggested that while humans and nonhumans may share much of their learning machinery, humans are differentiated by their ability to perform recursion operations—the capacity to generate an infinite range of expressions from a finite set of elements (see also Fitch & Hauser, 2004). On this view, humans and nonhumans should show similar performance when learning about such things as speech contrasts and word segmentation, and diverge as grammatical complexity increases (e.g., Saffran, Hauser, Seibel, Kapfhamer, Tsao, & Cushman, 2005). While these central questions remain to be resolved, their answers are likely to have broad impact on such issues as the modularity of mind and the ontogenesis of specific domains of knowledge.

There is another component to early language learning that may be relevant to species differences—social interaction between the speaker and the learner. While such issues as joint attention have played a prominent role in the literature on how young children map sound to meaning (e.g., Harris, Chapter 19; Tomasello, Chapter 6, this *Handbook*, this volume), the role of social interaction has not received significant attention in the literature on how infants acquire sound structure itself. Certainly, there is ample evidence that caregivers manipulate the input so it is well tailored to infants' perceptual predilections (e.g., Kuhl et al., 1997; see Trehab, 2003, for related evidence in the domain of music perception). The higher pitches and enhanced pitch contours of infant directed speech are well-established attention-getters and affect communicators (e.g., Cooper & Aslin, 1990; Fernald, 1992). Intriguing new results suggest, however, that the role of social interaction extends beyond the sound structure of the input. Kuhl, Tsao, and Liu (2003) manipulated infants' perception of nonnative speech contrasts such that English-learning infants maintained a Mandarin speech contrast well beyond the age at which their ability to discriminate the contrast would typically have declined. Critically, how-

ever, human social interaction was required in the presentation of the Mandarin input. When infants received the same input via high-quality DVD recordings, no impact on their speech perception was observed. These results suggest that, like some species of birds, the learning system requires a certain type of interactive input to affect perception. If this is the case, then differences in social interaction may also help to explain some cross-species differences in who learns what.

The Infant's Auditory World

In this review, we have considered recent developments in our understanding of how infants begin to make sense of their auditory environments. A great deal of progress has been made in elucidating the basic sensory and perceptual mechanisms that provide auditory input to infant learners, as well as the learning mechanisms that track this input and integrate it with infants' existing knowledge.

In future studies, we expect that the relationship between infants' auditory abilities and the rest of language acquisition (see Tomasello, Chapter 6; Waxman & Lidz, Chapter 7, this *Handbook*, this volume) will become clearer. Audition is the gateway to spoken language, and infants' early accomplishments in acquiring the sound structure of their native language(s) lay critical groundwork for subsequent learning. Recent studies linking the acquisition of sound structure to later accomplishments in word learning provide important suggestions about how infants' early abilities are likely to influence later language learning (e.g., Hollich, Jusczyk, & Luce, 2002; Saffran & Graf Estes, 2004; Swingley & Aslin, 2002; Thiessen, 2004; Werker et al., 2002). For example, early speech perception abilities may predict some aspects of word learning many months later (Tsao, Liu, & Kuhl, 2004). Similarly, researchers are beginning to investigate the effects of the amelioration of early sensory deprivation via cochlear implants on subsequent auditory perception and language learning abilities (Houston, Pisoni, Kirk, Ying, & Miyamoto, in press). Such integrative research enterprises will serve to illuminate the links between the talents of infant listeners in the auditory realm and the many linguistic (and nonlinguistic) tasks that lie ahead of them. Similarly, much remains to be learned about the neural underpinnings of the abilities described throughout our review, and knowledge about these neural substrates will help us to better understand the behaviors that they subserve. Many fasci-

nating open questions thus remain, and in the next edition of the *Handbook*, we hope to read the answers—including the answers to the many questions that we do not yet know to ask.

How visual perception develops has long been a central question in understanding psychological development generally. During its emergence as a separate discipline in the late 1800s, psychology was focused primarily on how human knowledge originates (e.g., Titchener, 1910; Wundt, 1862), an emphasis inherited from concerns in philosophy. Much of the focus was on the relation between sensation and perception, especially in vision. The prevailing view, inherited from generations of empiricist philosophers (e.g., Berkeley, 1709/1963; Hobbes, 1651/1974; Hume, 1758/1999; Locke, 1690/1971), was that at birth, a human being experiences only meaning-

less sensations. Coherent, meaningful, visual reality emerges only through a protracted learning process in which visual sensations become associated with each other and with touch and action (Berkeley, 1709/1963).

Through most of the twentieth century, even as psychology increasingly emphasized findings of empirical research, this primarily philosophical view cast a long shadow. Its influence was so great as to be essentially a consensus view of development. William James (1890) echoed its assumptions in his memorable pronouncement that the world of the newborn is a “blooming, buzzing, confusion.” Modern developmental psychology, shaped greatly by Piaget, incorporated the same ideas. Although Piaget combined contributions of both maturation and learning in his theories, his view of the starting points of perception was standard empiricist (e.g., Piaget, 1952, 1954). He did place greater emphasis on *action*, rather

Preparation of this chapter was supported in part by research grants R01 EY13518-01 from the National Eye Institute and REC 0231826 from the National Science Foundation to PJK. We thank Heidi Vanyo for helpful assistance.

than mere sensory associations, as the means by which meaningful reality emerges from initially meaningless sensations.

This basic story about early perception and knowledge persisted, in part, because researchers lacked methods for investigating these topics scientifically. The arguments of Berkeley and others were primarily logical ones. Claims about the origins of knowledge in the association of sensations initially came from theory and thought experiments. Later, a few experiments with adults were used to make inferences about aspects of perception that might be based on learning (e.g., Wallach, 1976) or not so based (e.g., Gottschaldt, 1926). Finding a more direct window into perception and knowledge of a young infant seemed unlikely. As Riesen (1947, p. 107) put it: "The study of innate visual organization in man is not open to direct observation in early infancy, since a young baby is too helpless to respond differentially to visual excitation."

In the time since Riesen's (1947) observation, the scientific landscape in this area has changed entirely. Although the development of visual perception is among the most long-standing and fundamental concerns in the field, it is also an area that is conspicuous in terms of recent and rapid progress. Beginning in the late 1950s, the door to progress has been the development of methods for studying sensation, perception, and knowledge in human infants. The results of scientific efforts, continuing to the present, have changed our conceptions of how perception begins and develops. These changes, in turn, have generated important implications about the early foundations of cognitive, linguistic, and social development.

In this chapter, we consider current knowledge of early visual perception and its development. Besides describing the origins and development of these perceptual capabilities, we use them to illustrate general themes: the several levels of explanation required to understand perception; the roles of hardwired abilities, maturation, and learning in perception; and some of the methods that allow assessment of early perception. These themes all have broader relevance for cognitive and social development.

THEORIES OF PERCEPTUAL DEVELOPMENT

As a backdrop for considering research in early vision, we describe two general theories of perceptual develop-

ment. These serve as valuable reference points in understanding how recent research has changed our conceptions of how perception begins.

The Constructivist View

The term *constructivism* here refers to the view that perceptual reality must be constructed through extended learning. Choosing one term to label this idea is efficient, but also unfortunate, as this set of ideas has many names. In philosophy, this kind of account is most often called *empiricism*, emphasizing the role of input from experience in forming perception. If, as is usually the case, associations among sensations are held to dominate perceptual development, the position may also be aptly labeled *associationism*. In the earliest days of psychology as an independent discipline, the merging of current and remembered sensations to achieve objects in the world was called *structuralism* (Titchener, 1910). Helmholtz (1885/1925) is often credited with applying the label *constructivism* to the idea that sensations are combined with previously learned information using unconscious inference to achieve perceptual reality. This pedigree, along with Piaget's later emphasis on inputs from the learner's actions in constructing reality, make constructivism perhaps the best term to characterize modern versions of this view. Unfortunately, the term has been used elsewhere with different shades of meaning. In considering issues in learning, developmental and educational psychologists often contrast constructivism with associationism, where constructivism emphasizes the active contributions of the learner. Although a common thread extends through the uses of constructivism, its use here will be confined to the notion that perception is constructed from sensations and actions through learning. Our primary concern in addressing perception is to consider, not particular modes of learning, but whether basic perceptual abilities are learned at all. For this reason, and others, the verdict on constructivism in this domain may differ from the fates of constructivisms in other studies of development.

The constructivist account of how perception develops is familiar to many. The key assumption is that at birth, sensory systems function to produce only their characteristic sensations. Stimulation of the visual system yields sensations of brightness and color, along with some quality (a "local sign") correlating with a position on the retina. Stimulation of the auditory system produces loudnesses and pitches, and so on. Of course, per-

ceptual reality consists not of disembodied colors and loudnesses, but of objects arranged in space, relations among them, and events, characterized by motion and change within that space. On the constructivist view of perceptual development, all these commonplace occupants of adult perceptual reality—*any* tangible, material object existing in the external world and, indeed, the external spatial framework itself—are hard-won constructions achieved by *learning*. What allows construction of external reality is associative processes. Experiences of visual sensations coupled with touch, according to Berkeley (1709/1963), allow creation of the idea that seen objects have substance. Connecting the muscular sensations of reaching with visual sensations allows the creation of depth and space. Sensations obtained from one view of an object at a given time are associated by contiguity in space and time, and by similarity. Sensations obtained a moment later from another view may become associated with the previous ones. An object becomes a structure of associated sensations stored in memory. In John Stuart Mill's memorable formulation, for the mind, an object consists of all the sensations it might give us under various circumstances: An object is “the permanent possibilities of sensation” (Mill, 1865). For Piaget (1952, 1954), the account is similar, except that voluntary *actions*, not just tactile and muscular sensations, become associated, making objects consist initially of “sensorimotor” regularities.

How did this basic story of perceptual development attain such preeminent status in philosophy and psychology? The question is puzzling because the account was not based on scientific study in any meaningful way. Just to anticipate a different possibility, we might consider the life of a mountain goat. Unlike a human baby, a mountain goat is able to locomote soon after birth. Remarkably, the newborn mountain goat appears to perceive solid surfaces on which to walk and precipices to avoid. When tested on a classic test apparatus for the study of depth perception—the “visual cliff”—newborn mountain goats unfailingly avoid the side with the apparent drop-off (Walk & Gibson, 1961).

This example puts a fine point on the issue. Although mountain goats appear innately able to perceive solidity and depth, generations of philosophers and psychologists have argued that, as a matter of logic, humans must be born helpless and must construct space, substance, and objects through a long associative process. The humble mountain goat, as well as many other species, provides a stark contradiction to any logical argument

that perception must be learned. From an evolutionary perspective, it might also be considered curious that humans have been so disadvantaged, beset with a frail and complicated scheme for attaining what mountain goats possess from birth.

The preceding questions are not meant to be critical of generations of serious thinkers who have held the constructivist position. Asking these questions helps to highlight what the issues were and how things have now changed. The key fact is that the constructivist position was embraced nearly universally because the arguments for it were logical. If valid, these arguments admitted few alternatives. We can better understand current views if we briefly review these logical arguments, sometimes described as the *ambiguity argument* and the *capability argument* (Kellman & Arterberry, 1998).

The ambiguity argument traces to Berkeley and his 1709/1963 book *Essay toward a New Theory of Vision*. Analyzing the projection of light onto the retina of a single eye, Berkeley pointed out that while the projection onto different retinal locations might carry information into the image about the left-right and up-down relations of objects in the world, there was no direct information to indicate the distance to an object. A given retinal image could be the product of an infinitely large set of possible objects (or, more generally, scenes) in the world. Because of this ambiguity, vision cannot provide knowledge of the solid objects in the world or their three-dimensional (3D) positions and relations. Since vision is ambiguous, the seeming ability of adult perceivers to see objects and space must derive from associating visual sensations with extravisual sensations (such as those involved in eye-muscle adjustments, and with touch and locomotion).

The capability argument drew more on physiology than philosophy. The history of progress in understanding the nervous system reflects a progression from the outside in. Long before much was known about the visual cortex of the brain, parts of the eye were somewhat understood. Even in the nineteenth century, it was clear that the retina contained numerous tiny receptors and that information left the eye for the brain in a bundle of fibers (the optic nerve). It is not surprising that reasoning about the capabilities of the visual system centered on these known elements. Consider the world of a single visual receptor, at some location on the retina. If it absorbs light, this receptor can signal its activation at that point. Receiving only tiny points of light, the receptor can know nothing of objects and spatial layout and, as

Berkeley contended, certainly nothing about the third dimension (depth). To understand the system in aggregate, one need only think of many receptors in many locations, each capable of signaling locally activations that the visual system encodes as brightness and color. Clusters of brightnesses and colors are not objects or scenes; thus, perceiving objects and scenes requires something beyond sensations generated by activity in these receptors.

To make matters worse, it was understood as a logical matter that such sensations existed not in the world but in the mind. As Johannes Muller (1838/1965) had emphasized in his famous doctrine of *specific nerve energies*, whether one presses on the eyeball or whether retinal receptors absorb light, the mind experiences brightness and color. Similarly, pressure or shock to the auditory system produces experiences of sound. It seems that sensory qualities are specific to the separate senses, regardless of the energy used to evoke them. If the visual system can produce only its own characteristic sensations, how can it be said to obtain knowledge of the world? This is the capability argument: The visual system, as a system that generates its own characteristic sensations, usually on stimulation by light, is not capable of directly revealing the objects, layout, and events of the external world.

These powerful logical arguments have two consequences. One is that the apparent direct contact that we have through vision with a structured, meaningful, external world must be a developmental achievement, accomplished through learning to infer the meanings of our sensations. The other consequence is that perceptual knowledge in general must be an inference. Different versions of this theoretical foundation have characterized perception as inference, hypothesis, results of past experience, and imagination. In Helmholtz's classic statement: "Those objects are imagined to be in the field of view that have frequently given rise to similar sensations in the past" (Helmholtz, 1885/1925). Lest one think that this section has only historical significance, it is not uncommon to encounter precisely these same arguments today (e.g., Purves & Lotto, 2003).

The Ecological View

Until recently, students of development have been less familiar with an alternative to constructivist views of perceptual development. The view is important, not only

as a viable possibility, but as we will see, a perspective compatible with much of the scientific evidence about how perception develops.

We call this view *ecological* because it connects perceptual capabilities to information available in the world of the perceiver. Crucial among this information are regularities and constraints deeply connected to the basic structure and operation of the physical world. These regularities have existed across evolutionary time, and have shaped the operation of perceptual mechanisms.

The emergence of ecological views of perception and perceptual development owes most to the work of James J. and Eleanor J. Gibson (E. Gibson, 1969; J. Gibson, 1966, 1979). Earlier influences included the work of the physiologist Hering (1861–1864), who described the operation of the two eyes in binocular depth perception as an integrated, and likely innate, system, and the Gestalt psychologists (e.g., Koffka, 1935; Wertheimer, 1923/1958) who emphasized the importance of abstract form and pattern, rather than concrete sensory elements, in perception. Important strands of J. Gibson's theories of perception have since been advanced in computational approaches to perception, especially that of Marr (1982).

Numerous facts lead naturally to a consideration of ecological ideas in perceptual development. Perhaps the simplest is the observation that some species exhibit effectively functioning perceptual systems from birth, as in the case of the mountain goat. Historically, however, the issue that raised the curtain for contemporary views is the nature of *information* in perception (J. Gibson, 1966, 1979).

In a certain sense, this is the logical starting point. If the constructivist view was deemed correct because of logical limits on information received by the senses, then any alternative view would need to address the ambiguity and capability arguments head-on. This is one way of summarizing a several-decades-long effort led by J. Gibson, foreshadowed in his 1950 book, *The Perception of the Visual World*, and emerging fully in *The Senses Considered as Perceptual Systems* (1966) and *The Ecological Approach to Visual Perception* (1979). According to Gibson, both the ambiguity and capability arguments rest on misunderstandings of the information available for perception.

Ecology and Ambiguity

Ambiguity claims about vision centered on analysis of static retinal images given to a single eye. If these con-

straints are admitted, the analyses by Berkeley and others are correct: For any given retinal image, there are infinitely many possible configurations in the world that could give rise to it. The problem with the analysis, however, is that the inputs to human vision are not restricted to single, static retinal images. As Hering (1861–1864) had already noted, the two eyes sample the world from two distinct vantage points. This arrangement makes possible direct information about the third dimension (which lay at the heart of Berkeley's ambiguity concerns). J. Gibson argued that another primary fact had been missed: Sophisticated visual systems are the property of *mobile* organisms. Motion and change provide important information for perception. Although a single retinal image is ambiguous, the transformations over time of the optic array as the perceiver *moves* are highly specific to the arrangement of objects, space, and events. If one can assume that the world is not deforming contingent on the perceiver's motion, this kind of information *specifies* the layout. Evolution may well have picked up on such sources of information, allowing perceptual systems to deliver meaningful information not derived from learning. Whereas the mountain goat provides an existence proof of functional perception without learning, the analysis given by J. Gibson explained how this might be possible.

Ecology and Capability

Ambiguity issues focus on the information in the world. Corresponding to the arguments about information are revised ideas about the capabilities of a perceptual system (J. Gibson, 1966). The description of inputs to vision in terms of brightness and color responses at individual locations is inadequate. Further along in the system are mechanisms sensitive to higher order relationships in stimulation. There were precedents to this view. Corresponding to Hering's point about triangulation (sampling from two positions) was his assessment that the brain handled inputs to the two eyes as a system, detecting disparities between the two eyes' views to perceive depth. Likewise, the Gestalt psychologists emphasized the contribution of brain mechanisms in processing relations in the input. J. Gibson pointed out the importance of higher order information and suggested that perceptual systems are naturally attuned to pick up such information. He did not deal much with neurophysiological or computational details, and he confused some by saying that perceptual systems "resonate" to information. Gibson's views still evoke controversy, yet

researchers in perception and perceptual development have been busy ever since exploring the computations and mechanisms that extract higher order information.

The Contemporary Situation in Perceptual Theory

Philosophers, most cognitive scientists, and psychologists embrace the notion that, in a formal sense, perception has the character of an inference (specifically, an *ampliative* inference, in which the conclusion is not guaranteed by the premises or data, Swoyer, 2003). As virtual reality systems show us (and as dreams and hallucinations impressed Descartes and others), the perceptual experience of 3D space and certain objects and events does not guarantee their objective existence.

Such arguments have been elaborated in detail (Fodor & Pylyshyn, 1981; Ullman, 1980; but see Turvey, Shaw, & Reed, 1981) to attack J. Gibson's assertion that perception is "direct" (it does not require inference). If perception is formally inferential, perhaps Berkeley and his intellectual descendants were correct after all about how perception must develop. Is there a paradox in holding an ecological view while admitting that perception has a formally inferential character?

Resolving this apparent paradox by separating the two issues is important to understanding perceptual development. Perception has the formal character of an inference, but that does not imply that perception in humans must be learned, or that vision must be supplemented by touch or action. Perceptual inferences may be exactly the kinds of things that have been built into perceptual systems by evolution. Rock (e.g., 1984), a perceptual theorist who stressed the inferential nature of perception, and Marr (1982), who put computational approaches to perception on a clear footing, were among the earliest to articulate that perception could be both inferential *and* innate.

The analyses by the Gibsons and later investigators influenced the debate about perceptual development by altering conceptions of the information available for perception. For a moving, two-eyed observer with mechanisms sensitive to stimulus relations, the ambiguities envisioned by Berkeley—many different ordinary scenes leading to the same retinal image—do not exist. For Berkeley, visual ambiguity is so expansive that vision requires lots of outside help. For J. Gibson (1979), visual information specific to arrangements of scenes and events is available, and humans possess perceptual mechanisms attuned to such information. In Marr

(1982) may be found a synthesis of the two extremes: Visual ambiguity is intrinsic but can be handled by relatively few, general constraints. The interpretation of optic flow patterns in terms of 3D spatial layout requires the assumption that the scene (or whatever provides images to the two eyes) is not changing contingent on the observer's movements. This assumption is rarely, if ever, violated in ordinary perception, although it is exactly the assumption that is violated when an observer dons the viewing goggles or helmet in a virtual reality system. Many researchers have suggested that certain assumptions (e.g., the lack of observer-contingent scene changes or the movement of objects on continuous space-time paths) have come to be reflected in perceptual machinery through evolution (J. Gibson, 1966; Johansson, 1970; Kellman, 1993; Kellman & Arterberry, 1998; Shepard, 1984).

This possibility has far-reaching consequences with the potential to overturn a persistent and dominant view of perception based on learning. Yet it is important to recognize that the mere *possibility* of innate perceptual mechanisms (incorporating assumptions about the world) does not decide their reality. Unlike mountain goats, human infants are not mobile at birth, and until recently, their perceptual abilities were mostly unknown. Our discussion of constructivist and ecological views of perceptual development culminates in the observation that the answer is a matter for empirical science. Moreover, different perceptual abilities may have different contributions from native endowments, maturation, and learning. Researchers must write the story of each perceptual capacity based on experimental evidence.

This conclusion sets our agenda for the remainder of this chapter. We consider the emerging scientific picture of development for the crucial components of visual perception. This picture indicates decisively that, although learning may be involved in calibration and fine-tuning, visual perception depends heavily on inborn and early maturing mechanisms. This picture has begun to strongly influence views in other areas of development, as well as conceptions of the nature of perception. More unsettling is the failure to attend to the evidence on infant perception in some recent trends in cognitive science and neuroscience. After considering the evidence, we return to these issues at chapter's end.

Our review of the field is necessarily selective. A goal of the present chapter is to place what has been learned about infant vision in a more general historical and philosophical context, so that it may be easily appreciated and used by those in related fields. The particular topics reflect our areas of expertise and our views of areas that are rapidly advancing and in which important knowledge has been gained. Some parts of this chapter are modestly updated from the previous edition of the *Handbook of Child Psychology* (Kellman & Banks, 1998), whereas others are new. In what follows, we first consider basic visual sensitivities in the infant, including acuity and contrast sensitivity, sensitivity to color, pattern, and motion. We then consider spatial perception, object perception, and face perception.

associated and used by those in related fields. The particular topics reflect our areas of expertise and our views of areas that are rapidly advancing and in which important knowledge has been gained. Some parts of this chapter are modestly updated from the previous edition of the *Handbook of Child Psychology* (Kellman & Banks, 1998), whereas others are new. In what follows, we first consider basic visual sensitivities in the infant, including acuity and contrast sensitivity, sensitivity to color, pattern, and motion. We then consider spatial perception, object perception, and face perception.

BASIC VISUAL SENSITIVITIES IN INFANCY

The function of visual perception is to provide the perceiver with information about the objects, events, and spatial layout in which he or she must think and act. Starting from this concern, the study of basic visual sensitivity and the psychophysical methods used to study infants' visual perception may seem arcane to the non-specialist. Yet, all higher-level abilities to see the forms, sizes, textures, and positions of objects, as well as to apprehend spatial relations of objects at rest and in motion, depend on basic visual capabilities to resolve information about spatial position. For this reason, the development of spatial vision has been a topic of great concern to those interested in infant perception.

We begin an examination of spatial vision by considering sensitivities to variation across changing locations in the optic array. Two of the most basic dimensions of sensitivity in describing spatial vision are visual acuity and contrast sensitivity. Our discussion of these basic capacities leads naturally into an assessment of basic pattern discrimination abilities. We then consider color vision and motion perception.

Visual Acuity

Acuity is a vague term, meaning something like "precision." A particular variety of acuity is so often used to describe visual performance that the phrase "visual acuity" has become its common label. This type of acuity is more technically known as *minimum separable acuity* or *grating acuity*. Object recognition and identification depend on the ability to encode differences across positions in the retinal image in luminance or spectral composition. *Visual acuity* thus refers to the resolving capacity of the visual system—its ability to distinguish fine details or differences in adjacent positions.

Measuring this type of visual acuity by various means is by far the most common way of assessing ocular health and suitability for specific visual tasks, such as operating cars or aircraft.

To assess acuity, high-contrast, black-and-white patterns of various sizes are presented at a fixed distance. The smallest pattern or smallest critical pattern element that can be reliably detected or identified is taken as the threshold value and is usually expressed in angular units. Many different acuity measures have been used with adults, but only two have been widely used in developmental studies, grating acuity and vernier acuity.

Grating acuity tasks require resolving the stripes in a repetitive pattern of stripes. The finest resolvable grating is taken as the measure of acuity and it is generally expressed in terms of spatial frequency, which is the number of stripes per degree of visual angle. Adult grating acuity under optimal conditions is 45 to 60 cycles/degree, which corresponds to a stripe width of $\frac{1}{2}$ to $\frac{2}{3}$ minutes of arc (Olzak & Thomas, 1986). By optimal conditions, we mean that the stimulus is brightly illuminated, high in contrast, presented for at least $\frac{1}{2}$ second, and viewed foveally with a well-focused eye. Change in any of these viewing parameters causes a reduction in grating acuity.

Vernier acuity is tested in tasks requiring discrimination of positional displacement of one small target relative to another. The most common variety involves distinguishing whether a vertical line segment is displaced to the left or right relative to a line segment just below it. In adults, the just-noticeable offset under optimal conditions is 2 to 5 seconds of arc (Westheimer, 1979). Because this distance is smaller than the diameter of a single photoreceptor in the human eye, this kind of performance has been called *hyperacuity* (Westheimer, 1979). As with grating acuity, the lowest vernier acuity thresholds are obtained when the stimulus is brightly illuminated, high in contrast, presented for at least $\frac{1}{2}$ second, and viewed foveally with a well-focused eye.

There have been numerous measurements of grating acuity (the highest detectable spatial frequency at high contrast) in human infants. Figure 3.1 plots grating acuity as a function of age for some representative studies. The displayed results were obtained using three response measurement techniques: Forced-choice preferential looking (FPL), optokinetic nystagmus (OKN), and the visual evoked potential (VEP). This figure illus-

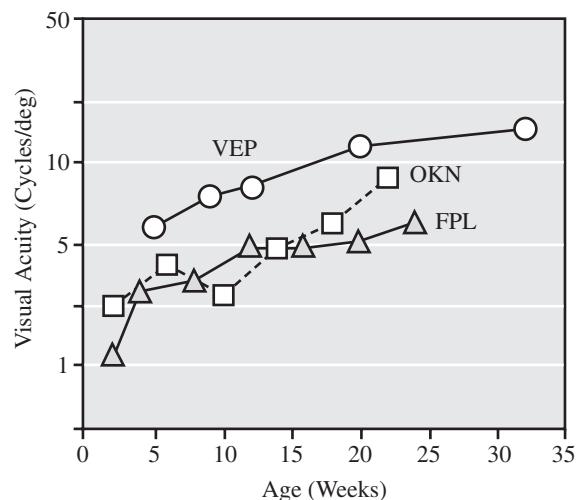

Figure 3.1 Visual acuity estimates at different ages. The highest detectable spatial frequency of a high-contrast grating stimulus is plotted as a function of age. Circles: Visual evoked potential estimates. Squares: Optokinetic nystagmus (OKN) estimates. Triangles: Forced-choice preferential looking estimates. Sources: “Measurement of Visual Acuity from Pattern Reversal Evoked Potentials,” by S. Sokol, 1978, *Vision Research*, 18, pp. 33–40. Reprinted with permission; “Maturation of Pattern Vision in Infants during the First 6 Months,” by R. L. Fantz, J. M. Ordy, and M. S. Udelf, 1962, *Journal of Comparative and Physiological Psychology*, 55, pp. 907–917. Reprinted with permission; “Visual Acuity Development in Human Infants up to 6 Months of Age,” by J. Allen, 1978, unpublished master’s thesis, University of Washington, Seattle, WA. Reprinted with permission.

trates two points. First, acuity is low at birth and develops steadily during the 1st year. Grating acuity during the neonatal period is so low that these infants could be classified as legally blind. Second, the acuity estimates obtained with behavioral techniques such as FPL and OKN are generally lower than those obtained using electrophysiological techniques such as VEP. Grating acuity develops beyond the 1st year and reaches adult levels around 6 years of age (e.g., Skoczenski & Norcia, 2002). We discuss the optical, receptor, and neural factors that determine grating acuity as a function of age in the section on contrast sensitivity.

There have been fewer measurements of vernier acuity; nonetheless, some intriguing observations have been reported. Shimojo and colleagues (Shimojo, Birch, Gwiazda, & Held, 1984; Shimojo & Held, 1987) and Manny and Klein (1984, 1985) used FPL to measure the smallest offset infants could respond to at different

ages. They found that vernier acuity was much poorer in 8- to 20-week-old infants than in adults. The ratio of adult vernier acuity divided by 8-week olds' vernier acuity is significantly greater than the corresponding ratio for grating acuity. A similar finding has emerged from VEP measurements of vernier and grating acuity; adult levels of hyperacuity were not reached until 10 to 14 years of age (Skoczenski & Norcia, 2002). This suggests that the visual mechanisms that limit vernier acuity undergo greater change with age than do the mechanisms limiting grating acuity. Different hypotheses have been offered concerning the differing growth rates (Banks & Bennett, 1988; Shimojo & Held, 1987; Skoczenski & Norcia, 2002); however, direct empirical tests are needed.

Contrast Sensitivity

Contrast sensitivity refers to the ability to detect variations in luminance. Most acuity testing is done at high contrast (e.g., black characters on a white background or gratings varying from white to black). Testing for contrast sensitivity involves finding the least difference between luminances that allows detection of structure. The contrast sensitivity function (CSF) represents the visual system's sensitivity to sinusoidal gratings of various spatial frequencies. The CSF has generality as an index of visual sensitivity because any two-dimensional pattern can be represented by its spatial frequency content and, consequently, one can use the CSF along with linear systems analysis to predict visual sensitivity to a wide range of spatial patterns (Banks & Salapatek, 1983; Cornsweet, 1970). Thus, measurements of contrast sensitivity as a function of age should allow the prediction of sensitivity to and even preference for many visual stimuli (Banks & Ginsburg, 1985; Gayl, Roberts, & Werner, 1983).

The adult CSF has a peak sensitivity at 3 to 5 cycles/degree, so the lowest detectable contrasts occur for gratings of medium spatial frequency. At those spatial frequencies, the just-detectable grating has light stripes that are only 0.5% brighter than the dark stripes. At progressively higher spatial frequencies, sensitivity falls monotonically to the so-called high-frequency cutoff at about 50 cycles/degree. This is the finest grating an adult can detect when the contrast is 100% and it corresponds to the person's grating acuity. At low spatial frequencies, sensitivity falls as well, although the steepness of this falloff is highly dependent on the conditions of measurements.

Adult contrast sensitivity and grating acuity are limited by optical, receptoral, and neural factors. Sensitivity is best with good lighting, foveal fixation, sufficiently long stimulus duration, and a well-focused eye. Decreased illumination reduces both contrast sensitivity and the high-frequency cutoff (van Nes & Bouman, 1967). Similar changes in contrast sensitivity occur when the stimulus is imaged on the peripheral retina (Banks, Sekuler, & Anderson, 1991) or the eye is not well focused (Green & Campbell, 1965). Understanding limitations on adult vision has been aided by modeling the early stages of vision as a series of filtering stages. Visual stimuli pass sequentially through the eye's optics, which are responsible for forming the retinal image; the photoreceptors, which sample and transduce the image into neural signals; and two to four retinal neurons, which transform and transmit those signals into the optic nerve and eventually to the central visual pathways. In these early stages of visual processing, considerable information is lost. The high-frequency falloff observed in the adult CSF is determined, by and large, by the filtering properties of the eye's optics and the photoreceptors (Banks, Geisler, & Bennett, 1987; Pelli, 1990; Sekiguchi, Williams, & Brainard, 1993). The loss of high-frequency sensitivity with peripheral viewing has been modeled successfully by examination of the optics, receptors, and retinal circuits of the peripheral retina (Banks et al., 1991). The sensitivity loss that accompanies a reduction in illumination has also been modeled reasonably successfully, at least at high spatial frequencies (Banks et al., 1987; Pelli, 1990) as has the loss that accompanies errors in the eye's focus (Green & Campbell, 1965). From the emerging understanding of the optical, receptoral, and neural mechanisms that determine contrast sensitivity in adults, attempts have been made to use similar techniques to understand the development of contrast sensitivity in human infants.

Figure 3.2 displays an adult CSF measured using a psychophysical procedure, along with infant CSFs measured using forced-choice preferential looking (Atkinson, Braddick, & Moar, 1977; Banks & Salapatek, 1978) and the visual evoked potential (Norcia, Tyler, & Allen, 1986; Pirchio, Spinelli, Fiorentini, & Maffei, 1978). These data illustrate two common observations. First, contrast sensitivity (and grating acuity) in young infants is substantially lower than that of adults, with the difference diminishing rapidly during the 1st year. Second, as we saw earlier in Figure 3.1, measurements with the visual evoked potential typically yield higher sensitivity

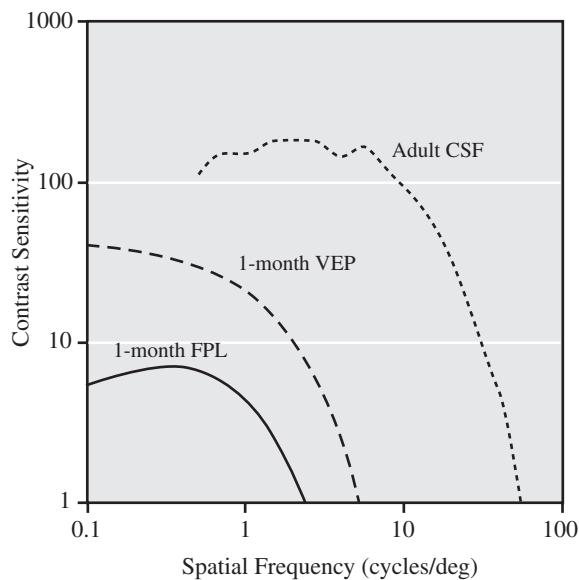

Figure 3.2 Adult and 1-month-old infant contrast sensitivity functions (CSFs). Contrast sensitivity is plotted as a function of spatial frequency (the numbers of grating cycles per degree of visual angle). The upper dotted curve is an adult CSF that was measured psychophysically. The lower solid curve is the average of 1-month CSFs, measured using forced-choice preferential looking. The middle dash curve is the average of 1-month CSFs, measured using visual-evoked potential. *Sources:* “Acuity and Contrast Sensitivity in 1-, 2-, and 3-Month-Old Human Infants,” by M. S. Banks and P. Salapatek, 1978, *Investigative Ophthalmology and Visual Science*, 17, pp. 361–365. Reprinted with permission and “Development of Contrast Sensitivity in the Human Infant,” by A. M. (and acuity) estimates than do behavioral techniques (see Mayer & Adrendt, 2001 for a review). The time course differs depending on whether a behavioral or electrophysiological technique is used. With evoked potential measurements, peak sensitivity approaches adult values by 6 months of age, whereas behavioral measurements exhibit a slower developmental time course. Not illustrated is the systematic variability in the CSF across infants (Peterzell, Werner, & Kaplan, 1995). Although group functions are smooth in shape, individual functions are not.

What accounts for the development of acuity and contrast sensitivity? Infants who experience visual deprivation early in life due to monocular or binocular cataracts show newborn levels of acuity once the cataract(s) are removed (Maurer & Lewis, 1999), despite being 1 to 9 months of age. Longitudinal follow-up, however, shows

rapid increases in acuity suggesting that visual input is necessary for visual functioning. Beyond knowing that visual input is necessary, the specific causes, anatomical and physiological, of the striking functional deficits observed during the first few months of life are still being debated. Some investigators have proposed that one can explain the low contrast sensitivity and grating acuity of neonates as due to information losses caused by optical and retinal immaturities (Jacobs & Blakemore, 1988; Wilson, 1988, 1993); others have argued that those immaturities are not the whole story (Banks & Bennett, 1988; Banks & Crowell, 1993; Brown, Dobson, & Maier, 1987).

Development of the eye and retina are important factors. Large ocular and retinal changes occur in development and they have profound effects on the ability to see spatial patterns. The eye grows significantly from birth to adolescence, with most growth occurring in the 1st year. The distance from the cornea at the front of the eye to the retina at the back is 16 to 17 mm at birth, 20 to 21 mm at 1 year, and 23 to 25 mm in adolescence and adulthood (Hirano, Yamamoto, Takayama, Sugata, & Matsuo, 1979; Larsen, 1971). Shorter eyes have smaller retinal images. So, for example, a 1-degree target subtends about 200 microns on the newborn’s retina and 300 microns on the adult’s (Banks & Bennett, 1988; Brown et al., 1987; Wilson, 1988). Thus, if newborns had the retinas and visual brains of adults, one would expect their visual acuity to be about two-thirds that of adults simply because they have smaller retinal images to work with.

Another ocular factor relevant to visual sensitivity is the relative transparency of the ocular media. Two aspects of ocular media transmittance are known to change with age: the optical density of the crystalline lens pigment and that of the macular pigment. In both cases, transmittance is slightly higher in the young eye, particularly at short wavelengths (Bone, Landrum, Fernandez, & Martinez, 1988; Werner, 1982). Thus, for a given amount of incident light, the newborn’s eye actually transmits slightly more to the photoreceptors than does the mature eye. This developmental difference ought to favor the newborn compared with the adult, but only slightly.

The ability of the eye to form a sharp retinal image is yet another relevant ocular factor. This ability is typically quantified by the optical transfer function. There have been no measurements of the human neonate’s optical transfer function, but the quality of the retinal image almost certainly surpasses the resolution performance of the young visual system (Banks & Bennett,

1988). Thus, it is commonly assumed that the optical transfer function of the young eye is adultlike (Banks & Crowell, 1993; Wilson, 1988, 1993). Refractive errors or accommodation errors diminish the sharpness of the retinal image and thereby decrease sensitivity to high spatial frequencies (Green & Campbell, 1965). Hyperopic and astigmatic refractive errors are common in infants (Banks, 1980a; Howland, 1982); they tend not to accommodate accurately until 12 weeks (Banks, 1980b; Braddick, Atkinson, French, & Howland, 1979; Haynes, White, & Held, 1965). Nonetheless, it is widely believed that infants' refractive and accommodative errors do not constrain sensitivity or visual acuity significantly (Banks, 1980a, 1980b; Braddick et al., 1979; Howland, 1982).

If optical imperfections do not contribute significantly to the visual deficits observed in young infants, receptor and postreceptor processes must do so. The retina and central visual system all exhibit immaturities at birth (Banks & Salapatek, 1983; Hendrickson, 1993; Hickey & Peduzzi, 1987; Yuodelis & Hendrickson, 1986), but morphological immaturities are evident in the fovea, particularly among the photoreceptors.

The development of the fovea is dramatic in the 1st year of life, but subtle morphological changes continue until at least 4 years of age (Yuodelis & Hendrickson, 1986). The fovea, defined as the part of the retina that contains no rods, is much larger at birth than in adulthood: Its diameter decreases from roughly 5.4 degrees at birth to 2.3 degrees at maturity. Moreover, the individual cells and their arrangements are very different at birth than they will be later on. The newborn's fovea possesses three discernible layers of neurons—the photoreceptors, the neurons of the outer nuclear layer, and the retinal ganglion cells—whereas the mature fovea contains only one layer, which is composed of photoreceptors. The most dramatic histological differences, however, are the sizes and shapes of foveal cones. Neonatal cones have inner segments that are much broader and shorter. The outer segments are distinctly immature, too, being much shorter than their adult counterparts. These shape and size differences render the newborn's foveal cones less sensitive than those of the adult (Banks & Bennett, 1988; Brown et al., 1987).

To estimate the efficiency of the neonate's lattice of foveal cones, Banks and colleagues calculated the ability of the newborn's cones to capture light in the inner segment, funnel it to the outer segment, and produce a

visual signal (Banks & Bennett, 1988; Banks & Crowell, 1993). They concluded that the adult foveal cone lattice is dramatically better at absorbing photons of light and converting them into visual signals. By their calculations, if identical patches of light were presented to newborn and adult eyes, roughly 350 photons would be effectively absorbed in adult foveal cones for every photon absorbed in newborn cones. Similar estimates were obtained by Wilson (1988, 1993). The newborn's fovea is less able to use light entering the eye than is the mature fovea.

The cones of the immature fovea are also more widely spaced than those of the adult (Banks & Bennett, 1988; Banks & Crowell, 1993; Wilson, 1988, 1993). Cone-to-cone separation in the center of the fovea is about 2.3, 1.7, and 0.58 minutes of arc in neonates, 15-month-olds, and adults, respectively. These dimensions impose a physical limit (the so-called Nyquist limit) on the highest spatial frequency that can be resolved without distortion or aliasing (Williams, 1985). From the current estimates of cone spacing, the foveas of newborns, 15-month-olds, and adults should theoretically be unable to resolve gratings with spatial frequencies above 15, 27, and 60 cycles/degree, respectively.

Investigators have calculated the contrast sensitivity and visual acuity losses that ought to be observed if the only difference between the spatial vision of newborns and adults were the eye's optics and the properties of the foveal cones (Banks & Bennett, 1988; Banks & Crowell, 1993; Wilson, 1988, 1993). The expected losses are substantial: Contrast sensitivity to medium and high spatial frequencies is predicted to be as much as 20-fold lower in neonates than in adults. Nonetheless, the observed contrast sensitivity and grating acuity deficits in human newborns are even larger than predicted (e.g., Skoczenski & Aslin, 1995), so this analysis of information losses in the optics and receptors implies that there are other immaturities, presumably among retinal neurons and central visual circuits, that contribute to the observed loss of contrast sensitivity and grating acuity.

Another hypothesis concerning the contrast sensitivity and visual acuity of young infants has been offered. Because of the obvious immaturity of the fovea, perhaps infants use another part of the retina to process points of interest in the visual scene. Cones in the parafoveal and peripheral retina are relatively more mature at birth than their foveal counterparts, but they, too, undergo postnatal development (Hendrickson, 1993). The data, however, do not support this hypothesis: Young infants'

best acuity and contrast sensitivity is obtained with foveal stimulation. Lewis, Maurer, and Kay (1978) found that newborns could best detect a narrow light bar against a dark background when it was presented in central vision, and D. Allen, Tyler, and Norcia (1996) showed that visual evoked potential (VEP) acuity and contrast sensitivity is higher in central than in peripheral vision in 8- to 39-week-olds, by an average factor of 2.3.

An important question that will be pursued vigorously in future research is what factors not considered in the preceding analyses account for the unexplained portion of the contrast sensitivity and grating acuity losses. There are numerous candidates including internal neural noise (such as random addition of action potentials at central sites; Skoczenski & Norcia, 1998), inefficient neural sampling, and poor motivation to respond.

Orientation Sensitivity

Sensitivity to orientation is an important foundation of much of higher level vision, such as perception of edges, patterns, and objects. In monkeys, it is well established that orientation sensitivity is innately present (Wiesel & Hubel, 1974), and in cats orientation sensitivity also appears soon after birth, with or without visual experience (Hubel & Wiesel, 1963). Paradoxically, development of orientation sensitivity has been the topic of numerous learning simulations in recent years (Linsker, 1989; Olshausen & Field, 1996; von der Malsburg, 1973). These results suggest interesting relations between orientation-sensitive cortical units and the statistics of images of natural scenes. Such studies are often interpreted as showing how the visual brain gets “wired up by experience” after birth (e.g., Elman, Bates, Johnson, Karmiloff-Smith, Parisi, & Plunkett, 1996).

Yet the evidence suggests that basic orientation sensitivity in humans, as in monkeys and cats, is present at birth. Some maturation of orientation processing was suggested by visual evoked potential (VEP) studies by Braddick, Atkinson, and Wattam-Bell (1986). Their results showed responses emerging at 2 to 3 weeks for slowly modulated orientation changes (3 reversals/second) and responses at 5 to 6 weeks for more rapid orientation changes. In an elegant analysis, these investigators showed that the pace of these developments was maturational, in that preterm infants of the same gestational age showed patterns of development similar to full-term infants. In other words, gestational age, not weeks of visual experience was crucial.

Direct behavioral tests of orientation sensitivity have revealed evidence that it is innate. Slater, Morison, and Somers (1988) used habituation measures with high-contrast striped patterns. They found dishabituation to changed orientation in situations where other stimulus variables (such as whether a particular screen position was black or white) could be ruled out. Their results were confirmed by Atkinson, Hood, and Wattam-Bell (1988). Orientation sensitivity appears to be innate in humans, although it improves in the early weeks of life.

Pattern Discrimination

Assessing acuity and contrast sensitivity largely involve comparing responses to something versus nothing. The exquisite spatial resolution of vision, however, serves functions beyond mere detection. Encoding and discriminating patterns, surfaces, and objects are key tasks of visual processing. Thus, describing pattern-processing capabilities in infant vision is important. But how can pattern-perception capabilities be assessed in a comprehensive way? As in studies of adult vision, linear systems theory from mathematics and signal processing is useful. Any distribution of luminance (light and dark) in an image can be described, using a 2D Fourier transform, as a set of sinusoidally varying luminance components having particular frequencies and amplitudes, in particular orientations. Because any image can be analyzed in this way, the frequency components form an important characterization of the pattern. If the spatial phase of each component is also encoded, the pattern is completely described. Researchers have made progress characterizing infant pattern discrimination using linear systems concepts. This work has used tests of infants' abilities to distinguish simple, suprathreshold patterns that vary in contrast or in phase.

Sensitivity to contrast differences is typically measured by presenting two sine-wave gratings of the same spatial frequency and orientation but differing contrasts. In experiments with adults, a participant is asked to indicate the grating of higher contrast. The increment in contrast required to make the discrimination varies depending on the common contrasts of the two stimuli; as the common contrast is increased, a successively larger increment is required (Legge & Foley, 1980). Six- to 12-week-old infants require much larger contrast increments than adults when the common contrast is near detection threshold. At high common contrasts, however, infants' discrimination thresholds resemble those

of adults (Brown, 1993; Stephens & Banks, 1987). These findings suggest that infants' ability to distinguish spatial patterns on the basis of contrast differences is poor at low contrast and reasonably good at high contrast. Different explanations for infants' performance in this task have been offered, but none has been confirmed by empirical observation (Brown, 1993; Stephens & Banks, 1987).

Studies have also addressed discrimination based on spatial phase differences. Spatial phase refers to the relative position of the spatial frequency components (the sine-wave gratings) of which the pattern is composed (Piotrowski & Campbell, 1982). Phase information is crucial for the features and relations that are involved in object perception, such as edges, junctions, and shape. Altering phase information in a spatial pattern greatly affects its appearance and perceived identity to adults (Oppenheim & Lim, 1981). In phase discrimination tasks, the subject is asked to distinguish between two patterns—usually gratings—that differ only in the phase relationships among their spatial frequency components. Adults are able to distinguish patterns that differ only slightly in the phases of their components when the stimulus is presented to the fovea (Badcock, 1984). The ability to discriminate phase can fall dramatically, however, when the stimulus is presented in the peripheral visual field (Bennett & Banks, 1987; Rentschler & Treutwein, 1985).

Relatively little work has directly addressed infants' ability to use phase differences to discriminate spatial patterns. Braddick et al. (1986) presented periodic patterns composed of different spatial frequency components. When the components were added in one phase relationship, the resultant was a square-wave grating (a repeating pattern of sharp-edged light and dark stripes); when the components were added in another phase, the resultant appeared to adults to be a very different, more complex pattern. Eight-week-olds were able to discriminate these patterns. Remarkably, however, 4-week-olds seemed unable to make the discrimination.

In a similar vein, Kleiner (1987) and Kleiner and Banks (1987) examined visual preferences for patterns in which the phases of the constituent components were altered. Kleiner and colleagues found that newborns and 8-week-olds exhibit reliable fixation preferences for a schematic face over a rectangle lattice (Fantz & Nevis, 1967). To examine the influence of spatial phase on fixation preference, Kleiner used an image-processing

technique in which the contrasts of the constituent spatial frequencies from one pattern were combined with the phases of the constituent frequencies from the other pattern. The perceptual appearance of these hybrid patterns is most closely associated with the pattern from which the phases rather than the contrasts came (Oppenheim & Lim, 1981; Piotrowski & Campbell, 1982); stated another way, the hybrid pattern that appears most facelike is the one that contains the phases from the original schematic face. Not surprisingly, 8-week-olds preferred to fixate the hybrid that contained the phases of the face and the contrasts of the lattice. Newborns' preferences, however, were for the hybrid that contained the phases of the lattice and the contrasts of the face. One interpretation of this finding is that newborns are relatively insensitive to spatial phase, but other interpretations have been suggested (e.g., Badcock, 1990).

The observation that young infants seem relatively insensitive to variations in spatial phase is extremely important. If valid, it suggests that young infants' ability to discriminate spatial patterns has a significant deficiency that is at least qualitatively similar to the deficiency observed in the peripheral visual field of normal adults (Bennett & Banks, 1987; Rentschler & Treutwein, 1985) and in the central visual field of amblyopic adults (Levi, Klein, & Aitsebaomo, 1985). In functional terms, infants' processing of basic perceptual properties of objects, such as unity, size, shape, texture, and so on depend implicitly on processing of phase information. To the extent that it is poor in the earliest weeks of life, these abilities will be limited. Conversely, tests of certain of these perceptual abilities, to be discussed, indicate striking newborn perceptual competencies (e.g., for seeing object size and faces). One of the challenges of infant vision research is reconciling certain poor sensitivity to basic sensory properties, such as phase, with evidence of higher order abilities, such as face perception. The most likely resolution of the apparent paradox is that infant sensory capacities for properties such as phase and orientation are worse than adults' but not completely lacking, even at birth (for further discussion, see Kellman & Arterberry, 1998).

Color Vision

The term *color* refers to the component of visual experience characterized by the psychological attributes of *brightness*, *hue*, and *saturation*. Two of these—hue and

saturation—are chromatic attributes, and the other—brightness—is actually an achromatic attribute. Hue is primarily correlated with the dominant wavelength of the stimulus whereas brightness is primarily correlated, but not isomorphic, with stimulus intensity. Saturation is correlated with the distribution of wavelengths in a stimulus; stimuli with more broad band light mixed in are seen as less saturated. We refer to visual discriminations on the basis of differences in hue or saturation as *chromatic discriminations* and discriminations on the basis of differences in brightness as *achromatic discriminations*.

The functional importance of perceiving color has been a matter of debate. Humans readily perceive objects and events from nonchromatic displays, such as those in black-and-white movies or television. Why, then, have we evolved elaborate color vision mechanisms? In ordinary seeing, chromatic information probably aids object segmentation and recognition. In cases in which an object and its background are equal or nearly equal in luminance, the object's shape can be perceived from chromatic differences. Chromatic information can also help distinguish one version of an object (a red apple) from another (a green apple). Less well understood, but important, are the obvious contributions of color to our aesthetic experiences.

The human visual system has four types of photoreceptors, one type of rod and three types of cones. The cones are active under daylight viewing conditions and subserve color vision; rods are active under quite dim illumination. We consider only cones in our discussion of color vision.

The three cone types are sensitive to different, but overlapping, bands of wavelength. The cone types are generally called *short-wavelength-sensitive (S)*, *medium-wavelength-sensitive (M)*, and *long-wavelength-sensitive (L)* cones. (We prefer this terminology to the terms *blue*, *green*, and *red* cones because those terms imply that each cone type is responsible for the perception of a particular hue, and this is not the case.) Each type of photoreceptor responds in an untagged fashion; that is, only response quantity, and nothing else, varies with changes in the incident light. The consequences of untagged responding are profound. The output of any single photoreceptor type can be driven to a given level by virtually any wavelength of light simply by adjusting the light's intensity. Thus, information about the wavelength of a stimulus cannot be extracted from the output of a single photoreceptor type. Instead the visual system must use

the relative activities of the three photoreceptor types to distinguish different colors.

The subsequent stages of the visual process must utilize the outputs of the different receptor types in a complex way to produce the conscious experience of color. Psychophysical evidence from adult humans and physiological evidence from adult monkeys indicate that the signals of the three cone types undergo a major transformation in the retina. Signals from two or three kinds of cones are combined additively to form achromatic channels (coding brightness primarily) and are combined subtractively to form two kinds of chromatic channels (coding hue primarily). The subtractive, chromatic channels (red/green and blue/yellow) have been called *opponent processes* because different wavelength bands evoke different directions of neural response.

Many of the characteristics of photoreceptors and subsequent neural stages were originally inferred from adult behavioral studies. Our discussion of color vision centers on two questions:

1. What hues are infants sensitive to and when?
2. What mechanisms account for the development of color vision?

Origins of Hue Discrimination

When can infants discriminate stimuli on the basis of hue alone? Before 1975, a large number of behavioral studies attempted to answer this question, but they all failed to eliminate the possibility that infants were basing their discriminations on brightness cues rather than hue (or saturation) cues (Kessen, Haith, & Salapatek, 1970). To demonstrate convincingly that infants can discriminate on the basis of hue alone, researchers have used two strategies to rule out brightness artifacts. (Elsewhere, we describe in detail the importance and difficulty of separating hue from brightness responses; Kellman & Arterberry, 1998; Kellman & Banks, 1997.)

The methods involve presenting two stimuli differing in hue (e.g., red and green) and looking for a systematic response (e.g., directional eye movement, VEP, or FPL) to one as evidence for hue discrimination. One strategy for eliminating brightness artifacts involves using the spectral sensitivity function to match the brightnesses of two stimuli to a first approximation and then by varying the luminances (a measure of stimulus intensity) of the stimuli unsystematically from trial to trial over a wide-enough range to ensure that one is not always

brighter than the other. Systematic responding by the infant to one of the two chromatic stimuli, across luminances, can therefore not be attributed to discrimination on the basis of brightness. Using this strategy, Oster (1975), and Schaller (1975) demonstrated hue discrimination in 8- and 12-week-old infants, respectively.

The second strategy for eliminating brightness cues was developed by Peeples and Teller (1975); subsequently, many others have used this strategy, so we explain it in some detail. They also used spectral sensitivity data to match approximately the brightnesses of their stimuli. They then varied luminance systematically around the estimate of the brightness match. Several luminances were presented, bridging a 0.8 log unit range in small steps. Consequently, at least one of the luminance pairings must have been equivalent in brightness for each of the infants. Peeples and Teller showed that 8-week-olds could discriminate red from white for all luminance pairings. They concluded that 8-week-olds make true hue discriminations.

Thus, three reports in 1975, using different techniques, provided the first convincing evidence that 8- to 16-week-olds can make chromatic discriminations. Today, the story has been further refined: M and L cones appear to function by 8 weeks of age and possibly as early as 4 weeks (e.g., Bieber, Knoblauch, & Werner, 1998; Kelly, Borchert, & Teller, 1997); however, S cone functionality does not appear to emerge until at least 3 to 4 months of age (e.g., Cognale, Kelly, Weiss, & Teller, 1998; Sutte, Banks, & Graf, 2002). At birth, infants may have very limited color experience, and during the first 4 months of life their world becomes increasingly filled with color. And by 4 months, infants have color preferences that mirror adults: Saturated colors (such as royal blue) are preferred over less saturated colors (such as pale blue; Bornstein, 1975).

Assessing Color Vision

Three sorts of hue discriminations—Rayleigh, tritan, and neutral-point—are particularly interesting theoretically, and research on infants' ability to make these discriminations fills out the picture of early competencies and deficits.

The *neutral-point test* is based on the observation that color-normal adults are able to distinguish all spectral (single wavelength) lights from white; that is, they do not exhibit a neutral point in such a comparison. Peeples and Teller (1975) and Teller, Peeples, and Sekel (1978)

used a neutral-point test to examine 8-week-olds' color vision. They examined both white-on-white luminance discrimination and discrimination of chromatic targets from white. The colors of the test targets and background are represented in Figure 3.3, which is a chromaticity diagram. Eight-week-olds discriminated many colors from white: red, orange, some greens, blue, and some purples; these colors are represented by the filled

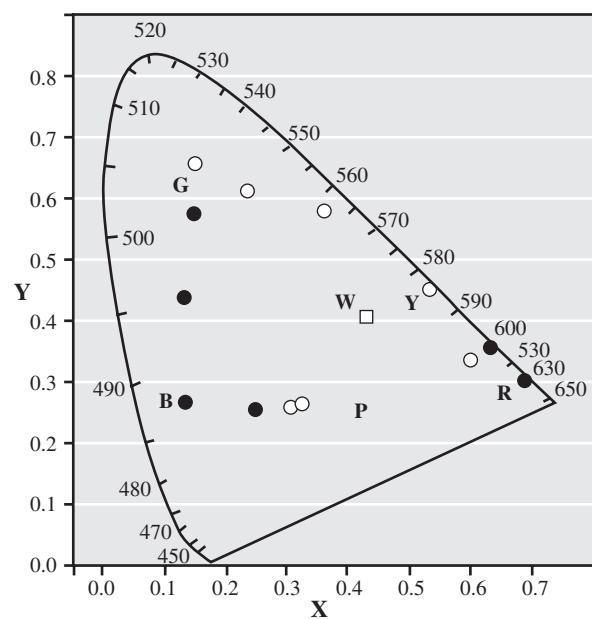

Figure 3.3 The stimuli used in neutral-point experiments. Participants in both experiments were 8-week-old infants. The format of the figure is the CIE Chromaticity diagram, which allows one to plot chromatic stimuli differing in hue and saturation. Saturated colors are represented at the exterior of the diagram, and unsaturated colors toward the middle. The right corner of the diagram (around 650) represents a hue of red, the top of the diagram represents a hue of bluish-green (labeled 520) and the lower left corner represents a hue of violet (near 400). Each circular symbol represents a color that was presented to infants in these two experiments. Open symbols represent hues that all infants failed to discriminate from white (W). Half-filled symbols represent hues that some, but not all, infants discriminated from white. Filled symbols represent hues that all infants reliably discriminated from white. Sources: "Color Vision and Brightness Discrimination in Human Infants," by D. R. Peeples and D. Y. Teller, 1975, *Science*, 189, pp. 1102–1103. Reprinted with permission and "Discrimination of Chromatic from White Light by 2-Month-Old Human Infants," by D. Y. Teller, D. R. Peeples, and M. Sekel, 1978, *Vision Research*, 18, pp. 41–48. Reprinted with permission.

symbols in the figure. Eight-week-olds did not discriminate yellow, yellow-green, one green, and some purples from white; these are represented by the open symbols in the figure. Thus, 8-week-old infants seemed to exhibit a neutral zone running from short wavelengths to yellow and green, resulting from deficient S cones (in color parlance, they have tritanopia or tritanomalous trichromacy; Teller et al., 1978). Later, Adams, Courage, and Mercer (1994) reported that the majority of newborns were able to discriminate broadband red from white and the majority were unable to discriminate blue, green, and yellow from white. These results are quite similar to the 8-week results reported by Teller et al. (1978).

A *tritan test* is designed to assess the function of S cones. By presenting two lights that activate M and L cones equally, the test isolates the S cones. Varner, Cook, Schneck, McDonald, and Teller (1985) asked whether 4- to 8-week infants could distinguish two such lights. Specifically, they presented violet targets in a green background. Eight-week-olds distinguished the two lights at all luminances, so they do not appear to have an S-cone deficiency. Four-week-olds, on the other hand, did not discriminate the two lights reliably, suggesting that they have an S-cone defect. D. Allen, Banks, and Schefrin (1988) and Clavadetscher, Brown, Ankrum, and Teller (1988) confirmed this finding: In their experiment, 3- to 4-week-olds could not distinguish a violet target on a green background, but 7- to 8-week-olds could. More recently, Teller, Brooks, and Palmer (1997) found that tritan stimuli did not drive directionally appropriate eye movements even at 16 weeks of age.

Rayleigh discrimination tests involve distinguishing brightness-matched, long-wavelength lights such as red and green. They are diagnostically important because adults with the most common color defects—deutanopia (lacking M cones) and protanopia (lacking L cones)—are unable to make such discriminations. Hamer, Alexander, Teller (1982) and Packer, Hartmann, and Teller (1984) examined the ability of 4-, 8-, and 12-week-olds to make Rayleigh discriminations. Either a green or red target was presented at one of a variety of luminances on a yellow background. Most 8-week-olds and essentially all 12-week-olds made these discriminations reliably, providing clear evidence that most infants do not exhibit deutan or protan defects by 8 weeks of age. In contrast, the majority of 4-week-olds did not exhibit the ability to make either discrimination. Packer et al. (1984) also found a significant effect of target size.

Twelve-week-olds were able to make Rayleigh discriminations with 4- and 8-degree targets, but not 1- and 2-degree targets. D. Allen et al. (1988) and Clavadetscher et al. (1988) confirmed the Rayleigh discrimination finding. They reported that 3- to 4-week-olds could not distinguish a red target on a green background; 7- to 8-week-olds could make this discrimination reliably.

In sum, there is little evidence that the majority of infants 4 weeks of age or younger make hue discriminations with the exception of discriminating red from white. The paucity of positive evidence is consistent with the hypothesis that human neonates are generally color deficient. By 4 months of age, infant color vision abilities approximate adult abilities, although there continue to be differences between infants' and adults' chromatic profiles throughout the 1st year of life (Cronin-Golomb et al., 1998). We now turn to the question of what mechanism(s) underlie this development.

How Does Early Color Vision Develop?

Two explanations have been proposed to account for young infants' hue discrimination failures. One possibility is the absence or immaturity of different cone types or immaturities among postreceptor chromatic channels. Banks and Bennett (1988) have called this the *chromatic deficiency hypothesis*. There is, however, another possibility, raised initially by Banks and Bennett (1988) and elaborated by Brown (1990), Banks and Shannon (1993), Teller and Lindsey (1993), and D. Allen, Banks, and Norcia (1993). Perhaps neonates have a full complement of functional cone types and the requisite neural machinery to preserve and compare their signals, but overall visual sensitivity is so poor that it does not allow them to demonstrate their chromatic capabilities. On this account, older infants may exhibit reliable chromatic discrimination because of increased visual sensitivity. In this context, visual sensitivity might include discrimination performance of a visual system limited by optical and photoreceptor properties plus a general postreceptor loss. This hypothesis has been called the *visual efficiency hypothesis* (D. Allen et al., 1993) and the *uniform loss hypothesis* (Teller & Lindsey, 1993).

There is an interesting way to compare the chromatic efficiency and visual efficiency explanations experimentally. Consider measurements of hue discrimination threshold (e.g., the chromatic contrast required to mediate the discrimination of two lights of equal brightness

but different wavelength compositions—the “chromatic threshold”) and a brightness discrimination threshold (e.g., the luminance contrast required to mediate the discrimination of two lights of the same wavelength composition but different luminances—the “luminance threshold”). The chromatic deficiency hypothesis predicts that the ratio of luminance threshold divided by chromatic threshold will decrease with increasing age. That is, luminance and chromatic thresholds may both improve with age, but chromatic thresholds change more. The visual efficiency or uniform loss hypothesis predicts that the ratio of luminance threshold divided by chromatic threshold is constant with age. That is, luminance and chromatic thresholds decrease at the same rates with increasing age because they are both limited by a common factor such as overall visual sensitivity. Banks and Bennett (1988) and Banks and Shannon (1993) showed that this hypothesis can in fact account for the poor Rayleigh and neutral-point discriminations of neonates.

Other investigators have tested the chromatic deficiency and visual efficiency hypotheses empirically, but no clear consensus has yet emerged. The challenge has been to develop paradigms in which infants' sensitivity can be made high enough to distinguish the predictions of the two hypotheses. In particular, recent work has focused on determining which hypothesis provides a better account of young infants' ability to use M and L cones to make Rayleigh discriminations (e.g., Adams & Courage, 2002; D. Allen et al., 1993, 1988; Clavadetscher et al., 1988; Morrone, Burr, & Fiorentini, 1993; Teller & Lindsey, 1993; Teller & Palmer, 1996; Varner et al., 1985). On balance, the discrimination failures observed with the youngest children and, for small targets, with older children do not necessarily imply deficiencies among chromatic mechanisms per se. Rather the ratio of chromatic divided by luminance sensitivity may well remain constant across age, suggesting that neonates' apparent inability to make Rayleigh and neutral-point discriminations is caused by an overall loss in visual efficiency. The predictions of the visual efficiency hypothesis, however, are inconsistent with the tritan discriminations. Therefore, young infants may in fact possess some form of color anomaly involving a deficiency among S cones.

Future work will be needed to illuminate infants' loss of visual efficiency and/or deficiency in S cones. Researchers are also taking an interest in the difference between processing moving versus static chromatic

stimuli, which has implications for the relative involvement and development of the magnocellular and parvocellular pathways, which are responsible for spatial and temporal locations of chromatic changes and color identity, respectively (e.g., Dobkins & Anderson, 2002; Dobkins, Anderson, & Kelly, 2001; Dobkins, Lia, & Teller, 1997; Teller, 1998; Thomasson & Teller, 2000).

Motion Perception

Moving and perceiving are deeply linked. Many of the most significant features of an environment to be perceived are moving objects and the events in which they participate. Motion of the observer is also crucial, in two ways. To locomote safely through space requires that our visual system be structured to deal with continuously changing views of the environment. Moreover, information given by transforming views of the world turn out to be a rich indicator not only of events but of persisting properties of the world, such as spatial layout (J. Gibson, 1966, 1979; Johansson, 1970). Later, in discussing space perception, we consider ways in which motions of objects and observers offer high-fidelity information about spatial layout and object form.

Early research on infant visual motion perception showed that motion strongly attracts infant attention (Fantz & Nevis, 1967; Haith, 1983; Kremenitzer, Vaughan, Kurtzberg, & Dowling, 1979; White, Castle, & Held, 1964). Progress has been made in analyzing the limits and probable mechanisms of motion sensitivity, including directional sensitivity, velocity sensitivity, and perception of motion and stability.

Directional Selectivity

The ability to detect motion direction is one of the most basic and important perceptual capacities, but its development has been poorly understood until the last decade or so. Using both behavioral and visual evoked potential (VEP) measures, Wattam-Bell (1991, 1992) tested directional sensitivity in longitudinal studies. In the VEP studies, it was expected that if infants detected direction reversals in an oscillating checkerboard pattern, a measurable electrical response should be found at the frequency of the stimulus reversals. Reliable VEPs were first found at a median age of 74 days for 5 degrees/second patterns and 90 days for 20 degree/second patterns. Behavioral studies (Wattam-Bell, 1992) employed a different type of display. In one condition, an array of randomly changing dots was shown in which appeared a

vertical strip of coherently (vertically) moving dots. In another condition, the vertical motion was shown against a background having opposite direction motion. A visual preference paradigm was used in which the target display appeared adjacent to a control display having random or uniform motion. If an infant detected the vertical target strip having unique, coherent motion, the infant was expected to look longer at this display. The element displacement per frame was manipulated to find the greatest displacement that supported motion detection (d_{\max}). This measure was found to increase markedly from 8 to 15 weeks of age. The younger infants (8 to 11 weeks) could tolerate only about a .25 degree of visual angle displacement (frame duration was 20 millisecond), whereas 14 to 15-week-olds showed a d_{\max} of about .65. (The value for adults is about 2 degrees in this task.)

Poor performance in the earliest weeks may be due to a lack of motion detectors sensitive to high velocities, that is, large displacements in short time intervals. This interpretation is supported by additional data that showed an increase in d_{\max} when the temporal interval between frames was lengthened (Wattam-Bell, 1992).

Velocity Sensitivity

Human adults perceive motion over a great range of velocities. Under optimal conditions, a motion as slow as 1 to 2 minutes of visual angle per second may be detected as motion, as may faster motions up to 15 to 30 degrees/second, at which blurring or streaking occurs (Kaufman, 1974). Estimates of the slowest velocity to which infants respond have varied. Volkmann and Dobson (1976) used checkerboard patterns (check size = 5.5 degrees) and found a moving display was clearly preferred to a stationary one by 2- and 3-month-olds for a velocity as slow as 2 degrees/second. One-month-olds showed a weaker preference. Using rotary motion displays, Kaufmann, Stucki, and Kaufmann-Hayoz (1985) estimated thresholds at about 1.4 degrees/second at 1 month and 0.93 degrees/second at 3 months, also using a visual preference technique.

Later studies designed to distinguish various possible mechanisms by which moving patterns might be detected have yielded higher threshold estimates. Danenmiller and Freedland (1989), using unidirectional linear motion of a single bar, found no reliable motion preferences at 8 weeks. They estimated thresholds at about 5 degrees/second for 16-week-olds and about 2.3 degrees/second for 20-week-olds. For vertically moving

gratings, Aslin and Shea (1990) found velocity thresholds of about 9 degrees/second at 6 weeks dropping to 4 degrees/second at 12 weeks. Thresholds for detecting a difference between two velocities were studied by Danenmiller and Freedland (1991) using paired displays with horizontal bars oscillating at different rates; their 20-month-old subjects distinguished bars moving at 3.3 degrees/second from 2.0 degrees/second, but not from 2.5 degrees/second.

Much lower thresholds for motion detection were obtained by von Hofsten, Kellman, and Putaansuu (1992). In habituation studies of observer-contingent motion with 14-week-olds, von Hofsten et al. found sensitivity to a differential velocity of .32 degrees/second but not .16 degrees/second. Infants were also found to be sensitive to the relation of the motion direction to their own motion. Higher sensitivity in this paradigm might have two explanations. It is possible that visual preference paradigms underestimate infant capacities. As is true in general with preference measures, infants might detect a difference (e.g., between moving and stationary patterns) but have no differential interest or attention to the two displays. A second possibility is that the key difference relates to observer motion contingency in the von Hofsten et al. study. It is plausible that small, observer-contingent motions are processed by the motion perspective system as specifiers of object depth, rather than as moving objects. Thus, a depth-from-motion system may have greater sensitivity than a motion detection system, and the former might be engaged only by observer movement (von Hofsten et al., 1992).

Mechanisms for Processing Moving Patterns: Velocity, Flicker, and Position

A moving stimulus may be characterized in different ways. Similarly, a response to a moving stimulus may be based on more than one kind of mechanism. Consider a vertical sine-wave grating drifting horizontally. Each edge moves at a certain velocity. At a given point, alternating dark and light areas will pass at a certain rate, presenting a temporal frequency of modulation or flicker rate. This flicker rate depends both on the velocity of the pattern and on its spatial frequency (cycles per degree). Now consider preferential attention to such a stimulus over a nonmoving grating or a blank field. The preference could be based on a direction-sensitive mechanism, a velocity-sensitive mechanism, or a flicker-sensitive mechanism. Sustained flicker could be avoided by use of a single object in motion as opposed to

a repetitive pattern, but then the possibility arises that the motion could be detected by noting the change in position of some unique object feature, that is, a position-sensitive mechanism may operate. Some research on motion sensitivity has aimed to separate these possibilities experimentally.

Perhaps the first effort to disentangle velocity-sensitive, position-sensitive, and flicker-sensitive mechanisms was carried out by Freedland and Dannemiller (1987). Several combinations of temporal frequency and spatial displacement were presented with random black and white checkerboard displays. Infants' preferences were affected by both of these factors and were not a simple function of velocity. The role of flicker could not be directly assessed in these experiments. Sensitivity to flicker versus velocity was examined by Aslin and Shea (1990) with vertically moving, square-wave gratings. Various combinations of spatial frequency and velocity were used to vary flicker independent of velocity. For example, the flicker rate (temporal frequency) at any point in the display remains constant if spatial frequency is doubled and velocity is cut in half. Aslin and Shea (1990) found that velocity, not flicker, determines preferences in infants 6 and 12 weeks of age. Converging evidence for velocity-sensitive mechanisms was reported by Dannemiller and Freedland (1991). By using a display with motion of a single bar flanked by stationary reference bars, they excluded ongoing flicker in any spatial position. Moreover, manipulating extent of displacement allowed them to test the possibility that infants' responses were determined by the extent of positional displacement. Results were consistent with velocity-sensitive mechanisms.

Perceiving Motion and Stability

Perceiving moving objects is inextricably tied to its converse: perceiving nonmoving objects and surfaces as stationary. The latter ability is less straightforward than it might at first appear. Neural models of motion detectors suggest that these should respond to image features, such as edges, that change position on the retina over time. Yet such retinal displacement occurs in perfectly stationary environments whenever perceivers make eye, head, or body movements. Perception of objects remaining at rest during observer motion, called *position constancy*, requires use of information beyond that available to individual motion-sensing units. Such information might involve comparison of retinal changes with those ex-

pected from self-produced movements (von Holst, 1954; Wallach, 1987) or more global relationships among optical changes occurring at a given time (Duncker, 1929; J. Gibson, 1966).

In the case of passive (non-self-produced) observer motion, relations in optic flow or some contribution from the vestibular system must be used in perceiving a stable world. There is some indication that young infants show position constancy under such conditions. Later, we mention work in object perception (Kellman, Gleitman, & Spelke, 1987) suggesting that moving infants discriminate moving from stationary objects and perceive object unity only from real object motion. More direct studies of position constancy and motion perception by moving observers have also been carried out (Kellman & von Hofsten, 1992). In these studies, infants were moved laterally while viewing an array of objects. On each trial, one object in the array, either on the left or right, moved while others remained stationary. The object motion was parallel to the observer's motion. Whether the optical change given to the observer in this situation comes from a moving or stationary object depends on the object's distance. Thus, a stationary object placed on the opposite side of the array at a different distance matched the optical displacement of the moving object. Infants were expected to look more at the moving object if its motion was detected. Both 8- and 16-week-olds showed this pattern when the object and observer motions were opposite in phase, but only 16-week-olds appeared to detect the motion when object and observer moved in phase (Kellman & von Hofsten, 1992). It is not clear why the younger infants showed detection of the moving object only in the opposite phase condition. Further study indicated that motion detection was eliminated in monocular viewing. It appears that some ability to distinguish moving and stationary objects during observer motion is in place as early as 8 weeks of age and that binocular convergence may provide the distance information needed in this task (Kellman & von Hofsten, 1992).

SPACE PERCEPTION

In considering how we obtain knowledge through perception, the philosopher Kant (1781/1902) concluded that the mind must contain built-in (*a priori*) categories of

space and time into which experience is organized. Psychologically, understanding the origins and development of spatial perception has more nuances. Whether we approach perception from the perspective of the philosopher, cognitive scientist, psychologist, or engineer, however, we will rediscover Kant's insight that space is fundamental. Our earlier treatment of basic spatial vision set out the sensory limitations—in acuity, contrast sensitivity, and sensitivity to pattern variation—that constrain the pickup of information. As we explore space perception here, our main concern is the acquisition of knowledge of positions and arrangements of objects and surfaces in the three-dimensional environment.

Theoretical controversy about the development of visual space perception has centered on depth perception. When we examine the human visual apparatus, it is relatively easy to see how we acquire information about two of three spatial dimensions. The optics of the eye ensure, to a high degree, that light originating from points in different directions from the observer will be mapped onto distinct points on the retina. The result is a map that preserves information about adjacency in two spatial dimensions (up-down and left-right). The apparent problem lies in the third (depth) dimension. Nothing in this map immediately indicates how far a ray of light has traveled to get from an object to the eye.

Traditionally, it has most often been claimed that perception of three-dimensional (3D) space is a product of learning (Berkeley, 1709/1963; Helmholtz, 1885/1925). Before the invention of methods to study infants' perception, the basis for this view was the logical problem of recovering three dimensions from a projection of the world onto a surface of two dimensions (the retina). Learning might overcome the limitation through the associating and storing of sensations of vision and touch, allowing relevant information about tactile correlates of visual sensations; these in turn could be retrieved when familiar visual input recurred (Berkeley, 1709/1963; Helmholtz, 1885/1925; Titchener, 1910). Piaget went a step further in arguing that self-initiated action and its consequences provide the necessary learning.

Modern analyses of the information available for vision have raised a radically different possibility for the origins of spatial perception. Transforming optical input given to a moving organism carries information specific to the particular 3D layout (J. Gibson, 1966, 1979; Johansson, 1970), and humans and animals may well have

evolved mechanisms to extract such information. On this *ecological* view of development (E. Gibson, 1979; Shepard, 1984), the rudiments of 3D perception might be present even in the newborn, and their refinement might depend on sensory maturation and attentional skill, rather than on associative learning.

Research on spatial perception has gone a considerable distance toward answering this question of the constructivist versus ecological origins of the third dimension. Moreover, the emerging picture of early abilities provides important insights about functionally distinct classes of information and their neurophysiological underpinnings. Anticipating some of these distinctions, we divide spatial perception abilities into four categories: kinematic, oculomotor, stereoscopic, and pictorial. The classification reflects both differences in the nature of information and in the perceptual mechanisms at work in extracting information (Kellman, 1995; Kellman & Arterberry, 1998; Yonas & Owsley, 1987).

Kinematic Information

For guiding action and furnishing information about the 3D environment, kinematic or motion-carried information may be the most important class of visual information for adult humans. One reason for its centrality is that it overcomes the ambiguity problems present with some other kinds of information, such as pictorial cues to depth. A stationary image given to one eye may be a cuddly kitten or a gigantic tiger further off, as Berkeley noted, or even a flat, 2D cutout of a cat or tiger. To the moving observer, the transforming optic array reveals whether the object is planar or 3D and furnishes information about relative distance and size. The mapping between the optical transformations and the 3D scene is governed by projective geometry, and under reasonable constraints, it allows recovery of many properties of the layout (Koenderink, 1986; Lee, 1974; Ullman, 1979). Among the residual ambiguities is a problem analogous to the one Berkeley raised about a single image. If objects and surfaces in the scene *deform* (alter their shapes) contingent on the observer's motion, a unique 3D scene is not recoverable. Now the problem is recovering four dimensions (spatial layout plus change over time) from three (two spatial dimensions of the input plus time). In ordinary perception, simulation of the exact projective changes consistent with a particular, but not present, layout, would almost never occur by chance.

It does, however, make possible the realistic depiction of 3D space in television, motion pictures, and in virtual reality setups. Because kinematic information about space depends on geometry, not on knowledge of what particular spatial layouts exist in the world, it is imaginable that perceptual mechanisms have evolved to make use of it. An additional reason to suspect that sensitivity to this kind of information might appear early is that early learning about the environment may be optimized by relying on sources of information that are most accurate (Kellman, 1993; Kellman & Arterberry, 1998). On the other hand, adults acquire much kinematic information from their own movements through the environment. The human infant does not self-locomote until the second half-year of life although kinematic information could still be made available from moving objects, from the infant being carried through the environment, or from self-produced head movements.

Motion-carried or kinematic information is often divided into subcategories, of which we consider three. Relative depths of surfaces can be specified by *accretion/deletion of texture*. Relative motion between an object and observer may be given by *optical expansion/contraction*. Relative depth, and under some conditions perhaps metric information about distance, can be provided by *motion parallax* or *motion perspective*. Another important kinematically based spatial ability, recovery of object shape from transforming optical projections (*structure-from-motion*), is discussed in connection with object perception.

Accretion/Deletion of Texture

In the late 1960s, Kaplan, Gibson, and their colleagues discovered a new kind of depth information, a striking achievement given that depth perception had at that point been systematically studied for over 200 years (J. Gibson, Kaplan, Reynolds, & Wheeler, 1969; Kaplan, 1969). Most surfaces have visible texture—variations of luminance and color across their surfaces. The new type of depth information involves what happens to visible points of texture (texture elements) when an observer or object moves. When the observer moves while viewing a nearer and more distant object, the elements on the nearer surface remain visible whereas those on the more distant surface gradually pass out of sight along one side (deletion) of the nearer object and come into view along the other side (accretion). The same kind of transformation occurs when the motion is given by a moving object instead of a moving observer. This kind of information

has been shown to be used in adult visual perception, to establish both depth order and shape, even when no other sources of information are available (Andersen & Cortese, 1989; Kaplan, 1969; Shipley & Kellman, 1994).

Infants' shape perception from accretion/deletion of texture was studied by Kaufmann-Hayoz, Kaufman, and Stucki (1986). They habituated 3-month-olds to one shape specified by accretion/deletion and tested recovery from habituation to the same and a novel shape. Infants dishabituated more to the novel shape. Although this result suggests that accretion/deletion specifies edges and shape at 3 months, we cannot tell much about perceived depth order from this study. That accretion/deletion specifies depth order at 5 to 7 months is suggested by a different study (Granrud, Yonas, et al., 1985). These investigators assumed that infants would reach preferentially to a surface perceived as nearer than another. Computer generated, random dot, kinematic displays were shown in which a vertical boundary was specified by only accretion/deletion information. Infants of 5 and 7 months of age were tested, and both groups showed modestly greater reaching to areas specified as nearer by accretion/deletion than to areas specified as farther. More recently Johnson and Mason (2002) provided evidence that 2-month-olds are able to use accretion/deletion of texture for perceiving depth relations.

Craton and Yonas (1990) suggested that ordinary accretion/deletion displays actually contain two kinds of information. In addition to the disappearance and appearance of texture elements, there are relationships of individual elements to the location of the boundary between surfaces. A visible element on one side of a boundary remains in a fixed relation to it, whereas an element on the other side (the more distant surface) changes its separation from the boundary over time. This separate information, termed *boundary flow*, appears to be usable by adults in the absence of element accretion/deletion (Craton & Yonas, 1990) and possibly by 5-month-old infants (Craton & Yonas, 1988).

Optical Expansion/Contraction

When an object approaches an observer on a collision course, its optical projection expands symmetrically. It can be shown mathematically that a ratio of an object point's retinal eccentricity and its retinal velocity gives its *time to contact*, that is, the time until it will hit the observer. Newborns of other species show defensive responses to this kind of information (Schiff, 1965).

When presented with optical expansion patterns, human infants of 1 to 2 months of age were reported to retract their heads, raise their arms, and blink (Ball & Tronick, 1971; Bower, Broughton, & Moore, 1970). Not all of these responses, however, may indicate perception of an approaching object (Yonas et al., 1977). Head movement may result from infants tracking visually the top contour of the pattern, and relatively undifferentiated motor behavior may cause the arms to rise in concert. Yonas et al. tested this hypothesis using a display in which only the top contour moved. This optical change is not consistent with approach of an object. Infants from 1 to 4 months displayed similar head and arm movements to this new display as to an optical expansion display. The result supports the hypothesis that tracking the top contour, rather than defensive responding, accounts for the behavior infants show to expansion displays.

It turns out, however, that both the tracking hypothesis and the hypothesis of defensive responding appear to be correct. When eye blink was used as the dependent measure, reliably more responding was observed to the approach display than to the moving top contour display. It appears that blinking may best access infant perception of object approach and does so reliably from about 1 month of age (Nanez, 1988; Nanez & Yonas, 1994; Yonas, 1981; Yonas, Pettersen, & Lockman, 1979).

Motion Perspective

Motion perspective is an important source of spatial layout information. When an observer moves and looks perpendicular to the movement direction, the visual direction of a nearer object changes at a faster velocity than that of a more distant object. Comparing two such objects or points defines the classical depth cue of motion parallax. J. Gibson (1950, 1966) argued that perceptual systems might use relative velocities of many points, that is, gradients of relative motion provide more information than a pair of points. To express this concept, he coined the term *motion perspective*. Some experimental evidence indicates that gradients are in fact used by human perceivers (e.g., E. Gibson, Gibson, Smith, & Flock, 1959).

Motion perspective is virtually always available to a moving observer in a lighted environment, and it ordinarily provides unambiguous indication of depth order. Given these considerations, one might expect that neural mechanisms have evolved to exploit this kind of information, and that accordingly, it might appear early in development. Several investigators have suggested that it

functions quite early, but these suggestions have been based on indirect evidence (Walk & Gibson, 1961; Yonas & Owsley, 1987). Walk and Gibson (1961) studied newborns of various species on the visual cliff and noted that some species made lateral head movements before choosing the "shallow" side of the cliff over the "deep" side. It is difficult to make a similar inference about human infants, because they do not self-locomote until around 6 months of age.

Some results relevant to the development of motion perspective in 4-month-old infants were reported by von Hofsten et al. (1992). Infants moved back and forth while viewing an array of three vertical bars. The middle bar was moved in concert with the infant's chair, giving it an optical displacement that would have been consistent with a stationary rod placed somewhat further away. If motion perspective operates, the observer contingent motion should indicate that the middle rod is furthest from the subject (see Figure 3.4). After habituation to such an array, moving infants looked more at a stationary array consisting of three aligned, stationary rods than to another stationary array with the middle rod 15 cm further away than the others. (The latter display produced identical motion perspective as the habituation display.) Two other experiments showed that the effect disappeared if the contingent motion was reduced from the original .32 degrees/second to .16 degrees/second and that infants were sensitive to the contingency between the optical changes and their own movement. These results are consistent with infants' early use of motion perspective. They might also be explained, however, by infants responding to particular optical changes and the contingency of these optical changes on the observer's movement. The results do not include any test to verify that the optical changes were taken to indicate depth. An interesting possibility is that the perceptual process that uses motion perspective to assign depth is far more sensitive to optical displacement than processes used to see moving objects.

Stereoscopic Depth Perception

Stereoscopic depth perception refers to the use of differences in the optical projections at the two retinas to determine depth. This ability is among the most precise in adult visual perception. Under optimal conditions, an adult observer may detect depth when the angular difference in a viewed point's location at the two eyes

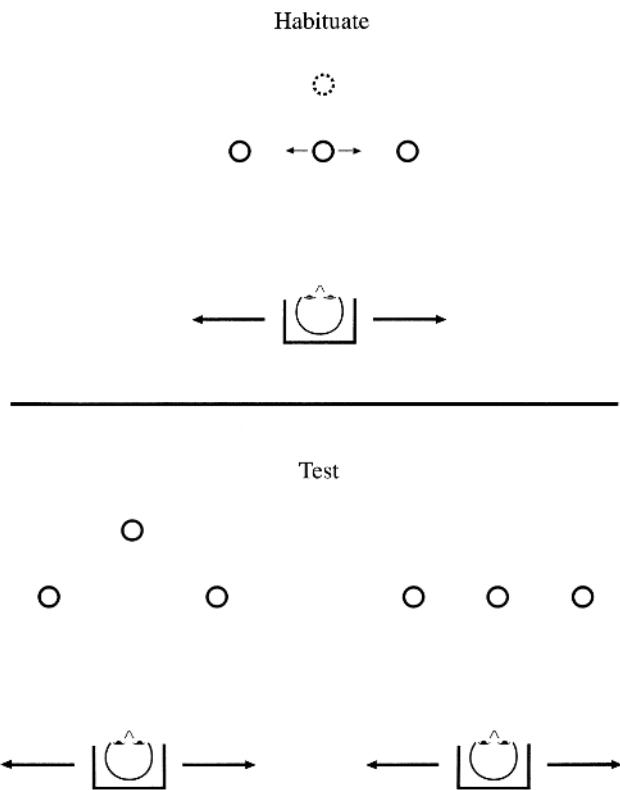

Figure 3.4 Top views of displays used in motion parallax experiment. *Top:* Moving observers were habituated to a linear array of rods in which the center rod moved in phase with the observer. The dotted line indicates the virtual object specified by motion parallax. *Bottom:* The two test arrays pictured were shown after habituation. *Source:* “Young Infants’ Sensitivity to Motion Parallax,” by C. von Hofsten, P. Kellman, and J. Putaansuu, 1992, *Infant Behavior and Development*, 15(2), pp. 245–264. Reprinted with permission.

(binocular disparity) is only 5 to 15 seconds of arc (Westheimer & McKee, 1980). A 5-second disparity would translate into detection of a 1.4 mm depth difference between two objects at a distance of one meter. We can distinguish two types of binocular disparity, *crossed* and *uncrossed*. A prerequisite for precise computation of disparity between the two eyes is fixation by the two eyes on a common environmental point. We can measure the disparities of other imaged points by comparison to this zero disparity fixation point. Other points at roughly the same distance from the observer as the fixated point will project to corresponding retinal locations, that is, having the same angular separation and direction from the fovea on each of the two eyes. Points

more distant than the fixation point will have *uncrossed disparity*. The visual direction of such a point will be more to the left in the visual field of the left eye than in the right eye. *Crossed disparity* characterizes points nearer than the fixated point. The visual direction of these points will be more leftward in the right eye than in the left.

Observations from other species suggest the existence of innate brain mechanisms subserving stereoscopic depth perception, specifically, cortical cells tuned to particular disparities at birth or soon after (Hubel & Wiesel, 1970; Pettigrew, 1974; Ramachandran, Clarke, & Whitteridge, 1977). Such single-cell recording studies are not possible in human infants; moreover, they do not directly address functional operation of stereoscopic depth perception. Evidence about human infants comes mostly from behavioral studies and suggests that stereoscopic depth perception arises around 4 months of age as a result of maturational processes.

A number of studies have used stationary displays and preferential looking as the dependent variable. One of two adjacently presented displays contains binocular disparities that might specify depth differences within the pattern. Infants are expected to look longer at a display containing detectable depth differences than at a similar one having no depth variation (Atkinson & Braddick, 1976; Held, Birch, & Gwiazda, 1980). A different method eliminates any possible monocular cues. Using random dot kinematograms, Fox, Aslin, Shea, and Dumais (1980) presented disparity information that would, if detected, specify a moving square. Using the forced-choice preferential looking method, adult observers judged the direction of motion on each trial solely by watching the infant’s responses.

Estimates of the age of onset of disparity sensitivity from these methods show reasonable agreement. In longitudinal studies by Held and his colleagues (Birch, Gwiazda, & Held, 1982; Held et al., 1980), reliable preferences for a vertical grating pattern with disparity variation appeared at 12 weeks for crossed disparities and 17 weeks for uncrossed. Fox et al. (1980) found that 3- to 5-month-olds reliably oriented to a moving square specified by disparity, but infants younger than 3 months did not. Petrig, Julesz, Kropfl, and Baumgartner (1981) found a similar onset of sensitivity using recordings of visual evoked potentials.

A thorny issue in the interpretation of these studies is whether the observed behavioral responses index depth

perception from binocular disparity or merely sensitivity to disparity itself. It is hard to settle this issue with certainty; however, some observations suggest that depth is perceived. Held et al. (1980), for example, found that infants who showed clear preferences for vertical line displays containing horizontal disparity showed no such preferences when the displays were rotated 90 degrees to give 34 minutes of vertical disparity (a condition that produces rivalry for adults). Fox et al. (1980) observed that infants did not track a moving object specified by very large disparities that do not signal depth to adults. They found instead that infants reliably looked away from such displays. This result is double-edged: Although it shows different reactions by infants to different magnitudes of disparity as might be expected if only some disparities produce perceived depth, it also shows that disparities *per se* can affect infants' fixation. From these studies, it is plausible but not certain that infants' responses in these studies indicate functional stereoscopic depth perception. Other studies have shown that disparity-sensitive infants outperform disparity-insensitive infants on tasks involving depth and three-dimensional shape perception (Granrud, 1986; Yonas, Arterberry, & Granrud, 1987a).

What mechanisms are responsible for the onset of stereoscopic sensitivity after several months of life? An argument for maturational causes is that sensitivity very quickly attains adultlike precision. Held et al. (1980) reported that thresholds change over 3 to 4 weeks from greater than 60 minutes to less than 1 minute of disparity, with the latter measured value limited by the apparatus; even so, this value is comparable to adult sensitivity under some conditions.

What mechanisms might be maturing at this time? One possibility is that disparity-sensitive cortical cells are coming online. Another is that improvements in the mechanisms of convergence or visual acuity that are prerequisites to fine stereopsis might explain the observed onset of disparity sensitivity. Some evidence suggests that the onset of stereopsis is not dependent on improvements in visual acuity (grating acuity). When both acuity and disparity sensitivity are measured longitudinally in the same infants, little or no change in grating acuity is found during the period in which stereopsis appears (Held, 1993). A different method pointing toward the same conclusion comes from a study by Westheimer and McKee (1980). Adults were given artificially reduced acuity and contrast sensitivity designed

to approximate those present at 2 months of age. Under these conditions, stereoacuity was reduced substantially, but not sufficiently to explain infants' inability to respond to large disparities before 3 to 4 months of age. Developmental changes in convergence also appear unlikely to explain the onset of stereoacuity. Evidence on the development of convergence (Hainline, Riddell, Grose-Fifer & Abramov, 1992) indicates that it may be nearly adultlike at 1 to 2 months of age. Also, convergence changes would not explain differences in the onset of crossed and uncrossed disparity (Held et al., 1980).

Given these considerations, most investigators believe the explanation for the onset of stereoscopic vision is some maturational change in cortical disparity-sensitive units. Such a mechanism underlies improvement of stereoscopic discrimination performance in kittens (Pettigrew, 1974; Timney, 1981). In humans, it has been suggested that the particular change in disparity-sensitive cells may be segregation of *ocular dominance columns* in layer 4 of the visual cortex (Held, 1985, 1988). At birth, cells in layer 4 generally receive projections from both eyes. Between birth and 6 months, inputs from the two eyes separate into alternating columns receiving input from the right and left eyes (Hickey & Peduzzi, 1987). Eye-of-origin information is needed to extract disparity information, so this neurological development is a plausible candidate for the onset of stereoscopic function.

Pictorial Depth Perception

The *pictorial cues* are so named because they allow depth to be portrayed in a flat, two-dimensional picture. Sometimes these are called the classical depth cues, because they have been discussed and used by artists and students of perception for centuries. Theoretically, they have been central to classical arguments about the need for learning in spatial perception. The fact that the same information can be displayed in a flat picture or a real 3D scene immediately points to their ambiguity as signifiers of reality. It is a short step to the classical perspective on the acquisition of such cues: If these cues are not unequivocally tied to particular spatial arrangements, our perception of depth from these cues must derive from learning about what tends to be the case in our particular environment. (The environment, until recently, had many more 3D scenes offering information than 2D representations.)

Ecologically, the pictorial cues to depth are diverse, but many of them rest on similar foundations. The laws of projection ensure that a given physical magnitude projects an image of decreasing extent at the retina with increasing distance from the observer. Applying this geometry in reverse, if two physical extents are known or assumed to have the same physical (real) size, then differences in their projected size can be used to establish their depth order. This information comprises the depth cue of *relative size*. Very similar is *linear perspective*. If two lines in the world are known or assumed to be parallel, then their convergence in the optical projection may be taken to indicate their extending away from the observer in depth. Generalizing this notion to whole fields of visible elements comprises the rich source of information in natural scenes known as *texture gradients* (J. Gibson, 1950). If a surface is assumed to be made up of physically uniform or stochastically regular tokens (pebbles, plants, floor tiles, etc.), then the decreasing projective size of texture elements indicates increasing depth. A different kind of assumed equality is illustrated by the depth cue of *shading*. If the light source comes from above, a dent in a wall will have a lower luminance at the top because the surface is oriented away from the light, whereas the bottom part, oriented toward the light, will have higher luminance. Perception of depth from these luminance variations implicitly assumes that the surface has a homogeneous reflectance; variations in luminance are then taken to indicate variations in surface orientation.

Pictorial cues are not as ecologically valid as kinematic or stereoscopic information because the assumptions behind them, such as the assumption of physical equality, may be false. In a picture, it is easy to make two similar objects of different sizes or two parts of a connected surface with different reflectances. Misleading cases of pictorial depth information are not difficult to find in ordinary environments. Sometimes apparently converging lines really are converging lines, and sometimes the average size of texture elements changes with distance, as do the sizes of particles at the seashore (smaller particles get washed further up the beach).

Studies of the development of pictorial depth perception reveal a consistent pattern. Sensitivity to these cues appears to be absent until about 7 months of age. Around 7 months of age, infants seem to be sensitive to virtually all pictorial depth cues that have been tested. Much of this emerging picture of the origins of pictorial depth has come from systematic studies by Yonas and his col-

leagues (see Yonas, Arterberry, & Granrud, 1987b; Yonas & Owsley, 1987 for reviews). For brevity, we consider only two examples: interposition and familiar size. The development of other pictorial cues that have been studied, such as linear perspective and shading, appears to be similar.

Interposition

The depth cue of *interposition*, sometimes called overlap, specifies relative depth of surfaces based on contour junction information. When surface edges form a "T" junction in the optical projection, the edge that comes to an end at the intersection point (the vertical edge in the letter T; see Figure 3.5A) belongs to a surface passing behind the surface bounded by the other edge (the horizontal edge in the letter T). Interposition is a powerful depth cue in human vision (Kellman & Shipley, 1991). Infant use of interposition information was tested by Granrud and Yonas (1984). They used three similar displays made of three parts each but differing in the presence of interposition information. In the interposition display, the left panel overlapped the middle, which overlapped the right. In a second display, all contours changed direction at intersection points, giving indeterminate depth order. In a third display, the three surface sections were displayed slightly separated, so that no contour junctions were relating them. Infants at 5 and 7 months of age viewed these displays monocularly (to eliminate conflicting binocular depth information), and reaching was measured. All parts of the displays were coplanar and located the same distance from the subjects. Infants' reaches to different parts of the displays were recorded. In one ex-

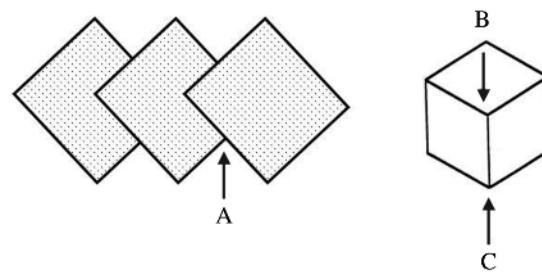

Figure 3.5 Examples of line junctions giving information for three-dimensional structure. A shows a T junction specifying ordering in depth. B and C show Y and arrow junctions, respectively, that contribute to the perception of three-dimensional structure.

periment, the interposition display was compared with the indeterminate control display and in a second experiment, the interposition display was compared with the control display having separated areas. In both experiments, 7-month-old infants reached reliably more often to the "nearest" part of the interposition display than to the same region in the control displays. Five-month-olds showed some tendency to reach more to the nearest part of the interposition display than one of the control displays, but not the other. These results provide evidence that interposition is usable by 7 months, but the results are equivocal or negative about its availability at 5 months of age.

Familiar Size

Perhaps the clearest case of learning in space perception involves the cue of familiar size. If an object has a known physical size (and this size is represented in memory) and the object produces a particular projective size in a given viewing situation, the distance to the object can in principle be calculated (Ittleson, 1951). Using a preferential reaching method, Yonas, Pettersen, and Granrud (1982) tested infants' perception of depth from familiar size. As with interposition, 7-month-olds showed evidence of using familiar size, whereas 5-month-olds did not. In a later experiment, Granrud, Haake, and Yonas (1985) tested familiar size using two pairs of objects unfamiliar to the subjects before the experiment. Each pair consisted of a large and small version of an object having identical shape and color. Infants were encouraged to play with the small object from one pair and the large object from the other pair for 6 to 10 minutes. After this familiarization period, infants viewed a simultaneous presentation of both large objects. It was expected that infants would reach more often to the object whose small version had been handled during familiarization if the cue of familiar size influenced perceived distance. (Memory for the physical sizes in the earlier exposure, combined with equal projective sizes in the test, would lead to interpretation of the previously smaller object as being much closer.) Infants at 7 months of age who viewed the test displays binocularly reached equally to the two objects, but infants of the same age who viewed the test displays monocularly reached more to the previously smaller object. Five-month-olds showed no variations in reaching related to the size of objects in the familiarization period. These results suggest that by 7 but not 5 months infants may obtain depth information

from familiar size, but this information is overridden when conflicting stereoscopic information is available.

Conclusions Regarding Pictorial Depth

Two decades ago little was known about the development of pictorial depth. Today, largely due to programmatic research by Yonas, Granrud, and their colleagues, we have a fairly clear picture about the timing of the appearance of pictorial cues. The picture is strikingly consistent across members of the category. Pictorial cues to depth arise sometime between the 5th and 7th month of age, and tests of individual infants across time reveal variability in the age of onset across this 2-month period (Yonas, Elieff, & Arterberry, 2002). It is possible that younger infants are sensitive to some of the informational properties of pictorial depth cues, such as different line junctions or textural arrangements, which may provide a foundation for perceiving the third dimension (Bhatt & Bertin, 2001; Bhatt & Waters, 1998; Kavsek, 1999).

The appearance of various pictorial cues around the same time has been interpreted as suggesting that maturation of some higher visual processing area in the nervous system is the mechanism (Granrud & Yonas, 1984). Research with macaque monkeys lends additional support to a maturational explanation. Pictorial cues appear as a group around 7 to 8 weeks of life (Gunderson, Yonas, Sargent, & Grant-Webster, 1993). As Gunderson et al. put it, this result is compatible with the idea that "pictorial depth perception may have ancient phylogenetic origins" (p. 96). A key to this interpretation is that the timing fits the rough ratio of 1:4 in terms of time after birth in nonhuman primates and humans, a relation that fits the maturation of numerous other abilities (a function that matures at 4 weeks in nonhuman primates appears at about 16 weeks in human infants).

Alternatively, the similarity of onset of these sources of information might be explained by learning. It is suggestive that the depth cue of familiar size, which necessarily involves learning, becomes operative in the same period as other pictorial depth cues. Their appearance at this time could reflect enhanced possibilities for learning brought about by some other developmental advances, such as the appearance of crawling abilities around 6 months of age. One study that correlated individual sensitivity to linear perspective and texture gradients with crawling ability (Arterberry, Yonas, & Bensen, 1989) found no predictive relationship, however. Seven-month-olds seemed to utilize pictorial depth in their reaching regardless of whether they had learned to crawl.

Further research is needed to discover the mechanisms underlying the onset of pictorial depth perception. Longitudinal studies of multiple pictorial depth cues would be helpful, as would be formulation and tests of more specific neurophysiological candidates for maturation and, alternatively, potential processes of learning.

OBJECT PERCEPTION

One of the most important functions of visual perception is to deliver representations of the environment in terms of discrete physical entities or *objects*. There are many ways to describe and encode the streams of light that hit the retinas of the eyes. In ordinary perceiving, we receive, not descriptions of light, but descriptions of the physical objects that last reflected the light. These descriptions of the locations, boundaries, shapes, sizes, and substances of objects are indispensable for action and thought. Normally, the separate objects in our perceptual world correspond to units in the physical world. This knowledge allows us to predict the results of action: how the world divides, which things will detach from adjacent things, and which will remain coherent if moved, thrown, or sat on. All this we can know visually from a distance, without actually contacting the objects.

Beyond these most basic kinds of knowledge, perception of shapes and sizes, object rigidity, and so on, gives us a wealth of information about objects' possible affordances for action. For the experienced observer, storing in memory the shapes and surface qualities of many perceived objects makes possible rapid and automatic recognition of familiar objects, even from partial information. The adaptive value of object perception and recognition systems can hardly be overestimated. Matching this importance is the complexity of understanding the processes and mechanisms of object perception. The challenges become apparent when we see how little of human object perception can currently be emulated by artificial vision systems. For the ordinary observer in a familiar environment, however, the task seems not complex, but easy.

The lack of a complete scientific understanding of adult object perception abilities might seem to handicap efforts to trace their development. Examining object perception in infancy has at least one advantage. The minimal experience of infants makes it easier to exam-

ine object perception *per se* as opposed to recognition from partial information, reasonable inferences based on prior knowledge, and other valuable cognitive talents that adults use to ruin otherwise sound perceptual experiments. Studies of early object perception reveal the developmental course of these abilities and shed light on the complexities of object perception in general.

Multiple Tasks in Object Perception

As the study of object perception has advanced, it has become clear that it is computationally complex, involving multiple tasks. (For recent discussions of the information processing tasks in object perception, see Kellman, 2003). One component is *edge detection*—locating significant contours that may indicate where one object ends and another object or surface begins. Edge detection alone is ambiguous, because visible contours can result from object boundaries but also from other sources, such as shadows or markings on a surface. A second requirement, then, is *edge classification*—sorting visible contours into object boundaries as opposed to other sources. Next is *boundary assignment*. When an edge corresponding to an object boundary is located, it most commonly bounds one object, while the surface or object seen on the other side of the boundary passes behind the first object. Determining which way each boundary bounds is crucial for knowing, for example, whether we are viewing objects or holes. Along with edge processes, detection and classification of junctions of edges is important in the segmentation and grouping processes that lead to perceived objects.

Early processes involving edges and junctions do not by themselves yield perceived objects. Several other problems need to be solved to accomplish object formation. For one thing, because of occlusion a single object in the world may project to multiple, spatially separated locations on the retinas of the eyes. Also, at each occlusion boundary, some surface continues behind; recovering the structure of objects in the world requires solutions to how visible parts connect. These are the questions of *segmentation* and *unit formation*. A single static image raises these issues; more complex versions occur when observers move, causing the visible fragments of objects to change continuously. To form units, the visual system assigns shape descriptions. Thus perceiving *form*—the three-dimensional arrangement of the object—is another important component. Finally, there are perceptible properties relating to *object sub-*

stance: its rigidity or flexibility, surface texture, and so on. We consider what is known about each of these aspects of object perception early in development.

Edge Detection and Edge Classification

What information makes edge detection possible? In general, the answer is discontinuities across space in some perceptible properties. These differences can be in the luminance or spectral composition of light coming from adjacent areas. These differences may mark object boundaries because objects tend to be relatively homogeneous in their material composition. Parts of a homogeneous object will absorb and reflect light in similar fashion, whereas an adjacent object, made of some different material, may differ. Thus, discontinuities of luminance and spectral composition in the optic array may mark object boundaries. When average luminance and spectral characteristics are similar for adjacent objects, higher order patterns of optical variation—texture—may distinguish them. Another source of information comes from depth gradients. Depth values of visible points of a continuous object will change smoothly, but at an object boundary discontinuities will often occur. In similar fashion, optic flow provides information about edges. When the observer moves, the optical displacements for visible points will tend to vary more smoothly within objects than between objects.

None of these sources of information for detecting objects' edges is unequivocal. Discontinuities in luminance and/or spectral values may arise from reflectance differences of cast shadows along the surface of a continuous object. They may also come from surface orientation differences in a complex object, due to different geometric relations between a light source, surface patches, and the observer. The same may be true for depth or motion discontinuities: They will often but not always mark object boundaries. A second requirement for object perception, then, is edge classification. Which luminance variations are probably object edges and which arise from illumination changes, such as shadows or patterns on a continuous surface?

We have primarily indirect evidence about infant edge detection and edge classification abilities. The literatures on visual acuity and pattern discrimination both offer useful clues. One implication of newborns' poor acuity relative to adults is that their ability to process object edges must be much reduced, especially for distant objects.

If the shape of a 2D pattern is detected, one might argue, the contour comprising that edge must certainly be detected and perhaps classified as an object boundary. Since the pioneering studies of Fantz and colleagues (e.g., Fantz, Fagan, & Miranda, 1975), many studies have shown that infants discriminate patterns from the earliest weeks of life. Discrimination, however, can be based on any registered difference between patterns; contour perception may not necessarily be implied. A visual pattern may be analyzed into sinusoidal luminance components. An object's edge may trigger responses in a population of cortical neurons but not be represented as a single pattern feature. In short, different patterns may evoke different neural activity but not perception of edges or forms *per se*. This possibility is consistent with the evidence noted earlier that infants are somewhat insensitive to spatial phase information before about 8 weeks of age.

Other lines of research, however, imply that edges and forms may be perceived by newborns under at least some circumstances. Slater and colleagues (Slater, Mattock, & Brown, 1990) reported evidence for some degree of size and shape constancy in the first few days of life. Size constancy is the ability to perceive the physical size of an object despite changes in the object's projected size for an observer at different distances. Shape constancy in this context refers to the perceiver's ability to detect a constant planar (2D) shape despite variations in its 3D slant (e.g., perceiving a rectangle although its slant in depth produces a trapezoidal retinal projection). Size and planar shape constancy are discussed later in this chapter. Here we merely note that both seem to require some boundary perception abilities. It is hard to imagine any way to achieve constancy if the newborn's visual representation consists of an unintegrated collection of activations in independent frequency channels. More likely, higher stages of processing function to some degree to localize edges of objects.

Several observations suggest that early edge classification and boundary assignment capacities may depend selectively on a subset of information sources available to adults. For adults, surface quality differences such as luminance and spectral differences can specify object boundaries. As noted by Rubin (1915) in his classic studies of figure-ground organization, an area whose surround differs in luminance or spectral characteristics ordinarily appears as a bounded figure in front of a background surface. There is reason to believe that

infants do *not* segregate objects using this information before about 9 months of age. Piaget (1954) noted that his son Laurent at 7 months reached for a box of matches when it was placed on the floor but not when it was placed on a book; instead he reached for the edges of the book. If the box slid on the book, Laurent reached for the box. This sort of observation led to three tentative conclusions:

1. A stationary object on a large extended surface (a floor or table) may be segregated from the background.
2. A stationary object adjacent to another stationary object will not be segregated by surface quality differences.
3. Two objects can be segregated by relative motion.

Subsequent experimental work has supported Piaget's interpretations. Spelke, Breinlinger, Jacobson, and Phillips (1993) tested infants' responses to adjacent object displays. *Homogeneous* displays had parts with identical luminance, color, and texture, and the parts' boundaries were continuous at their intersection points. *Heterogenous* displays had two adjacent parts differing in luminance and color, and also had discontinuities (T junctions) at the intersection points. After familiarization with a display, infants viewed two test events. In one, both parts moved together, whereas in the other only the top part moved, detaching from the other part. If the original display had been perceived as two separate objects, infants were expected to look longer at the event in which the whole display moved as a unit. If the two parts had been perceived as connected, infants were expected to look longer at the detachment event. Three-month-old infants showed this latter result, suggesting they had perceived both the homogeneous and heterogeneous displays as connected. Ambiguous results were found with 5- and 9-month-olds; infants looked longer at the detachment event for the homogeneous display, but when the heterogeneous display moved as one piece, they did not show a novelty effect. Similarly, Needham (1999) showed that 4-month-olds did not respond to differences in surface features for segregating static objects.

These conclusions are consistent with earlier research. Von Hofsten and Spelke (1985) used infants' reaching behavior to address perceived unity. Displays were designed to approximate closely the situations considered by Piaget. Spatial and motion relationships were varied among a small, near object, a larger, further object, and an extended background surface. It was as-

sumed that reaches would be directed to perceived boundaries of graspable objects. When the whole array was stationary and the objects were adjacent, greater reaching was observed to the edges of the larger, further object. Separation of the two objects in depth led infants to reach more for the nearer, smaller object. When the larger object moved while the smaller object did not, reaching was directed more toward the smaller object. This result suggested that motion segregated the objects rather than merely attracted reaching, because infants reached more to the stationary object. From these results, it appears that discontinuities in motion or depth segregate objects, whereas luminance discontinuities and overall shape variables do not. These results make sense in that motion and depth indicate object boundaries with greater ecological validity than luminance or spectral variations alone (Kellman, 1995; von Hofsten & Spelke, 1985). That is, ambiguous or misleading cases are less likely to arise with motion or depth discontinuities.

Detection and Classification of Contour Junctions

Detecting and classifying contour junctions is important for many aspects of object perception. Many models of object perception and recognition, as well as other aspects of perceptual organization, include contour junctions as important sources of information (e.g., Heitger, Rosenthaler, von der Heydt, Peterhans, & Kubler, 1992; Hummel & Biederman, 1992; Kellman & Shipley, 1991). Junctions are important in unit formation, both in segmenting objects from their backgrounds and in triggering contour interpolation processes (e.g., Heitger et al., 1992; Kellman & Shipley, 1991) and in encoding object representations for recognition (Barrow & Tenenbaum, 1986; Hummel & Biederman, 1992; Waltz, 1975). Beyond mere detection, classification of junction type is important (see Figure 3.5). As mentioned, a T junction in an interposition display indicates where one contour intersects another contour, thus allowing for the separation of the two surfaces in depth (Waltz, 1975; Winston, 1992). Line junctions can also play a role in specifying the three-dimensional shape of an object. For example, "Y" and "arrow" junctions specify the three-dimensional structure and orientation of objects.

Until recently, not much was known about the development of sensitivity to contour junctions. Studies on interposition suggest that by 7 months of age, infants are

responsive to T junctions. In addition, Yonas and Arterberry (1994) showed that 7.5-month-olds distinguish between lines in two-dimensional drawings that represent edge contours (arrow and Y junctions) and lines that represent surface markings, an important first step in using line junction information for perceiving spatial structure. More recently, Bhatt and Bertin (2001) found evidence that 3-month-olds are sensitive to line junction cues that signal three-dimensional structure and orientation information to adults. Whether infants perceive the three-dimensional structure has not been directly tested but would be a good question for future investigation.

Boundary Assignment

The question of boundary assignment applies to perhaps the most important subcategory of edges—occluding edges. These are contours that mark the end of an object or surface. As has been known for a long time (Koffka, 1935), most such edges are “one-sided,” in that the contour marks the edge of an object on one side but on the other, some surface continues behind. Boundary assignment involves the question of which way such edges bound. Some of the same considerations we raised regarding edge classification apply to boundary assignment. Evidence that infants distinguish shapes, or figures from grounds, might indicate that boundary assignment is occurring. It is problematic, however, to prove that infants perceive shape rather than a hole. These two possibilities differ in terms of the direction of boundary assignment.

We noted that early shape constancy seems to presuppose boundary assignment. If this inference is correct, the relevant information probably comes from discontinuities in depth at object edges. Boundary assignment from depth discontinuities follows the straightforward rule that the nearer surface owns the boundary. Another source of boundary assignment information is accretion/deletion of texture. When one surface moves relative to a more distant surface, texture elements on the latter surface go out of sight at the leading edge of the nearer object and come into sight at the trailing edge. This information constitutes a powerful source of boundary information, depth order, and shape in adult perception (Andersen & Cortese, 1988; J. Gibson et al., 1969; Shipley & Kellman, 1994). Infants as young as 3 and 5 months of age respond to accretion and deletion of texture to perceive object shape and depth, respectively,

suggesting perception of both depth order and boundary ownership (Granrud, Yonas, et al., 1985; Kaufmann-Hayoz, Kaufmann, & Stucki, 1986).

Other behavior suggests appropriate detection of object boundaries in younger infants. When an object approaches an infant, certain defensive responses often occur, including withdrawal of the head and blinking, as discussed earlier. The importance of boundary assignment for this ability was tested by Carroll and Gibson (1981). They presented 3-month-old-infants with arrays in which all surfaces were covered with random dot texture. Using accretion/deletion of texture, an approaching object was specified in one condition and an approaching aperture (opening in the surface) was specified by the information in the other condition. Infants appeared to use the information: They responded defensively more often to approaching objects than to approaching apertures.

Perception of Object Unity

Processes of edge detection, classification, and boundary assignment parse the optic array into significant pieces and reveal some of the boundaries of objects, but they do not yield representations corresponding to physical objects. Together, they may feed into a representation of distinct visible areas along with the labeling of which way contours dividing these areas bound (Kellman, 2003; Palmer & Rock, 1994). As mentioned earlier, the difference between such representations and perceived objects is that objects may unify multiple visible areas. How can the visual system move from visible pieces to complete objects when some parts of objects are partly hidden? This is the question of perceiving object unity, or unit formation. It involves problems of spatial occlusion as a 3D world is projected onto 2D receptive surfaces and also changes in the optic projections over time as the observer or objects move.

Multiple Processes in Unity Perception

Research suggests several kinds of information lead to perceived unity. One is the common motion process (“common fate”) first described by Wertheimer (1923/1958): Things that move together are seen as connected. Some more rigorous definition of “move together” is needed, of course. The class of rigid motions as defined in projective geometry, as well as some non-rigid motion correspondences, can evoke perception of

unity in human adults (Johansson, 1970, 1975). The common motion process does not depend on relationships between oriented edges and for that reason has been called the *edge-insensitive process* (Kellman & Shipley, 1991).

The other process depends on continuity in edge relationships. Related to the Gestalt principle of good continuation (Wertheimer, 1923/1958), it has been termed the *edge-sensitive process*. Whereas good continuation applies to the breakup of fully visible arrays into parts, perception of unity across gaps in the input depends on particular relationships of oriented edges. Specifically, they appear to be governed by a mathematical criterion of *relatability* (Kellman, Garrigan, & Shipley, 2005; Kellman & Shipley, 1991). Informally, relatability characterizes boundary completions as smooth (differentiable at least once) and monotonic (singly inflected). Figure 3.6 gives some examples of relatable and nonrelatable edges. These are illustrated both in occlusion cases and in illusory figure cases (in which completed surfaces appear in front of other surfaces, rather than behind). Research suggests that interpolation of contours in occluded and illusory contexts depend on common mechanisms (Kellman et al., 2005; Kellman, Yin, & Shipley, 1998; Ringach & Shapley, 1996). Complementing the contour interpolation process is a surface interpolation process. Correspondences in surface quality (e.g., lightness and color) can also unify visible areas (Grossberg & Mingolla, 1985; Kellman & Shipley, 1991; Yin, Kellman, & Shipley, 1997, 2000).

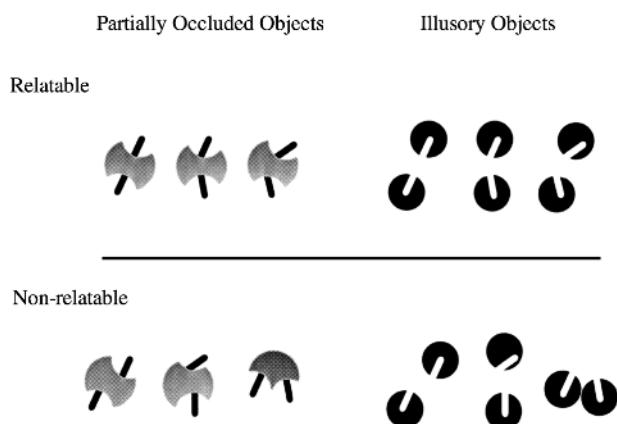

Figure 3.6 Relatable and nonrelatable edges. Connections (occluded surfaces or illusory surfaces between the two visible bars) are seen in the relatable displays, but not in the nonrelatable ones.

How does unit formation develop? We consider these several information sources in attempting to answer that question.

The Edge-Insensitive Process: Common Motion

Evidence suggests that the edge-insensitive (common motion) process appears earliest in development. Infants' perception of partly occluded objects can be assessed using generalization of habituation (Kellman & Spelke, 1983). If two visible parts whose possible connection is occluded are perceived as connected, then after habituation of visual attention to such a display, infants should look less to an unoccluded complete object (because it is familiar) and more to an unoccluded display containing unoccluded, separate pieces (because it is novel).

In a series of studies of 16-week-old infants, Kellman and Spelke (1983) found evidence that common motion of two object parts, visible above and below an occluding object, led to infants' perception of unity. After habituation to such a display, infants attend more to a moving "broken" display—two parts separated by a visible gap—than to a moving complete display. This outcome occurs no matter whether the two visible parts are similar in orientation, color, and texture. Initial studies used a common lateral translation (horizontal motion, perpendicular to the line of sight), but later research indicated that vertical translation and translation in depth also specify object unity at 16 weeks (Kellman, Spelke, & Short, 1986). Translation in depth is especially informative about the underlying perceptual process, because its stimulus correlates are much different from the other translations. Whereas translation in the plane (a plane perpendicular to the line of sight) is given in terms of image displacements at the retina or pursuit eye movements to cancel such displacements, translation in depth is specified by optical expansion or contraction in the object's projection or by changes in convergent eye movements as the object moves. The use of stimuli that specify object translation in space suggests that infants' unity perception depends on registered object motion, not on a particular stimulus variable.

The class of motion relationships effective early in life does not appear to encompass the full range of rigid motions as defined mathematically. Rigid motions include all object displacements in 3D space that preserve 3D distances among object points. After habituation to a rotation display in which two visible parts rotate around the line of sight, 16-week-olds generalized habituation

equally to rotating complete and broken displays (Eizenman & Bertenthal, 1998; Kellman & Short, 1987b). Eizenman and Bertenthal (1998) found that 6-month-olds perceived a rotating rod as complete only if it underwent a complete rotation (360 degrees) as opposed to merely oscillated (90-degree rotation with reversal of direction). It appears that infants' unity perception is governed by a subset of rigid motions.

Further research revealed that perception of object unity is dependent on perceived object motion, not merely retinal motion (Kellman, Gleitman, & Spelke, 1987). Most experiments on motion relationships in unity perception have used stationary observers and moving objects. Many theorists have observed that certain optical consequences of motion may be duplicated when a moving observer looks at a stationary object (Helmholtz, 1885/1925; James, 1890). The retinal displacement of a laterally moving object, for example, may be duplicated by an observer's head or body movement while a stationary object is in the observer's visual field. This similarity raises a crucial question about the role of motion in object unity: Does perceived unity depend on actual object motion or on certain optical events, such as image displacement, that may be caused by either observer motion or object motion?

Embedded in this question is another one, at least as fundamental. Can infants tell the difference between optical changes caused by their own motion and those caused by the motions of objects? Recall this ability is called position constancy: perceiving the unchanging positions of objects in the world despite one's own motion. Kellman et al. (1987) took up these questions in a study of 16-week-olds. In each of two conditions, the infant's chair moved in a wide arc around a point between the observer and occlusion displays in front. In one condition (conjoint motion), the moving chair and a partly occluded object were rigidly connected underneath the display table, so that they both rotated around a point in between. In this condition, the object's motion was real; however, there was no subject-relative displacement. Thus, no eye or head movements were required to maintain fixation on the object. If perceiving the unity of this partly occluded display depends on real object motion, infants were expected to perceive unity in this condition. In the other condition (observer movement) the observer's chair moved in the same way, but the partly occluded object remained stationary. If optical displacement caused by observer motion can specify unity, infants were expected to perceive a complete object in this

condition. As in earlier research, dishabituation patterns to unoccluded complete and broken displays after habituation were used to assess perception of unity, and the test displays in each condition had the same motion characteristics as in habituation.

Results indicated that only the infants in the conjoint-motion condition perceived the unity of the partly occluded object. Analyses based on looking-time differences suggested that infants in the conjoint-motion condition perceived object motion during their own motion, whereas observer-motion infants responded as if they perceived the occlusion display as stationary. These results suggest that the common motion or edge-insensitive process depends on perceived object motion. The outcome makes sense ecologically, in that rigid relationships in truly moving visible parts are highly unlikely to occur unless the parts are actually connected. For optical displacements caused by movement of the observer, areas at similar distances from the observer will share similar displacements, yet it is hardly the case that all objects near each other are connected.

What are the origins of the edge-insensitive process? From findings that the motion relationships specify object unity to infants before they actively manipulate objects or crawl through the environment, Kellman and Spelke (1983) hypothesized that perceiving unity from motion is accomplished by innate mechanisms. The hypothesis also reflects the ecological importance of common motion information. Coherent motion is closely tied to the very notion of an object (Spelke, 1985), and common motion of visible areas has very high ecological validity as a signifier of object unity (Kellman, 1993).

The basis of unity perception in innate or early maturing mechanisms is consistent with more recent studies showing perception of unity by 2-month-old infants under conditions in which the block occluded less of the rod than in traditional displays (Johnson & Aslin, 1995, 1996; Johnson & Nanez, 1995). Also, it has been found that the ability to perceive unity of partly occluded objects from common motion is innate in chicks (Lea, Slater, & Ryan, 1996).

Studies of human newborns, however, have not found evidence for perceived unity from common motion. Slater and his colleagues have shown a consistent preference for the complete rod following habituation to moving rod-block displays (Slater, Johnson, Brown, & Badenoch, 1996; Slater, Johnson, Kellman, & Spelke, 1994; Slater, Morison, Somers, Mattock, Brown, & Taylor, 1990). This finding suggests that newborn infants

perceived the rod as broken during the habituation phase, even though the size of the rod and depth separation of the rod and block was increased compared with that used with 4-month-olds (Slater, Johnson, Kellman, & Spelke, 1994) and when the block height was reduced and texture was added to the background to increase the available information specifying the depth relations (Slater, Johnson, Brown, & Badenoch, 1996). The implication of these findings is that newborns make their perceptual judgments based on the visible parts of the displays, and they cannot make judgments about the parts of the visual array that are occluded.

Using a somewhat different stimulus, Kawabata, Gyoba, Inoue, and Ohtsubo (1999) have found at least one condition in which 3-week-old infants perceive a partly occluded region as complete. Instead of using the traditional rod-block display, they presented infants with drifting sine-wave gratings that were occluded by either a narrow or broad (wide) central occluder. When the spatial frequency of the grating was low (.04 cycles per degree [cpd] of visual angle; that is, the black and white bars were thick) and the occluder was narrow (1.33 degrees, LN in Figure 3.7) infants looked significantly longer at the broken test display (SG). This finding suggests that they perceived the low frequency

grating as continuing behind the narrow occluder. In contrast, when the spatial frequency was high (1.2 cpd; the black and white bars were narrow) and the occluder was broad (4.17 degrees; HB in Figure 3.7), 3-week-olds looked significantly longer at a complete grating (CG) as opposed to a broken grating (SG). This finding suggests that they perceived the high spatial frequency grating as two separate regions. Further manipulations revealed that there is an interaction between spatial frequency and occluder width. Infants looked equally to the two test gratings when they viewed a high spatial frequency grating behind a narrow occluder (HN in Figure 3.7) and when they viewed a low spatial frequency grating with a broad occluder (LB in Figure 3.7). In both of these conditions, infants provided ambiguous results regarding whether they perceived the gratings as complete or broken.

These several findings permit at least two explanations. One is that the use of common motion to specify object unity arises by learning between 3 and 8 weeks of life. This account would fit with classical empiricist notions about the starting point of perceptual development: Infants may see visible patches but may have to construct whole objects. One problem with this account is the learning mechanism. Both the findings of Kawabata et al. (1999) at 3 weeks and several researchers at 8 weeks are inconsistent with any of the traditionally proposed means by which infants might learn about objects, namely association of visual impressions with touch (e.g., Berkeley, 1709/1963) or with self-initiated action (e.g., Piaget, 1954). Infants at these early ages do not walk, crawl, or even perform directed reaching. One can imagine, however, purely visual forms of learning. Two parts of an object seen at one time may emerge from behind an occluder, allowing learning of the rule about common motion. This account, while imaginable, would have as its primary virtue minimizing what must be attributed to innate or rapidly maturing capacities. Paradoxically, as Kellman and Arterberry (1998) noted, this account places a heavy burden on innate concepts of physics. To unlearn an incorrect perceptual rule (two moving visible pieces are not connected) through later images, the child must be constrained by an assumption that it is impossible (or unlikely) for two pieces to have been separate and subsequently to have merged.

A more plausible account of these findings is that infant unity perception from common motion depends on sensory capacities that are maturing in the first 8 weeks

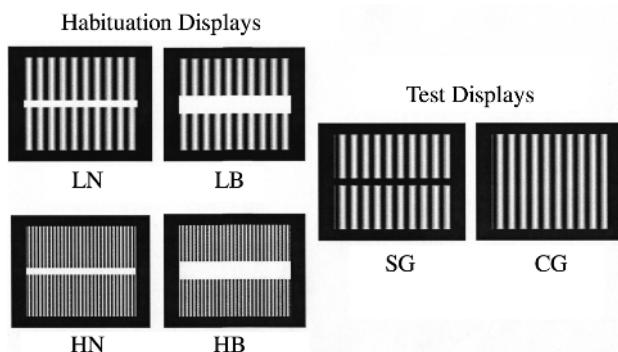

Figure 3.7 Habituation and test displays to test 3-week-old infants' perception of unity. LN refers to the low-spatial frequency display behind a narrow occluder. LB refers to low-spatial frequency display behind a broad occluder. HN refers to a high-spatial frequency display behind a narrow occluder. HB refers to high-spatial frequency display behind a broad occluder. SG refers to "separate grating" (analogous to a broken rod). CG refers to "complete grating" (analogous to a complete rod). *Source:* "Visual Completion of Partly Occluded Grating in Young Infants under 1 Month of Age," by H. Kawabata, J. Gyoba, H. Inoue, and H. Ohtsubo, 1999, *Vision Research*, 39, pp. 3586–3591. Reprinted with permission.

of life. Common motion may well be an unlearned principle of object perception, but using it requires accurate mapping of the direction and velocities of separated, moving regions of the visual field. The preference for a complete rod after habituation in newborns may arise from their ability to see motion (allowing segmentation of visible regions) but with poor direction and/or velocity sensitivity. Recall our earlier consideration of the emergence of directional sensitivity in infant motion perception. Programmatic work by Wattam-Bell (1991, 1992, 1996a, 1996b) addressed the emergence of directional sensitivity and velocity perception in infants. Using both behavioral and electrophysiological techniques, Wattam-Bell found no reliable visual evoked potential (VEP) to reversals of motion direction until about 74 days of age. Behavioral discriminations of coherent from random motion in random dot displays showed no evidence of this discrimination in 1-month-olds with either visual preference or habituation methods (Wattam-Bell, 1996a, 1996b). This discrimination was found to be robust at 15 weeks and weakly present at 8 weeks of age.

Connecting these two lines of research, it appears that perception of unity from common motion in humans is found at the same age that reliable discrimination of motion direction is first observed. This account fits with the variation found with stimulus variables (e.g., Kawabata et al., 1999), as directional selectivity is improving steadily through the period studied. It may not be a coincidence that the earliest use of common motion was found in studies using multiple, moving, oriented edges. Developing abilities to detect motion direction may have been better engaged by such displays.

In the absence of accurate encoding of motion direction, it is not surprising that unity based on common motion is not found in the human newborn. The evidence of how motion sensitivity develops is hard to reconcile with a learning account of common motion as a determinant of perceived unity. Based on available evidence, directional sensitivity and perceived unity appear at about the same time. Whereas unit formation from common motion with the standard kinds of stimuli appears around 8 weeks, the first discernible VEP to motion direction was reported at 74 days of age (Wattam-Bell, 1992). In short, in addition to the question of what kind of learning process could generate unity perception at this age, there is no discernible interval during which learning might occur. Available evidence is consistent

with the idea that perception of unity from common motion is unlearned, awaiting only the development of mechanisms of direction sensitivity in the infant's visual system.

The Edge-Sensitive Process: Unity Based on Edge Orientations and Relations

Whereas the edge-insensitive process is dependent only on motion relationships, the edge-sensitive process involves completion based on spatial orientations and relations of edges. These relations can be revealed in a static display or dynamically, over time, as when an observer views a scene through shrubbery (Palmer, Kellman, & Shipley, 2004). Thus the edge-sensitive process includes object completion in stationary arrays as well as in dynamic ones where edge relationships are crucial, such as kinetic occlusion and kinetic illusory contours (Kellman & Cohen, 1984).

Most work with infants on the edge-sensitive process has involved static displays. In contrast to the perception of unity from common motion, unity from edge relationships in static displays does not appear during the first half year of life (Kellman & Spelke, 1983; Slater, Morrison, et al., 1990). The typical result is that after habituation to a stationary, partly occluded display, infants show equal looking to the complete and broken test displays. Based on evidence that infants do encode the visible areas and are sensitive to occlusion (Kellman & Spelke, 1983), this pattern has been interpreted as indicating the perceiver's neutrality about what happens behind the occluder.

By 6.5 months, infants perceive partly occluded objects as complete in the absence of kinematic information, thus relying on static information. Craton (1996) found that 6.5-month-olds perceived a static rectangle as unified when a bar occluded its center. However, infants at this age provided no evidence of perceiving the shape of the occluded region. When the removal of the occluder revealed a cross instead of a rectangle (the horizontal piece of the cross had been completely hidden behind the occluder), infants younger than 8 months did not show looking patterns indicative of surprise. At 8 months of age, infants looked longer at the "cross event" than at the "complete object event," suggesting that before 8 months infants expected the partially occluded rectangle to be a single unit but were agnostic regarding its specific form. Even when motion is present, such as the case of a rectangle appearing out from either side of

a central occluder, infants' perception of unity appears to precede their perception of form (van de Walle & Spelke, 1996). In this case, 5-month-olds perceived the rectangle as unified but showed no evidence of knowing the shape of the occluded parts. Converging evidence comes from studies of illusory contours, which appear to depend on the same underlying process (Kellman et al., 1998). Infants of 7 months, but not 5 months, appear to be sensitive to static and kinetic illusory contour displays (Bertenthal, Campos, & Haith, 1980; Kaufmann-Hayoz, Kaufmann, & Walther, 1988).

How does perceived unity from edge-sensitive process emerge? Maturation, learning, or some combination are possible explanations. Granrud and Yonas (1984) suggested that pictorial depth cues appearing around 7 months of age might depend on maturation of a perceptual module, a finding bolstered by evidence from macaque monkeys (Gunderson et al., 1993). It is possible that edge-sensitive unity perception might be connected to this emergence. It has been noted that the depth cue of interposition is closely related to boundary completion under occlusion (Kellman & Shipley, 1991). Another argument for maturational origins comes from work on the neurophysiology of the edge-sensitive process (von der Heydt, Peterhans, & Baumgartner, 1984). It appears that some edge-sensitive interpolation processes are carried out at very early stages of visual processing, certainly as early as V2 and possibly V1, the first visual cortical area (von der Heydt et al., 1984). Models of early visual filtering at these levels typically postulate operations carried out by dedicated neural machinery in parallel across much of the visual field. Although learning explanations for such circuitry can be imagined, the existence of early parallel operations that carry out interpolation is congenial to maturational accounts. Other considerations suggest that learning may play a role (e.g., Needham, 2001; see Cohen & Cashon, 2001b; Kellman, 2001; Quinn & Bhatt, 2001; Yonas, 2001 for related discussions). Of interest to potential learning accounts is recent work by Geisler and colleagues (Geisler, Perry, Super, & Gallogly, 2001). Their work in analyzing natural scenes suggests that the edge relationships described by contour relatability are highly diagnostic of visible edges that belong to unitary objects. Such ecological facts, of course, might be relevant to both evolutionary and learning accounts of the edge-sensitive process, but the relatively late onset of this ability at least makes it possible that experience

with an object's views under occlusion contributes to this ability.

Perception of Three-Dimensional Form

Form is among the most important properties of an object because it is closely tied to its functional possibilities. Representations of form are also primary in triggering object recognition processes. Even when some other property of an object may be of greatest concern to us, we often locate and recognize the object by its form. There are many levels of form—local surface topography, the two-dimensional projection of an object seen from a stationary vantage point, and three-dimensional (3D) form, to name a few. Arguably, it is the 3D forms of objects that are most important in human cognition and behavior. Whereas the particular 2D projection from an object varies with the observer's position, the object's arrangement in 3D space does not. Perceiving the unchanging object given changing optical information constitutes the important ability of *shape constancy*. In addition to being of greatest significance among form concepts, 3D form also constitutes the greatest battleground in perceptual theory. Adults are versatile in their 3D form perception abilities, and each mode of perceiving naturally suggests a different account of the development of 3D form perception (Kellman, 1984). Adults can usually detect the overall form of an object from a single, stationary view. If the object is a familiar one, this ability is compatible with the idea that an object's 3D form is a collection of 2D views obtained from different vantage points, and any single view recalls the whole collection to mind (e.g., Mill, 1865). On this account, 3D form develops from associating experiences of different views, perhaps guided by activity in manipulating objects (Piaget, 1954).

Another way to get whole form from a single view is to apply general rules that extrapolate 3D form. Use of rules would explain how we might see 3D forms of unfamiliar objects from a single viewpoint. Gestalt psychologists argued for unlearned, organizational processes in the brain that serve this purpose. An alternative account of rules of organization was suggested by Helmholtz (1885/1925) and elaborated by Brunswik (1956). Perceptual rules might be abstracted from experiences with objects. These two accounts of perceptual rules that map 2D views into 3D objects make diametrically opposed developmental predictions. On the Helmholtz/Brunswik

account, these rules must be learned laboriously through experiences in seeing objects from different viewpoints and manipulating them. On the Gestalt view, organizational processes should operate as soon as the underlying brain mechanisms are mature.

Several decades ago, a new and different analysis of 3D form perception emerged. Based on initial discoveries such as the *kinetic depth effect* (Wallach & O'Connell, 1953) and later programmatic research on *structure-from-motion* (e.g., Ullman, 1979), the idea is that perceived 3D form results from mechanisms specifically sensitive to optical transformations. Transformations in an object's optical projection over time, given by object or observer movement, are governed by projective geometry. These transformations provide information that can specify the 3D structure of an object. Several theorists have proposed that human perceivers extract this kind of information using neural mechanisms specially evolved for this purpose (J. Gibson, 1966; Johansson, 1970; Shepard, 1984). Such an arrangement makes sense for mobile organisms: The complexity and speed of human adult perception of structure from motion makes it seem unlikely that these abilities derive from general purpose mechanisms that encode motion properties and general purpose inference mechanisms that might have allowed relevant regularities to be discovered.

Optical Transformations in Infant Form Perception

Research with human infants indicates that the most basic ability to perceive 3D form involves optical transformations. This dynamic information indicates 3D form as early as it has been tested, whereas other sources of information about form appear unusable by infants until well past the first half year.

A method to separate responses to 3D form from responses to particular 2D views was developed by Kellman (1984). When an object is rotated, its projection contains optical transformations over time, but it also might be registered as several discrete 2D snapshots. A way to separate 3D form from 2D views is to habituate infants to an object rotating around one axis and test for recognition of the object (by generalization of habituation) in a new axis of rotation. For a suitably asymmetrical object, each new axis of rotation provides a different set of 2D views, but providing there is some rotation in depth, each conveys information about the same 3D structure. A remaining problem is that dishabituation by

infants may occur for either a novel form or a novel rotation. To combat this problem, infants were habituated to two alternating axes of rotation on habituation trials and tested afterward with familiar and novel 3D objects in a third, new axis of rotation. This manipulation reduced novelty responding for a changed rotation axis in the test trials. Sixteen-week-old infants tested with videotaped displays showed the effects expected if 3D form was extracted from optical transformations. When habituated to one of two 3D objects, they generalized habituation to the same object in a new rotation and dishabituated to a novel object in the same new rotation axis. Two control groups tested whether dynamic information was the basis of response or whether generalization patterns might have come from 3D form perception based on single or multiple 2D views. In the two control groups, infants were shown sequential static views of the objects taken from the rotation sequences. Two numbers (6 and 24) of views were used along with two different durations (2 seconds and 1 second per view); in neither static view case, however, were continuous transformations available as in the dynamic condition. Results showed no hint of recognition of 3D form based on the static views, indicating that 3D form perception in the dynamic case was based on optical transformations.

Later research showed that this result occurs at 16 weeks with moving wire frame objects having no surface shading information, a finding that implicates the importance of projective transformations of edges. Moreover, 3D form perception occurs when infants are moved around stationary objects (Kellman & Short, 1987a), indicating that projective transformations, not object motions per se, provide the relevant information. By 8 weeks, infants perceive 3D form in kinetic random dot displays in which the relative motions of the dots create surfaces and the edges between them (Arterberry & Yonas, 2000). Yonas et al. (1987a) showed that 3D form obtained from optical transformations could be recognized when form information was subsequently given stereoscopically. Paradoxically, transfer does not seem to occur in the other direction; that is, initial representations of 3D form do not seem to be obtained by infants from stereoscopic depth information in stationary viewing.

Static Form Perception

Form perception from optical transformation appears to be a basic foundation of human perception. It appears

early and depends on information of great complexity, suggesting the existence of neural mechanisms evolved to map changing 2D projections onto 3D object representations. Another reason for regarding dynamic information as fundamental is that other sources of form information do not seem to be usable in the early months of life. This picture of early form perception turns on its head the classical empiricist notion that psychologically an object's 3D form is a construction from stored collections of static views.

Earlier, we described two conditions in which sequences of static views evoked no representation of 3D form in 16-week-olds. This finding—inability to perceive 3D form from single or multiple static views—has appeared consistently in research using real objects or photographic slides, up to an age of 9 months (Kellman, 1984; Kellman & Short, 1987a; Ruff, 1978). The inability to extract 3D form from static views is perplexing given that adults ubiquitously develop 3D form representations from single or multiple static views of objects. The one situation in which infants show some 3D form perception from static viewing involves recognition of 3D forms that had previously been given kinematically (Owsley, 1983; Yonas et al., 1987a). Perhaps this task of detecting similarity to a previously obtained representation is simpler than developing a full 3D object representation initially by means of static, binocular views. Alternatively, it could be a more general limitation of developing representations based on static information. In studies of categorization, infants transfer information about object category from kinetic to static conditions but not vice versa (Arterberry & Bornstein, 2002).

Nonrigid Unity and Form

Both the concept and process of 3D form perception are easiest to understand in the case of rigid objects whose forms do not change. Perception of rigid structure from motion is well understood computationally in terms of the projective geometry relating 3D structure, relative motion of object and observer, and transforming 2D optical projections at the eye. Many objects of ordinary experience, however, do not have rigid shape. In a moving person, a point on the wrist and one on the waist do not maintain a constant separation in 3D space. Nonrigidities may be given by joints, as in animals or people, but also by flexible substances, as in a pillow whose shape readily deforms. The possibility of perceiving or representing any useful information about shape for an object

whose shape varies depends on the existence of constraints on the variation. A human body can assume many, but not unlimited, variations in shape; the class of possibilities is constrained by factors such as joints and musculature. A jellyfish may be even less constrained, but even it has a shape, defined as a constrained class of possibilities, and characteristic deformations that depend on its structure and composition. Some progress has been made in the analysis of nonrigid motion and processes that might allow us to perceive it (Bertenthal, 1993; Cutting, 1981; Hoffman & Flinchbaugh, 1982; Johansson, 1975; Webb & Aggarwal, 1982), but the problems are difficult.

Whereas scientists have not succeeded in discovering the rules for determining nonrigid unity and form, such rules appear to exist in the young infant's visual processing. In work with adult perceivers, Johansson (1950, 1975) pioneered methods for testing form and event perception from motion relationships alone. His use of moving points of light in a dark surround, in the absence of any visible surfaces, has become the method of choice in structure from motion research. When such lights are attached to the major joints of a walking person, adult observers viewing the motion sequence immediately and effortlessly perceive the lights as forming a connected walking person. Turning such a display upside down eliminates recognition of a human form (Sumi, 1984).

Studies of the development of perception of nonrigid unity and form have been carried out by Bertenthal, Proffitt and their colleagues (Bertenthal, 1993; Bertenthal, Proffitt, & Cutting, 1984; Bertenthal, Proffitt, Kramer, & Spetner, 1987). A basic finding is that when infants of 3 to 5 months are habituated to films of an upright walking person, specified by light points, they subsequently dishabituate to an inverted display. This result suggests some level of perceptual organization, rather than apprehension of the displays as containing meaningless, individual points. The younger infants (at 3 months) may not perceive a person walking, however. Some later experiments used phase shifting of the lights to disrupt the impression of a walking person. Three-month-olds discriminated phase-shifted from normal walker displays whether the displays were presented in an upright or inverted orientation (Bertenthal & Davis, 1988), and they appear to process the absolute and relative motions within a single limb (Booth, Pinto, & Bertenthal, 2002). Both 5- and 7-month-olds, in contrast, showed poorer discrimination with inverted than with upright displays,

and 5-month-olds perceive relations among limbs in walkers and runners (Booth et al., 2002). One interpretation of these findings is that older infants, like adults, perceive only the upright, normal phase displays as a walking person, so that disruption of the phase relations is salient for these displays. Because inverted displays are not perceived as people, phase disruption is not so noticeable. On this line of reasoning, 3-month-olds show perceptual organization of the displays but not classification of the upright displays as a walking person (*biomechanical motion*). The younger infants are thus sensitive to differences in upright or inverted displays.

Although a more direct measure of perception of a walking person has been difficult to devise, the findings suggest the attunement of the infant's visual system to certain nonrigid motion relationships. The basic sensitivity that allows detection and encoding of motion relations may begin much earlier than the point at which recognition performance is measurable. Preferences for motion patterns generated by a walking person or a hand opening and closing have been demonstrated in 2-month-olds (Fox & McDaniel, 1982).

Conclusions Regarding Form Perception

Earliest competence to perceive 3D form depends on mechanisms that recover object structure from optical transformations. These abilities are present before abilities to extrapolate 3D structure from single views of objects and also before the maturation of self-locomotion and directed reaching. Both rigid and nonrigid motion relationships provide structural information to young perceivers. What we know about early 3D form perception fits the conjecture of ecological views that perception of structure from motion depends on dedicated perceptual machinery developed over evolutionary time (J. Gibson, 1966, 1979; Johansson, 1970; Shepard, 1984).

Perception of Size

An object of constant real size projects a larger image on the retina when it is close to the observer than when it is farther away. Perception of constant physical size can be achieved by running this geometry in reverse: From the projective size at the eye and information about distance, the physical size of the object can be perceived (Holway & Boring, 1941). In some situations, relational variables may allow more direct perception of size, such as the amount of ground surface covered by an object in

a situation where the surface has regular or stochastically regular texture (J. Gibson, 1950).

Among the most exciting developments in infant perception research has been the emerging conclusion that some degree of size constancy—the ability to perceive the correct physical size of an object despite changes in viewing distance (and resulting changes in projective size)—is an innate ability of human perceivers. Early research suggested that infants of about 4 months of age perceive an object's constant physical size at different distances and show a novelty response to a different-sized object, even when the novel object has a projective size similar to the previously seen object (Day & McKenzie, 1981). Studies of newborns have provided evidence that size constancy may be present from birth. Slater, Mattock, et al. (1990) tested visual preferences for pairs of identically shaped cubes of two real sizes (5.1 cm or 10.2 cm) at different distances (23 to 69 cm). Infants preferred the object of larger retinal (projective) size whenever it differed between the two displays. In a second experiment, infants were familiarized with either a large or small cube of constant physical size that appeared at different distances (and varying projective sizes) across trials in the familiarization period. After familiarization, infants were given a paired-preference test between the large and small cube on each of two test trials. For the test trials, the large and small cubes were placed at distances giving them equal projective sizes. This projective size was novel, that is, the cube that had been presented in familiarization was placed at a distance at which it had not appeared earlier (61 cm away for the 10.2 cm cube and 30.5 cm away for the 5.1 cm cube). Figure 3.8 illustrates the arrangements in familiarization and test conditions. Every infant ($n = 12$) looked longer at the object of novel physical size in the test trials, and the percentage of test trial looking allocated to the novel object was about 84%. Other evidence tends to support the conclusion that size constancy is observable in neonates (Granrud, 1987; Slater & Morrison, 1985).

Research on newborn size perception has not addressed directly the possible mechanism(s) underlying constancy. This topic would seem to be an important one for future research. There are not many possibilities, however. The objects in both the Slater et al. (1985) and Granrud (1987) experiments hung in front of homogeneous backgrounds, precluding use of relational information potentially available when an object rests on a textured ground surface. In the situations used, it would

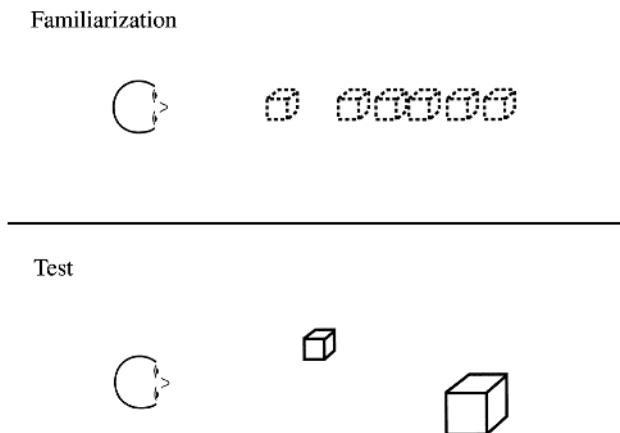

Figure 3.8 Familiarization and test displays used in a size constancy experiment. Each infant was familiarized with one object—either a large (10.2 cm/side) or small (5.1 cm/side) cube—at several viewing distances. The test pair consisted of the large and small cube placed at different distances (61 cm and 30.5 cm) to produce equal projective size. Object distances were different from those used during familiarization. *Source:* “Size Constancy at Birth: Newborn Infants’ Responses to Retinal and Real Size,” by A. Slater, A. Mattock, and E. Brown, 1990, *Journal of Experimental Child Psychology*, 49(2), pp. 314–322. Reprinted with permission.

appear that some information about egocentric distance, that is, distance from the observer, must be combined with projective size to allow computation of real size. Certain features of the experimental situations and newborns’ abilities suggest that binocular convergence is the likely source of egocentric distance information (Kellman, 1995). Estimates of the precision of convergence vary (Aslin, 1977; Hainline et al., 1992; Slater & Findlay, 1975), but some data and an analysis of the required precision of distance estimates needed to support size discriminations in the Slater et al. and Granrud experiments support this possibility (Hainline et al., 1992; Kellman, 1995).

FACE PERCEPTION

Perhaps the most important class of objects in the infant’s world is people. Not only are people perceptually very exciting for infants because they move, their motion is nonrigid, and they provide multimodal experiences; people are also important for ensuring the well-being of the infant. It is not surprising, then, that face perception is one of the oldest topics in infant perception, beginning with the writings of Darwin

(1872/1965) on facial expressions, and it continues to be one of the most researched topics today. Key questions pertain to how early in life infants perceive faces, information infants obtain from faces (e.g., recognition of familiar people, gender, emotional expression), and what processes underlie face perception.

Preference for Facelike Stimuli

Early work in infants’ face perception was concerned with the question of when infants perceive faces and in particular, when they know that faces have a particular set of features arranged in a particular way. Fantz (1961) conducted one of the earliest demonstrations that infants prefer facelike displays over other patterned stimuli. Further work using similar methods showed a consistent preference: Infants before 2 months of age showed no preference for a schematic versus a scrambled face (see Maurer, 1985 for an early review). However, the results were not altogether clear. Complicating the story was the use of different methodologies and different stimulus types by different researchers. In addition, at least one study did not fit this pattern: Goren, Sarty, and Wu (1975) used a tracking paradigm and showed that newborn infants tracked a schematic face farther than a scrambled face or a blank face shape. Replication of these results by Johnson, Dziurawiec, Ellis, and Morton (1991; but see Easterbrook, Kisilevsky, Muir, & Laplante, 1999) demanded a revision of the developmental story to include some face perception abilities by newborn infants.

Perceiving a face, particularly perceiving the internal details to recognize a face or to discriminate a scrambled face from a schematic face, requires a certain level of visual resolution on the part of the perceiver. Some research suggests that newborns lack adequate acuity or some other component of face processing to accomplish the task. As mentioned, Kleiner (1987) suggested that before 2 months of age, infants’ face preferences are driven by amplitude spectra (as derived from Fourier analysis). Consequently, infants’ early preferences for faces may not be driven by how a stimulus looks but by some rule about the population of frequency detectors. Using a clever manipulation, she presented infants with faces that contained the phase and amplitude spectra of a face or a lattice (see Figure 3.9b), the phase of the lattice and the amplitude of the face, and the phase of the face and the amplitude of the lattice. She found partial support for the sensory hypothesis. Newborn infants

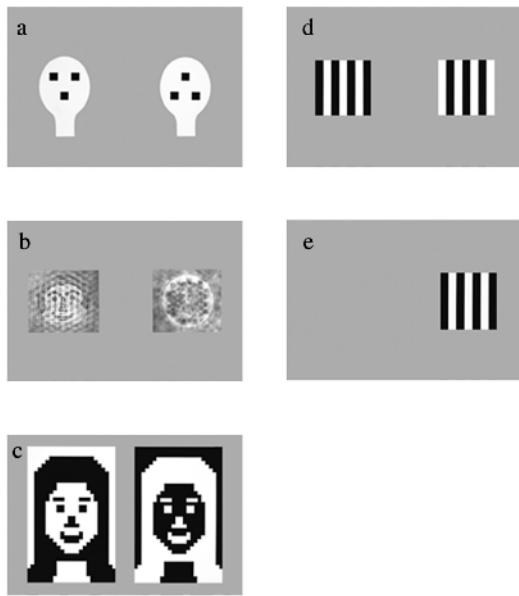

Figure 3.9 Stimuli used by Mondloch et al. (1999) to study newborn, 6-week-old, and 12-week-old infants' face perception. A, B, and C depict displays used previously (see text). D and E are control stimuli. *Source:* “Face Perception during Early Infancy,” by C. J. Mondloch et al., 1999, *Psychological Science*, 10, pp. 419–422. Reprinted with permission.

preferred the displays with the amplitude spectrum of the face, although they showed the strongest preference for the stimulus that had *both* the phase and amplitude of the face. Two-month-old infants preferred the displays with the phase spectra of the face.

A different explanation of the early data on face processing was proposed by Morton and Johnson (1991) and revised by M. H. Johnson (1997). Their account suggests that there are two mechanisms for face processing. The first, called CONSPEC, underlies early face perception. This process is innate, and it allows newborn infants to recognize structural information specifying conspecifics without exposure to specific stimuli. Infants respond to facelike stimuli because they look like a face; however, the structural information is very general, such that crude representations of faces (e.g., the upright *config* stimulus shown in Figure 3.9) can trigger this process. Around 2 months of age, a second mechanism emerges. This process, CONLERN, is dependent on visual experiences with faces, and it leads to representations of particular faces.

In an attempt to resolve some of the conflicting findings, Mondloch et al. (1999) conducted a preference study with newborns, 6-week-olds, and 12-week-olds

using pairs of stimuli from three different laboratories: the upright and inverted *config* stimulus used by M. H. Johnson, Dziurawiec, Ellis, and Morton (1991, see Figure 3.9a), mixed phase and amplitude spectra stimuli from Kleiner (1987, see Figure 3.9b), and positive- and negative-contrast faces from Dannemiller and Stephens (1988, see Figure 3.9c). In addition, they included a control stimulus to test for no preference (Figure 3.9c) and a clear preference (Figure 3.9e). They found that newborns preferred the *config* stimulus over its inversion and the amplitude spectrum of the face over the phase spectrum of the face (Figure 3.9b), but newborns showed no preference for the positive or negative contrast faces. Six-week-olds showed no preference for the *config* display or its inversion, a preference for the phase of the face over the amplitude of the face, and no preference for the positive or negative contrast faces. Finally, 12-week-olds showed no preference between the *config* stimulus and its inversion, but they showed a preference for the phase of the face over the amplitude of the face and they showed a preference for the positive contrast over the negative contrast face. From these results, Mondloch et al. concluded that newborns' preferences are guided by both the visibility of the stimulus and its resemblance to faces, and it is likely that newborns are predisposed to look toward faces. This explanation is similar to one proposed by Simion, Cassia, Turati, and Valenza (2001). They suggest that newborn preferences are determined by the match between both the sensory properties and the structural properties of the stimulus and the constraints of the visual system. One other finding worth mentioning is that 6- and 12-week-olds preferred the phase spectrum of a face—they looked more at the stimulus that looked like a face. These results suggest that face processing improves rapidly after birth, through maturation or through experience with faces, consistent with (but a bit earlier) than the sequence proposed by Morton and Johnson (1991).

These explanations for the early development of face processing are sensitive to the nuances of some experiments, but they may yet underestimate the capabilities of newborns. A number of startling findings have appeared, suggesting that newborn abilities go well beyond merely discriminating a schematic face from a scrambled face. Infants just a few hours old are reported to discriminate their mothers from a stranger (Bushnell, 2001; Bushnell, Sai, & Mullin, 1989; Pascalis, de Schonen, Morton, Deruelle, & Fabre-Grenet, 1995), and they show a preference for attractive faces over unattractive

faces as older infants do (Rubenstein, Kalakanis, & Langlois, 1999; Slater, Quinn, Hayes, & Brown, 2000; Slater et al., 1998). Newborns' recognition of their mothers may be based on external features such as hairline (Pascalis et al., 1995), but perception of attractiveness appears to rely on internal features and possibly their configuration (Bartrip, Morton, & de Schonen, 2001; Slater et al., 2000). The data on attractiveness suggest that infants must process the internal features of faces to a fine level of detail. At this time, we do not know how they do it, either in terms of specific face perception mechanisms or general capacities of the neonate visual system.

Perceiving Information about People through Faces

Beyond the newborn period, infants are sensitive to facial information that may be useful for recognizing specific people, perceiving characteristics of people, and for engaging in nonverbal communication. The ability to recognize a person across different views, or person constancy, is an important skill because faces (and people in general) are dynamic objects. Faces show differing expressions, and infants have the opportunity to view them from different perspectives. To recognize key people in their environment, infants must be able to perceive the constancy of a person despite proximal stimulus differences. One of the earliest studies of infants' perception of people across different views was conducted by Cohen and Strauss (1979). In this study, infants were habituated to views of the same female and then tested with an *enface* view. Infants did not recognize the *enface* view as the same person until 7 months of age. More recent studies have shown that babies may be able to recognize familiar faces (their mother but not a stranger) in different views, *enface*, but not in profile, as early as 1 month of age (Sai & Bushnell, 1988); and babies recognize faces across differing intensities of an emotional expression, namely smiling, at least by 5 months of age (Bornstein & Arterberry, 2003).

Infants have the opportunity to view faces in many perspectives, and certainly from angles different from those adults typically experience. Supine infants may often see faces oriented at 90 degrees or even completely upside down. For adults and older children, inversion of a face significantly disrupts recognition. This has been attributed to a processing strategy based on the relation between facial features ("configural" processing) as opposed to processing the facial features inde-

pendent of each other ("featural" processing; e.g., Carey & Diamond, 1977, 1994; Sergent, 1984). If and when infants are susceptible to this inversion effect (reduced recognition of inverted faces) has generated interest because of its implications for how infants may be processing faces. Presenting stimuli upside down to infants has been a procedure used by some researchers as a control for responding to specific features within a face (e.g., Bahrick, Netto, & Hernandez-Reif, 1998; Kestenbaum & Nelson, 1990; Slater et al., 2000); however, few direct tests of the inversion effect have been conducted. Cashon and Cohen (Cashon & Cohen, 2004; Cohen & Cashon, 2001a) habituated infants to two female faces. They were tested with a familiar face (one of the two viewed in the habituation phase), a novel face, and a combination face that consisted of the internal features of one of the habituation faces and the external features of the other habituation face. For half of the infants, the faces were presented upright and for the other half the faces were inverted. Across 3 to 7 months of age, infants showed movement toward configural processing of upright faces, and this type of processing was clearly evident by 7 months of age (see Cohen & Cashon, Chapter 5, this *Handbook*, this volume, for a representation of these data). For inverted faces, at most of the ages tested, infants showed no evidence of configural processing. An unexpected result was the lack of a monotonic change between 3 and 7 months in configural processing, a finding Cashon and Cohen (2004) attribute to general information-processing strategies that are not necessarily specific to face perception (see Cohen & Cashon, Chapter 5, this *Handbook*, this volume).

In addition to recognizing particular faces, infants may use information contained in faces to categorize people into classes, such as male and female. Perception of gender by adults can be based on superficial cues, such as hair length, facial hair, and makeup or on structural cues, such as the distance between the eye and brow (e.g., Bruce et al., 1993; Campbell, Benson, Wallace, Doesbergh, & Coleman, 1999). Infants' perception of gender has been assessed in the context of categorization tasks; infants are shown either male or female faces and are tested with a novel face of the same gender and a novel face of the opposite gender. Using this procedure, Leinbach and Fagot (1993) showed that infants categorize gender by 9 months of age with the aid of superficial features (stereotyped hair length and clothing). However, their findings were asymmetrical. Infants habituated to male faces looked significantly longer to

the female face in the test phase but infants habituated to female faces did not. Quinn, Yahr, Kuhn, Slater, and Pascalis (2002) further explored this asymmetry and found evidence that experience may have an influence on infants' preferences for male or female faces. In their study, 3- to 4-month-old infants were familiarized to either male or female faces and then tested for a preference for a novel same gender face or a novel opposite gender face. Infants familiarized to male faces preferred the female face, but infants familiarized to female faces did not show a preference for the male face. When Quinn et al. presented infants with the male and female test pairs without the familiarization phase, infants showed a strong preference for the female faces. This preference dipped only slightly when the hair was covered. When Quinn et al. recruited infants who had a male primary caregiver, a preference for male faces emerged. Finally, Quinn et al. familiarized infants, who had female primary caregivers with male or female faces and then tested them with a novel and familiar face of the same gender that was presented in the familiarization phase. Infants familiarized to female faces showed a preference for the novel female face, suggesting that they remembered the familiar female face. Infants familiarized to male faces showed equal amounts of attention to the novel and familiar male faces in the test phase. Quinn et al. concluded that infants' caregiver experience provides them with the opportunity to learn the details that define individual female faces relative to male faces. This may be the first study to indicate the role of experience in infants' face perception.

Faces also convey information about emotional states through facial expressions. Facial expressions may play an important role in communication for the nonverbal infant (e.g., Rochat, 1999; Russell & Fernandez-Dols, 1997), and infants have the opportunity to experience a variety of facial expressions. Moreover, there is evidence of similar expressions appearing in child-adult interactions across cultures (Chong, Werker, Russell, & Carroll, 2003). Consequently, perception and discrimination of emotional expressions become crucial for infants to be engaged social partners.

Infants between 5 and 7 months of age show evidence of discrimination of the facial expressions of happiness, anger, fear, and surprise (Bornstein & Arterberry, 2003; Kestenbaum & Nelson, 1990; Ludemann & Nelson, 1988; Serrano, Iglesias, & Loches, 1992). Moreover, they are able to categorize one or more of these expressions across different people. For example, Born-

stein and Arterberry (2003) habituated 5-month-olds to different intensities of smiling, from a slight upturning of the mouth to a full toothy grin, modeled by four females. Following habituation, infants viewed a fifth female modeling a never-before-seen mid-range smile and a sixth female modeling a fearful expression. Infants looked significantly longer to the fearful expression suggesting that they categorized the facial expression of smiling and treated the new smiling exemplar as fitting within that category. Other findings show that infants as young as 3 months discriminate different intensities of smiling (Kuchuk, Vibbert, & Bornstein, 1986), and at least by 6 months infants discriminate different intensities of frowning (Striano, Brennan, & Vanman, 2002). To date, little attention has been paid to the role of experience and infants' perception of facial expressions. However, Striano et al. found some relationship between 6-month-old infants' preferences for smile and frown intensities based on symptoms of depression in their mothers, and Montague and Walker-Andrews (2002) found that 3.5-month-olds can match the voice and facial expression (sad, happy, and angry) of their mothers, but not of their fathers or an unknown male or female.

Mechanisms of Face Perception

Researchers have made considerable progress documenting early infant face perception abilities. Given the wide array of recent findings, we may reconsider what possible mechanisms could underlie these abilities. There is strong evidence that infants are predisposed to attend to faces. Some claim this predisposition is the result of an innate representation for faces (e.g., Slater et al., 1998, 2000), whereas others claim it is the result of a quick learning process (e.g., Bednar & Miikkulainen, 2003; Bushnell, 2001). Advances in neuroimaging and electrophysiological techniques have provided researchers with the opportunity to identify areas of the nervous system that are involved with face perception (e.g., Gauthier & Nelson, 2001). Key areas that have been identified are the middle fusiform gyrus in the right hemisphere for perception of upright faces (Kanwisher, McDermott, & Chun, 1997) and the amygdala for perceiving facial expressions (Whalen et al., 1998). Work with nonhuman primates has identified face-responsive cells in the inferior temporal cortex (e.g., Rolls & Baylis, 1986). Explanations for the development of face perception abilities in infants have to greater and lesser degrees been linked to these neurophysiological findings.

Several proposals have been advanced. One is that face processing in infants shows a right hemispheric advantage with implication of the fusiform gyrus (e.g., Deruelle & de Shonan, 1991). These areas develop more quickly in the right hemisphere than in the left, and experience with faces contributes to the specialization of this area for face perception. A second explanation proposed by Johnson and his colleagues (e.g., Morton & Johnson, 1991) is that the two processes, CONSPEC and CONLERN, are subserved by different mechanisms. They claim that CONSPEC is a subcortical process involving the superior colliculus and that CONLERN is a cortical process involving the primary visual cortex. The later emergence of CONLERN reflects the maturational constraints of these areas.

Nelson (2001) provides a third possibility. Relying on speech perception as a model, he proposes that face perception abilities initially are responsive to a wide variety of facelike stimuli, including faces from other species, and these abilities are tuned with age as a result of specific experiences. The development of speech perception begins with some specific skills—infants recognize their mother's voice, and they discriminate a range of speech sounds. More impressive is that young infants are able to discriminate speech sounds ("nonnative speech contrasts"; Werker, 1994) that adults in their environment cannot. The ability to discriminate nonnative speech contrasts diminishes with exposure to language, and infants' speech perception abilities are generally tuned to their linguistic environment by 10 to 12 months of age. In other words, there is a perceptual window that narrows throughout the 1st year of life depending on experience. Nelson suggests a similar fine-tuning of face perception abilities. For example, young infants are better than adults in recognizing faces of monkeys, an advantage that decreases across the 1st year of life (de Haan, Pascalis, & Johnson, 2002; Pascalis, de Haan, & Nelson, 2002). Nelson also cites other areas of face processing, such as the "other race" effect (e.g., O'Toole, Deffenbacher, Valentin, & Abdi, 1994) and the inversion effect, as examples of the fine-tuning of face perception. Further relying on the speech perception model, Nelson (2001) suggests that neural tissue has the potential to become specialized for face perception, and the nature of this specialization depends on specific experiences. Support for this idea comes from studies of children and adults who were born with cataracts: Visual deprivation during the first 7 weeks of life due to congenital

cataracts resulted in significant and apparently permanent impairment in face processing later in life (Geldart, Mondloch, Maurer, de Schonen, & Brent, 2002).

More work is needed to fully understand the underlying mechanisms of face perception. A commonality among emerging explanations is a role for experience in the tuning of face perception abilities.

CONCLUSION

In this concluding section, we touch on a few issues relevant to all the research we have described. We draw some conclusions about levels of analysis in research on perceptual development, identify some priorities for future work, and consider the consequences of what has already been learned for understanding the development of perception.

Levels of Analysis

Research in infant vision involves work at different levels of analysis. Ordinarily, this idea would be offered in an introduction, but perhaps it is easier to see looking back at the research we have surveyed (for a more extensive discussion of levels, see Kellman & Arterberry, 1998, chap. 1; Marr, 1982). Consider the issues about kinematic information in early perception. We described relations in optical transformations, such as motion perspective, that underlie perception of 3D form, and accretion and deletion of texture, which provides information about relative depth. The description of perceptual tasks, such as seeing form and depth, and the information that allows perception to occur, has been called the *computational* (Marr, 1982) or *ecological* (Kellman & Arterberry, 1998) level of analysis. More crucial than the specific name used is the realization that understanding vision (and other information-processing tasks) begins with an account of the task to be achieved and the information and constraints that make it possible. In infant vision, we ask whether and how information in reflected light allows infants to see objects, motion, and the layout of space.

Information at a second level—the level of representation and process—involves the ways that information is represented and transformed. Whereas the ecological level describes how information is manifest in the world, the level of representation and process describes information processing inside the perceiver. Investigations of

the common motion process in infant perception of object unity is an example of work that addresses information processing in early perception; evidence showing the combining of distance information with retinal size or motion is another. As we note below, infant perception research has been far more successful at revealing the sensory and perceptual capabilities of infants than at probing detailed processes and representations.

Finally, many of the findings we have reviewed involve the biological mechanisms that carry out perceptual information processing. To encompass both human and artificial systems, Marr (1982) called this level the *level of hardware implementation*. For humans, the question is about *biological mechanisms* (as opposed to silicon and germanium chips that might process stereoscopic disparities in a computer vision system). Work on the maturation of retinal receptors, on color vision mechanisms, neurological regions implicated in face perception, and on the maturation of stereoscopic depth perception are all examples of work primarily at the level of biological mechanism.

It is a relatively recent realization that all three levels must be addressed to understand visual perception. This understanding, which applies to information processing phenomena in general, owes much to the work of J. Gibson (1966, 1979), who emphasized the study of the information available for perception. Although seldom explored, Gibson's work has important parallels with the work of Chomsky (e.g., 1965, 1980) who emphasized that the structure of language is an object of study in its own right and that this study is an important starting point of linguistic analysis. For Gibson, the structure to be uncovered exists in the physical world; for Chomsky, it is in language. Most directly, however, the framework of three levels we have presented here derives from Marr (1982).

The need for multiple levels of analysis has been discussed extensively elsewhere, so here we merely note some of the important implications. One is that the levels are relatively independent of each other. Finding data that disconfirm a particular neural model does not invalidate an accompanying algorithm or ecological theory. Another is that one cannot simply catalog the anatomy and neurophysiology of the optical pathways and brain structures and expect to understand vision (Marr, 1982). One might catalog indefinitely many properties of neural structures but understand their functions only when these are tied to a particular task,

process, and representation. One of Marr's (1982) favorite examples was the relation between a bird's feathers and the laws of aerodynamics. It would be foolish to believe that the laws of aerodynamics could have ever been derived from an intensive study of feathers. In fact, the flow of understanding runs in the opposite direction. Knowing something about aerodynamics helps us understand what feathers are doing on birds. Without understanding the demands of flight, we could aimlessly record many details of feathers and note their presence on birds as a curiosity.

Finally, an encouraging trend in the cognitive and neural sciences is an improved ability to understand relations among facts at the three levels. Although a complete understanding of the task, information, processes, and mechanisms is not in hand for any domain of infant visual perception, considerable progress is being made on each level, and on their relationships.

Hardwiring versus Construction in Visual Development

As mentioned, one reason for long-standing interest in infant visual perception is to help understand the contributions of nature and nurture in the development of the mind. Although many important questions remain, we can make some global statements about the origins of visual abilities. Vision develops from innate foundations. The basics of many visual abilities can be discerned at birth, and some others appear to unfold according to a maturational program. Input from the environment may play a role in refining or calibrating many visual functions, and it may yet turn out to be the driving force in the development of a few.

These general statements contradict a long history in philosophy, psychology, and cognitive science in which the dominant view of perception's origins has been that it emerges gradually through a constructive process, shaped largely by external input. The development and ingenious application of methods for studying early perception, over the past several decades, have produced this radical change in perspective in understanding vision. When we look at basic visual sensitivities, such as sensitivity to orientation and pattern, we see that infants' capabilities do not match those of adults, but are clearly present to some degree at birth. Other basic components of visual sensitivity, such as sensitivity to motion direction, appear over the first 6 to 8 weeks of life,

a period during which rapid brain maturation occurs and most visual sensitivities improve markedly.

Most interesting for general accounts of how perception works is the story of early *perceptual* abilities. Research on infant vision indicates that infants attend from birth to faces, and they show some face recognition abilities in the first few days of life (Bushnell, 2001; Bushnell et al. 1989). Under at least some conditions, they perceive the shapes and sizes of objects despite variations in their depth and slant (Slater et al., 1990). These findings refute theories claiming that perception of the third dimension and perception of objects are hard-won developmental acquisitions dependent on associative learning. Perception of a 3D world of objects, surfaces, and events appears to be the starting point, not the result, of early perceptual contact with the world (Kellman & Arterberry, 1998).

Propelled in part by interest in connectionist networks, there has been a resurgence in recent years of strongly empiricist views of development (e.g., Elman et al., 1996). One often encounters one or another version of the claim that the human visual system “gets wired up by experience,” much as the weights in a connectionist network change by interacting with input patterns (e.g., Purves & Lotto, 2003, although these authors acknowledge that initial architecture providing basic sensitivities, such as orientation, is innate). Evidence of early-appearing abilities, such as face perception, tend to be interpreted as “nonrepresentational” or as attentional biases that can lead to rapid learning (Elman et al., 1996).

Although perceptual learning is important throughout the life span (see Kellman, 2002, for a review), the basic issue of whether perceptual systems reveal a meaningful reality from birth appears to have a positive answer. These abilities seem to pass the tests required of true perceptual knowledge and implicate capacities to represent objects, space, and events (Kellman & Arterberry, 1998). The findings about early perception rule out the time-honored idea that perceptual reality is initially constructed from experience and also casts doubt on the idea that early experience consists of “image schemas” or some other product that falls short of representing aspects of the world. Meaningful perception operates from birth.

This global conclusion may revolutionize our view of early development, but it should not obscure the complexities of infant vision. In one domain after another—

in pattern perception, space perception, object perception, and face perception, to name a few—we see a similar picture: Certain kinds of information are usable by infants much earlier than others. The infant has perceptual contact with a 3D world from birth, but does not use pictorial depth cues until 6 to 7 months of age. Perception of object unity from motion can be found in experiments as early as the infant has basic motion direction sensitivity, but the value of edge relatability in producing perceived unity cannot be demonstrated until later. Moreover, most aspects of sensitivity in the infant’s visual system improve for many months after birth or first appearance. Many of these changes are not yet well understood. There are ample ways in which both maturation and the effects of external signals in tuning neural circuitry could be involved. Some acquisitions may even fit the classic paradigm of cue learning, such as the depth cue of familiar size.

Future Directions

In the fifth edition of this *Handbook*, the final paragraph of the chapter on infant visual perception began “Further progress in understanding the characteristic pace and sequencing of visual abilities will require a deeper understanding of processes and mechanisms.” This statement remains true and suggests some of the most difficult challenges in the field. Obtaining a description of early perceptual abilities, once thought to be scientifically impossible, has turned out to be easier than obtaining detailed insight into the processes and mechanisms of development. Understanding the computations and neural bases underlying specific visual abilities, and discovering the contributions of maturation and learning that build on the infant’s early endowment, are among the highest priorities for future research.

RECLAIMING MOTOR DEVELOPMENT

For many years, motor development has been the area of developmental psychology that dare not speak its name. In lieu of *motor development*, researchers have preferred terms like *perceptual-motor development*, *perception and action*, and *motor skill acquisition*. Perhaps the eponym “motor development” does not sound sufficiently psychological, whereas names like perceptual-motor development remind readers that the adaptive control of motor actions involves proper psychological processes such as perception, planning, decision making, memory, motivation, intentions, and goals.

The field of motor development has lost two of its great leaders, Esther Thelen (1941–2004) and Eleanor Gibson (1910–2002). We dedicate this chapter to them. We thank Robert Siegler, Beatrix Vereijken, Peter Gordon, Scott Robinson, Rick Gilmore, Blandine Bril, Rachel Keen, Neil Berthier, Claes von Hofsten, Catherine Tamis-LeMonda, Dick Aslin, Amy Joh, Jesse Young, Simone Gill-Alvarez, Jessie Garciaguirre, and Katherine Dimitropoulou for their helpful comments. We thank Jessie Garciaguirre, Sharon Lobo, and Felix Gill-Alvarez for their tireless assistance and Judy Kwak and Lana Karasik for their gracious help. Work on this chapter was supported by National Institutes of Health grants HD-33486 and HD-42697 to Karen Adolph.

REFERENCES	202

Sure, every introductory textbook contains a chapter called “Motor Development,” usually paired with physical growth. But, the textbook inventories of infantile reflexes, motor milestones, and growth charts do not reflect the kind of work that currently characterizes the field. Most of us do, in fact, study perception-action coupling with the aim of understanding developmental changes in the perceptual, cognitive, social, and emotional processes that contribute to the adaptive control of motor actions. However, many developmental psychologists also study the formal structure of movements with the aim of using motor development as a model system for understanding more general developmental processes and principles. In recognition that motor development involves two kinds of research—using the formal structure of infants’ movements to elucidate general principles of development as well as a focus on developmental changes in the perceptual control of motor actions—we have, without apology, entitled this chapter, “Motor Development.”

The Formal Structure of Movements

A remarkable thing about motor skills is that movements are directly observable. Most domains of psychological

development are the hidden denizens of mental activity. The content of children's thoughts, percepts, emotions, intentions, concepts, memories, and linguistic representations must be inferred from overt motor behaviors such as speech, gestures, facial expressions, and eye movements, or in more technically sophisticated labs, from images of brain activity. Likewise, the moment-to-moment time course of mental activities must be inferred from children's vocalizations, patterns of looking behavior, manual and facial expressions, or from the traces of brain activity on an electroencephalogram. Descriptions of developmental changes in mental activity can be even more removed from direct observation because researchers frequently must rely on different tasks and procedures to study children at different ages, typically looking behaviors at younger ages and manual or vocal behaviors at older ages (Hofstadter & Reznick, 1996; Keen, 2003).

In contrast to the covert nature of mental events, motor behaviors are out in the open. As Gesell (1946) wrote in an earlier chapter in this *Handbook*, motor behaviors "have shape" (p. 297). Every wiggle and step occurs over measurable time and space. The traces of motor activity on a video monitor or three-dimensional motion-recording device are a direct readout of the movement itself. No inferential leap separates a motor skill from a description of its form. What you see is what you get.

Moreover, researchers can observe the changing form of children's movements over multiple, nested time scales. The time-space trajectory of infants' first awkward arm extensions can be compared with changes in the speed and straightness of the reaching trajectory over the trials in a single session, and across multiple sessions conducted over days, weeks, and months of practice. Milliseconds and millimeters are nested within larger time-space units. Changes in real time can be tracked directly over learning and development.

A benefit of being so conspicuously available to observation is that motor development makes a unique model system for studying general developmental processes—the origins of new behavioral forms; the extent to which development is patterned, orderly, and directional; the role of variability in facilitating or impeding development; whether developmental trajectories are continuous or stagelike; whether changes are universal across individuals and cultures; and so on. Such general issues of form and timing can be fruitfully addressed with a model system in which form and timing are transparent.

Inspired by Coghill's (1929) example of linking developmental changes in the swimming patterns of salamander embryos with general principles of embryological development, the great pioneers in motor development—McGraw, Gesell, and Shirley—used changes in the form and temporal structure of infants' movements as illustrations and existence proofs of general developmental processes. The focus on formal structure is beautifully exemplified in the line drawings that figured prominently in the work of the early pioneers (see Figure 4.1). Infants (like salamanders) are drawn abstracted from the surrounding context to highlight the changing morphology of the movements. Gesell (1946) described changes in the temporal structure and spatial configuration of infants' crawling movements to demonstrate the existence of qualitative changes in human development. Likewise, contemporary researchers, led by Thelen and her colleagues (e.g., Thelen & Ulrich, 1991), have used the changing shape of infants' reaching, grasping, kicking, stepping, crawling, walking, and jumping movements to illustrate developmental trajectories, propose general principles of developmental change, and speculate about biologically plausible developmental mechanisms.

Whereas most model systems are scaled-down versions of the target phenomenon, the beauty of using the changing shape of infants' movements to understand development stems solely from the fact that we can see infants' movements, not from their simplicity or

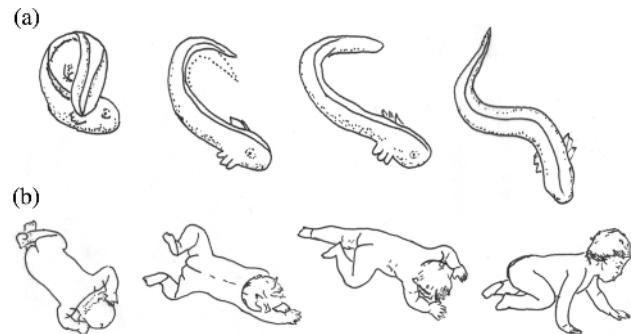

Figure 4.1 Examples of line drawings used by early pioneers in motor development to illustrate the changing morphology of movements. Ames, 1940, *Journal of Genetic Psychology*, 56, pp. 247–263. Reprinted with permission.

tractability. Coghill (1929) expressly selected salamanders for a model system of embryological development because salamanders' primitive C- and S-shaped swimming movements and simple nervous systems are scaled-down versions of locomotion and its correlated activity in the central nervous system (CNS) of higher vertebrates. In contrast, infants' movements are not scaled-down versions of adults' movements, nor are infants' movements easy to elicit or record. Rather, babies' clumsy walking steps, reaches, and head and eye movements are notoriously variable and complex compared with those of adults. Even newborn reflexes and infants' spontaneous writhing and flailing have a variable and complex spatial and temporal structure.

In fact, to describe developmental changes in the time-space trajectories of infants' movements, researchers in motor development have led the field of developmental psychology in devising techniques to elicit, catalog, record, and analyze time-based behavioral data. In the 1930s, Gesell and Thompson (1934, 1938) designed a "behavioral interview" to systematically elicit developmental changes in various motor skills over infants' first 2 years of life. Gesell's tasks and detailed catalog of age-based changes are the basis for the famous Bayley Scales of Infant Development (1993) and other modern developmental screening tests (e.g., Frankenburg & Dodds, 1967).

Decades before behavioral coding from video recordings was a mainstay of every developmental laboratory, McGraw (1935, 1945) and Gesell and Thompson (1934, 1938) had devised sophisticated techniques for capturing infants' movements on high-speed film. Long before researchers in other areas of development had compiled databases of children's behaviors such as the CHILDES database of children's language, McGraw (1935), Gesell and Thompson (1938), Shirley (1931), and their contemporaries had constructed archival libraries of infants' movements. A century before the recent advent of time-based eye-tracking and brain-imaging techniques with infants, researchers in motor development struggled with the problem of representing and analyzing time-based data.

Perceptual Control of Motor Actions

Being out in the open has implications beyond visibility: The functional outcome of motor actions is inextricably bound to the biomechanical facts of children's bodies and the physical properties of their environments. In A. Clark's (1997) words, motor actions are always "em-

bodied" and "embedded," always performed by a creature with certain bodily capabilities and deficiencies and always performed in an environment with certain supports and hindrances. James and Eleanor Gibson's concept of "affordances" captures the functional significance of embodiment and embeddedness: Possibilities for action depend on the fit between actors' bodies and the surrounding environmental properties (E. J. Gibson, 1982; E. J. Gibson & Pick, 2000; J. J. Gibson, 1979). Whereas mental activity can be modeled profitably with a mathematical equation or a computer program at some remove from the limits and propensities of a physical body in a real world, a formal model of motor action is probably best simulated in a physically instantiated, free-wheeling robot (Brooks, 1991; Kuniyoshi et al., 2005). Like us, but unlike equations or computer software, robots are subject to physical forces.

Possibilities for action depend on all the myriad facts of embodiment. The size, shape, mass, compliance, strength, flexibility, and coordination of the various body parts can all affect the biomechanical constraints on action. The same functional outcome can require very different motor actions depending on the body's status. For example, to bring their hands to their mouths at 7 weeks after conception, fetuses must raise their arms at the shoulder because their arm buds are so short (Moore & Persaud, 1993). To produce the same hand-to-mouth action several weeks later, fetuses must deeply bend their arms at the shoulder and elbow because their arms are much longer (Robinson & Kleven, in press).

Reciprocally, affordances for action depend on the mundane constraints of the environment in which infants' bodies are embedded—the surfaces and media that support the body, the objects toward which movements are directed, and the effects of gravity acting on the various body parts. Again, fetal development provides a simple but compelling example. At 7 weeks post-conception, vigorous leg kicks can somersault the fetus through the amniotic fluid (deVries, Visser, & Prechtl, 1982). At 38 weeks, when the growing fetus is pressed against the walls of the uterus, the same muscle actions will fail even to extend the legs. After birth, when infants have ample room to move freely but have lost the buoyancy of a watery environment, the same muscle actions are subject to the pull of gravity. Now a vigorous kick merely flexes and extends the leg.

Our examples from fetal development illustrate a central and inescapable feature of motor action: The constraints of the body and the environment are continually changing. The facts of embodiment vary due to

developmental changes in the body (such as the lengthening and differentiation of the fetal arm) and the flux of everyday activities (Adolph, 2002; Reed, 1989). Carrying a toy under one arm, lifting a leg, or even drawing a deep breath create moment-to-moment changes in functional body dimensions and in the location of the body's center of mass. Similarly, the environmental context is a shifting landscape, not a still life. Developmental changes in infants' bodies and skills continually introduce them to new objects and surfaces and invite new possibilities for interaction. Observing children at a playground, for example, is a revelation in attention to new affordances (E. J. Gibson, 1992). The slide might serve as tent, downhill track, or uphill path; the monkey bars as canopy or ground surface; the swing set leg as barrier, maypole, or fire pole, depending on children's changing propensities. The perfect robot simulation of infant motor development would require a machine whose body and environment develop.

Novelty in local conditions is the rule, not the exception. Behavioral flexibility is imperative, not optional. Contemporary researchers in motor development have focused so much of their attention on perception-action coupling because it is only through perceptual information that infants can guide their movements prospectively and adaptively (e.g., von Hofsten, 2003, 2004). Changes in the biomechanical constraints on action alter the forces required to produce the desired functional outcome. Perception specifies the current status of the body and the environment in which it is embedded, thereby giving infants access to the current constraints on action (J. J. Gibson, 1979). Perception allows actions to be planned prospectively and gears action to the environment. Motor actions complete the perception-action loop by generating information for perceptual systems and bringing the appropriate sensory apparatus to the available information. In Gibson's (1979) words, "We must perceive in order to move, but we must also move in order to perceive" (p. 223). The interreliance between perception and action is so important for the adaptive control of motor actions that the chapter on motor development in the fifth edition of this *Handbook* (Bertenthal & Clifton, 1998) was entitled "Perception and Action."

Chapter Overview

In addition to the chapter in the previous edition of the *Handbook* (Bertenthal & Clifton, 1998), the literature has amassed several detailed and comprehensive reviews

of research on motor development, including chronologies of normative changes in motor skill acquisition and in-depth treatments of particular action systems such as looking, reaching, object manipulation, posture, and locomotion (e.g., Adolph, 1997; Adolph & Berger, 2005; Bushnell & Boudreau, 1993; Campos et al., 2000; E. J. Gibson & Schmuckler, 1989; Vereijken, 2005; von Hofsten, 1989; Woollacott & Jensen, 1996). Moreover, numerous articles and books present the two dominant theoretical perspectives in research on motor development, the dynamic systems and ecological approaches (e.g., Adolph, Eppler, & Gibson, 1993b; E. J. Gibson, 1988; E. J. Gibson & Pick, 2000; Goldfield, 1995; Smith & Thelen, 1993; Spencer & Schöner, 2003; Thelen, 1995; Thelen, Schöner, Scheier, & Smith, 2001; Thelen & Smith, 1994, 1998; von Hofsten, 2003, 2004; Zanone, Kelso, & Jeka, 1993). Proponents of dynamic systems views tend to stress the formal structure of movements with the aim of building a unified theory of development. Proponents of the ecological approach emphasize the functional links between perception and motor actions in an effort to understand the psychological underpinnings of motor development. However, most researchers agree that the ideas and methods of each approach are highly compatible and complementary (e.g., Bertenthal & Clifton, 1998).

Our aims are somewhat different from the previous efforts. Instead of presenting a comprehensive chronology of motor behaviors, updating earlier reviews of the various body parts and action systems, or evaluating the relative merits of the dynamic systems and ecological approaches, we focus on the concepts, questions, issues, and principles that excite researchers in motor development and that are likely to be of interest to readers in other areas of developmental psychology. Thus, our review is organized around ideas.

The chapter is divided into two large sections representing the two kinds of research programs that characterize current work in motor development. The first section treats motor development as a model system. We focus on the formal structure of movements and describe how researchers have used the changing shape of infants' movements as a model system to address general issues of developmental processes and to propose general principles of change. The second section treats motor development as a perception-action system. We focus on the functional links between perceptual information and motor actions and describe how developmental changes in the interplay between perception and

action make infants' motor actions increasingly flexible and adapted to features of the environment. In principle, findings generated by the perception-action approach could be used to draw general lessons about development. In practice, however, researchers have focused on the particular perception-action system that they are studying. In both sections, we present case studies that are especially useful illustrations of conceptual insights, fruitful arguments, and new ways of thinking about motor development. The case studies highlight motor development during the first 2 years of life to reflect the period where most research has focused.

MOTOR DEVELOPMENT AS A MODEL SYSTEM

Motor development in infancy is truly remarkable. Developmental changes in the form and structure of infants' movements are tremendous in scope. At birth, babies can barely lift their heads. Eighteen months later, infants run across the room and navigate a tiny bit of food from plate to mouth with a pincer grip. Even to an untrained eye, many of infants' dramatic accomplishments involve a clear mapping of babies' clumsy head/eye, arm/hand, torso/leg movements onto adult-like looking, reaching, sitting, and walking movements. Conversely, some of the most dramatic developmental changes involve apparent disjunctions between behavioral forms—the disappearance, for example, of “newborn reflexes” and infants’ abandonment of transient forms such as “tripod sitting” (propped on the arms between the outstretched legs), crawling on belly and hands and knees, and sideways “cruising” while hanging onto furniture for support.

The case studies in this section highlight many of the dramatic accomplishments and disjunctions in motor development to illustrate general issues of developmental process. In addition, we focus on an equally remarkable aspect of infants' movements: the ubiquity of movement across real time and development. Mundane eye scans, startles, wiggles, and flails of every body part from toes to tongue constitute a pervasive background of movement against which the more dramatic motor milestones appear in spotlight. Normally, background movements are so ubiquitous and seamless that they go unnoticed. However, when infants' development goes awry due to prematurity or impairment, abnormalities in muscle tone, coordination, and motor control bring background

movements to the fore. Simply breathing can become a struggle. Thus, we conclude this section by describing the background chorus of movements that are so typically overlooked by researchers and parents.

Qualitative Changes

Motor development has always been a testing ground for addressing the nature of developmental change. Is development continuous, marked solely by changes in the relative quantities of behaviors? Or, are changes discontinuous, such that development also entails qualitative, stagelike transformations?

Developmental Stages

The most widely recognized legacy of the early pioneers in motor development is their normative descriptions of stagelike changes in reaching, grasping, crawling, and walking and their focus on maturation as the driving force of development (Ames, 1937; Burnside, 1927; Gesell & Ames, 1940; Gesell & Thompson, 1934; Halverson, 1931; McGraw, 1945; Shirley, 1931). McGraw (1945) described visually guided reaching as a six-stage progression beginning with neonates who cannot unequivocally fixate a target object and ending with children in Stage 6 who retrieve objects casually and successfully, taking the target's location and size into account without outward signs of “undue attention” (p. 99). Halverson (1931) described 10 milestones in the development of grasping, beginning with the “primitive squeeze” and culminating in the “superior-forefinger grasp.” Shirley (1931) described four stages in the development of walking: newborn stepping movements, standing with support, walking when led, and finally walking alone toward the end of the 1st year. Gesell, the consummate list-maker, described detailed series of stages for 40 different motor behaviors—58 stages of grasping a pellet, from newborns' visual regard to toddlers' “plucks pellet with precise pincer prehension” at the finale; 23 stages of crawling, from “passive kneeling” in Stage 1 to crawling on hands and knees in Stage 19; and so on (Ames, 1937; Gesell, 1933, 1946; Gesell & Thompson, 1938).

To modern researchers in motor development, the reifying of behaviors into stagelike lists seems old-fashioned, and attributing maturation as the driving force for infants' progress through the various stages seems simplistic (Bertenthal & Clifton, 1998; Thelen & Adolph, 1992). Ironically, Gesell (1946), McGraw

(1935), and Shirley (1931) explicitly noted that most children straddled adjacent stages, skipped stages, reverted to earlier stages, exhibited behaviors that did not fit the structural descriptions of stages, and displayed vast individual differences. The enterprise of distilling real-time structure from variable motions and essentializing invariant sequences from developmental variability was instigated by a direct and conscious opposition to prevailing theories of conditioning and habit formation (Adolph & Berger, 2005; Thelen & Adolph, 1992). Likewise, the intense focus on maturation as the causal agent for development was a response to the extreme versions of behaviorism that were so popular at the time (Senn, 1975).

What's New?

What then, might we take from the early pioneers? The so-called stages of infants' motor skills highlight a central question in developmental psychology: Is there ever anything truly new? On the one hand, the qualitative changes in formal structure between earlier and later appearing stages of motor skills provide *prima facie* evidence that new behavioral forms can appear in development. Visual prehension, crude raking motions, and precise pincer prehension do not merely reflect changes in the speed, accuracy, and variability of a grasp. These behaviors are qualitatively different forms. Passive kneeling, belly crawling, hands-knees crawling, and Gesell's 20 other stages of crawling share the common feature of prone body position, but these behaviors are qualitatively different in terms of the relevant body parts used for balance and propulsion and the temporal-spatial coordination of the various limbs. Such qualitative changes in the directly observable domain of motor skills provide a model system for evaluating arguments that development can entail qualitative change. One of the most influential ideas in research on cognitive development is that children's mental structures can reorganize into qualitatively different, incommensurable ways of thinking (Carey, 1985; Piaget, 1954).

On the other hand, the reasonableness of each behavioral series points to core commonalities between stages in motor skill acquisition. Armed with modern, high resolution recording technologies that allow exquisitely detailed descriptions of infants' movements, muscle actions, and force profiles, current research findings have tended to blur the distinction between stages by highlighting more continuous changes in the subtle elabora-

tion and increasing precision of reaching and walking movements (Berthier, Rosenstein, & Barto, 2005; Bril & Breniere, 1992). Moreover, the notion that earlier appearing behaviors may be preformations of later appearing behaviors is a well-accepted concept in developmental psychology (Thelen & Adolph, 1992), as witnessed in von Hofsten's (1984) prereaching, Meltzoff and Moore's (1983) neonatal imitation, and Trevarthen's (1993) protocommunication. In cognitive development, Spelke and others (Spelke, Breinlinger, Macomber, & Jacobson, 1992; Spelke & Newport, 1998) argue that core concepts presage mature thinking in domains of physical, biological, and psychological reasoning. On these views, the adultlike endpoint is an elaboration of the initial concept, rather than a metamorphosis or true transformation.

Emergent Developments

The most prevalent view of development among both academics and laypersons is that developmental changes are driven by some factor or set of factors, located in the environment, the brain, or the genes. These factors, either acting alone or in combination, are the drivers—the causal agents—of developmental change. An alternative *systems* view of development was spearheaded largely by Thelen and colleagues' work on infants' leg and arm movements (e.g., Thelen & Smith, 1994). On this account, motor development, like developmental changes in any domain, may result from the spontaneous self-organization of the various components in the system. The emergent product of the mix is different from and greater than the sum of its component parts.

Brain-Based Explanations

Although most modern researchers scoff at Gesell's idea that neural maturation drives motor skill acquisition lockstep through a series of stages, many modern researchers assume that neural maturation plays a pivotal role in motor development. Researchers presume that differences in pre- and postnatal neural maturation contribute to differences in locomotor abilities between precocial animals such as chicks and altricial animals such as rats (Muir, 2000). Maturation of postural mechanisms in the central nervous system (CNS) underlie age-related changes in children's response to balance disruptions (Forssberg & Nashner, 1982; Riach & Hayes, 1987; Shumway-Cooke & Woollacott, 1985).

Maturational changes in the speed of information processing facilitate walking onset toward the end of infants' 1st year (P. R. Zelazo, 1998; P. R. Zelazo, Weiss, & Leonard, 1989). Alternatives to maturation tend to emphasize experience-driven changes in the CNS. For example, some of the differences in motor precocity between chicks and rats may result from the longer period of time that chick embryos spend moving their legs compared with rat fetuses prior to hatching or birth (Muir & Chu, 2002). Experience maintaining balance in a variety of upright postures and tasks may reorganize how the CNS controls the various body parts when balance is disrupted (Ledebt & Bril, 1999; Roncesvalles, Woollacott, & Jensen, 2001).

Modern brain-based explanations for motor development are in good company. Theoretical debates about the sources of cognitive and perceptual development also center around maturation versus experience-driven changes in the CNS (e.g., M. H. Johnson, Munakata, & Gilmore, 2002; Spelke & Newport, 1998). Researchers' shared partiality for the brain over other body parts makes sense: The brain is of psychological interest, whereas the elbow and the knee are not. Using the developmental trajectory of infants' leg movements as an extended case study, we describe the alternative possibility that no factor, including the brain, is logically responsible for development. In this alternative account, changes in more homely factors normally outside the purview of psychologists' interest, may be the critical facilitators of development. Undoubtedly, important changes in the brain and nervous system occur throughout development. At issue is whether these changes must enjoy a privileged status in explaining developmental progress.

Alternating Leg Movements

We begin with the observations and puzzles that originally fascinated researchers. The observations are these: Newborn infants perform alternating leg movements if an experimenter holds them upright with their feet against a solid surface (see Figure 4.2a). The "steps" are painfully slow and exaggerated (Forssberg & Wallberg, 1980; Shirley, 1931), but, like mature walking, first one leg moves and then the other. At approximately 8 weeks of age, upright stepping movements disappear. Infants either stand rooted to the ground (McGraw, 1935) or perform bouncing movements by simultaneously flexing both legs and then extending them

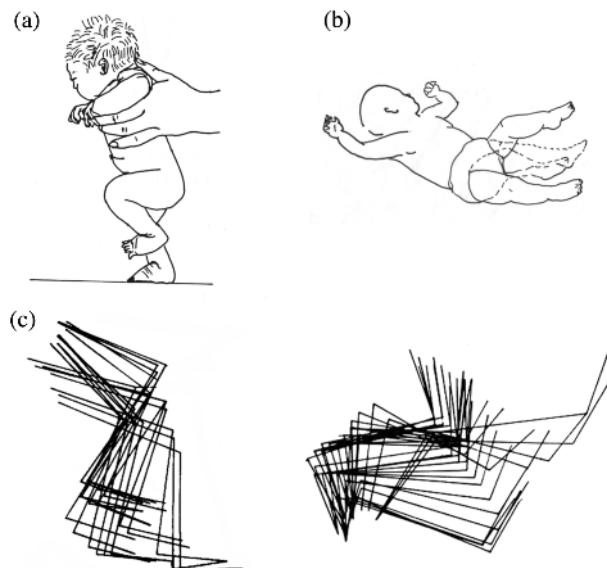

Figure 4.2 Alternating leg movements in newborn infants. (a) Upright stepping. Courtesy of Karen E. Adolph, New York University. (b) Supine kicking. *Source:* From "Rhythmic Stereotypies in Normal Human Infants," by E. Thelen, 1979, *Animal Behavior*, 27, pp. 699–715. Reprinted with permission. (c) Stick diagrams of leg movements in upright stepping and supine kicking in a representative 2-week-old infant. The lines chart the movements of one of the infant's legs at toe, ankle, knee, and hip every 33 milliseconds. *Source:* From "Newborn Stepping: An Explanation for a 'Disappearing Reflex,'" by E. Thelen and D. M. Fisher, 1982, *Development*

(J. E. Clark, Whitall, & Phillips, 1988; McGraw, 1932). Upright stepping returns toward the end of the 1st year when infants begin to walk with support and eventually to take independent walking steps. This U-shaped developmental progression raises three intriguing puzzles:

1. What makes newborns step?
2. Why do infants exhibit the alternating pattern rather than some other pattern of leg movements?
3. What makes upright stepping disappear and then reappear months later to cause the U-shaped trajectory?

Reflexes

Puzzle 1—why newborns step—is a question about proximal cause. The most commonly held answer is that the movements are a spinal reflex elicited by the upright position and the feeling of the floor beneath infants' feet (McGraw, 1945; P. R. Zelazo, 1976, 1983). In fact, stepping is prominently featured in most developmental textbooks as an example of a newborn reflex (e.g., Berk,

2003; Siegler, DeLoache, & Eisenberg, 2003). However, newborn stepping does not fit well with a traditional notion of a reflex. In contrast to an eye blink response to a puff of air or a withdrawal response from a pinprick, stepping is inconsistent across infants and instances (Saint-Anne Dargassies, 1986) and particular eliciting stimuli are not necessary. Infants exhibit stepping movements on walls and ceilings in sideways and upside-down positions (Andre-Thomas & Autgaerden, 1966; Peiper, 1963). They step spontaneously without any stimulation to the bottoms of their feet while in the uterus (Prechtl, 1986) and while held with their legs dangling in the air (Thelen & Fisher, 1982; Touwen, 1976; B. D. Ulrich, 1989). Moreover, as illustrated in Figure 4.2b, infants frequently kick their legs in the same alternating pattern while lying on their backs (Thelen, 1979; Thelen, Bradshaw, & Ward, 1981; Thelen & Fisher, 1982, 1983b). Stepping and kicking appear so similar in form that stick diagrams of stepping look like kicking if you turn the figure sideways (see Figure 4.2c).

Stepping and kicking movements are most frequent when infants are aroused and fussy but not crying and tonically rigid (e.g., Thelen, 1981a; Thelen, Fisher, Ridley-Johnson, & Griffin, 1982). Similarly, when late gestation rat fetuses and newborn rat pups are aroused by sensory stimulation or drug injections, they also increase the frequency of alternating stepping movements in their fore and hind limbs while held in various positions (Robinson & Smotherman, 1992). Thus, some researchers view newborns' alternating leg movements as a spontaneous by-product of arousal, rather than a reflex (Thelen et al., 1982). The upright posture, pressure of the experimenter's hands around the chest, feeling of the floor under the feet, and so on may increase infants' arousal. As infants become aroused, energy flows through their muscles and powers up their legs (Thelen & Smith, 1994).

Pattern Generators

Puzzle 2—why the alternating pattern instead of some other pattern—concerns the real-time, moment-to-moment control of movements. In principle, newborns might move one leg at a time or both legs simultaneously (and they occasionally do), so why might the alternating pattern predominate? Neither a spinal reflex nor an arousal account specifically addresses the alternation between the legs. The similarity in form between newborn stepping and later walking has led many researchers to view newborn stepping as an example of a

core competence that is later co-opted and adapted for functional purposes in mature walking (Spelke & Newport, 1998). The core propensity to move the legs in alternation might reside in animals' neural anatomy in a so-called central pattern generator (e.g., Forssberg, 1985; Muir, 2000; Yang, Stephens, & Vishram, 1998)—a neuronal network in the spinal cord that produces locomotor movements of the legs through rhythmic alternations in flexor and extensor muscles (Grillner, 1975; Grillner & Wallen, 1985; Kiehn & Butt, 2003). Indeed, anencephalic infants step (Monnier, 1973), indicating that higher brain regions are not necessary for performing the movements. Similarly, insects and spinal preparations of rats, cats, lampreys, and chicks produce alternating bursts of neural activity in the flexor and extensor muscles responsible for locomotion (e.g., Orlovsky, Deliagina, & Grillner, 1999).

Intact animals, however, may display the alternating pattern without the benefit of (or despite the availability of) a neural pattern generator. Although researchers cannot study the neural activity in the isolated spinal cords of human infants, muscle activations revealed by electromyography are not strictly consistent with the notion of a central pattern generator. In some studies, infants' alternating leg movements do not appear to result from rhythmic bursts of flexor and then extensor muscles. Instead, infants bend their legs to kick or to step by co-contracting flexor and extensor muscles in their hips and ankles simultaneously (Forssberg, 1985; Thelen & Cooke, 1987; Thelen & Fisher, 1982, 1983b). Because the flexor muscles are stronger, the leg bends. Infants straighten their legs without the need for muscle activation. Instead, the springiness of the leg reverses the direction of motion from flexion to extension and the force of gravity pulls the leg straight (Thelen, 1996).

In fact, co-contraction of the muscles that power up a movement and the muscles that oppose the movement may be the norm rather than the exception in infants' movements (e.g., Forssberg, 1985; Forssberg & Wallberg, 1980). Co-contraction makes movements slower and stiffer and can even freeze a movement (as when crying infants become tonically rigid or when we "make a muscle" by co-contracting biceps and triceps). Although undifferentiated muscle actions are emblematic of early periods in skill acquisition and produce clumsy-looking, energetically costly movements (Damiano, 1993), co-contraction may serve a useful function by "chunking" individual muscles into larger groups and thereby simplifying the control prob-

lem (Spencer, Vereijken, Diedrich, & Thelen, 2000; Thelen & Spencer, 1998).

Co-contractions and springy muscles highlight a central maxim in current views of real-time motor control: Central pattern generators, like any other neural mechanism in the CNS, can only control muscle forces (Pearson, 1987; Winter & Eng, 1995). Movements, however, are composed of multiple forces (Bernstein, 1967; Woollacott & Jensen, 1996; Zernicke & Schneider, 1993). The net force responsible for a movement can be decomposed into the active forces produced by the muscles and the passive forces produced by the springiness and stickiness of the muscles and joints, gravity, inertia, and the motion-dependent torques created by moving other body parts (the hip bone is connected to the thigh bone, etc.). If you lift your arm from a stationary position at your side, muscle force contributes significantly to the total force required for the movement. However, if you drop your arm downward from overhead, the movement is nearly entirely controlled by gravity and inertia. If you wave your upper arm while allowing your wrist to go limp, the movement of your hand results from motion-dependent torques. Thus, movements with the same outward appearance can be caused by very different patterns of muscle activation (reciprocal enervation, co-contraction, etc.). The CNS acts more like a team player than a star soloist in determining real-time movement outcomes.

Behavioral Flexibility

A final piece to Puzzle 2 concerns the flexibility of the alternating pattern. A central pattern generator that can flexibly modulate, alter, and discard its pattern to suit the task is just a fancy name for the CNS (Thelen & Spencer, 1998). Although leg alternation normally predominates, it is not obligatory, and although leg alternation is displayed by anencephalic infants, the movement pattern is not impervious to perceptual feedback and supraspinal influences. One reason for alternation may be movement economics. Lifting both their legs off the floor simultaneously while an experimenter holds infants upright under their arms and bending and straightening both legs together while infants lie on their backs might require infants to exert more work in their abdominal and torso muscles than lifting their legs in alternation (Thelen & Smith, 1994). Under task constraints that alter the balance of effort, infants switch from alternating to simultaneous leg movements. An elastic yoke between the legs of 4-month-olds caused infants to

switch from predominately alternating and single leg movements to simultaneous movements that did not require them to pull against the yoke (Thelen, 1994). Similarly, in several studies, a pliable yoke between the hind limbs of fetal rats and newborn rat pups elicited a switch from alternating and single leg kicks to simultaneous leg movements (Robinson & Kleven, in press). A yoke between the fore and hind limbs on one side elicited increased synchrony between that pair of limbs. In other words, human infants and baby rats might simply perform the easiest pattern of movements given the current circumstances.

Like simultaneous leg movements, single-leg movements can also predominate when researchers arrange the appropriate contingencies. With the new biomechanical constraints introduced by a weight around one ankle, 6-week-old infants maintained their overall kick rate relative to baseline, but they broke up the alternating pattern by kicking more frequently with their unweighted leg (Thelen, Skala, & Kelso, 1987). With a tiny weight attached to one leg, 1- and 2-day-old rat fetuses produced more kicks on their unweighted leg and they scaled their kick frequency to the size of the weights (Brumley & Robinson, 2002, in press).

With the introduction of motivational factors, infants kick a single leg quite purposefully. In the most popular paradigm, researchers link an infant's leg movements with a desirable goal by attaching one end of a soft ribbon to the infant's foot and the other end to an overhead mobile. Dozens of experiments by Rovee-Collier and her colleagues showed that infants increased the frequency and size of leg kicks when their movements caused the mobile elements to jiggle (e.g., Rovee & Rovee, 1969; Rovee-Collier & Gekoski, 1979; Rovee-Collier, Sullivan, Enright, Lucas, & Fagen, 1980). In terms of intralimb kinematics and electromyogram (EMG) patterns, the spontaneous baseline kicks were continuous with the exploratory kicks during acquisition and the intentional kicks during extinction, meaning that infants harnessed the available movements for functional action (Thelen & Fisher, 1983a). After learning the contingency with one leg, 3-month-olds quickly learned to kick the formerly noncontingent leg when the ribbon was switched (Rovee-Collier, Morrongiello, Aron, & Kupersmidt, 1978). Perhaps most impressive in terms of flexibility, 3-month-olds learned to flex and extend their contingent leg to particular criterion angles under a strict conditioning arrangement that required these specific joint angles to activate the mobile (Angulo-Kinzler, 2001;

Angulo-Kinzler & Horn, 2001; Angulo-Kinzler, Ulrich, & Thelen, 2002).

Regressions

Puzzle 3—why upright stepping disappears and subsequently reappears—concerns regressions and continuity over development. A long-held explanation credits neural maturation as the primary factor in driving the U-shaped developmental trajectory (e.g., Forssberg, 1985, 1989; Forssberg & Wallberg, 1980; McGraw, 1940, 1945). On this account, cortical maturation suppresses newborns' spinally generated stepping movements at 8 weeks. With increasing myelinization of the cortical-spinal tract, stepping movements reappear under volitional, cortical control at 8 months. Finally, maturation of neural structures and circuitry increases information-processing speed and efficiency so that infants walk independently at approximately 12 months (P. R. Zelazo, 1998; P. R. Zelazo et al., 1989).

Several lines of evidence indicate that continuity may underlie the apparent regression. That is, alternating leg movements are only masked in an upright position; they do not disappear. One line of evidence is that infants continue to display spontaneous kicking movements during the same 2- to 8-month time period when they do not display upright stepping (Thelen, 1979; Thelen & Fisher, 1982). Given the structural similarities between kicking and stepping in their real-time trajectories, the difference in developmental trajectories appears due to posture rather than propensity.

A second argument for continuity is that normally nonstepping 2- to 7-month-old infants exhibit alternating steps when they are supported over a motorized treadmill (Thelen & Ulrich, 1991). Like stepping in newborns, stepping in older treadmill walkers appears to be nonvolitional; infants rarely look down or show interest in the movement of their lower limbs (Thelen, 1986). However, as in kicking, the legs are responsive to the biomechanical context. In several studies, infants altered the speed of their steps in accordance with treadmill speed (Thelen, 1986; Vereijken & Thelen, 1997; Yang et al., 1998). With one leg on a faster moving treadmill belt and the other leg on a slower moving belt, infants maintained alternating movements. But, to do so, they relinquished the normal 50% phasing relationship between the legs and treadmill walking looked like limping (Thelen, Ulrich, & Niles, 1987). When the movements of one leg were disrupted by manually holding the leg in place or by pulling the leg back at a speed

faster than the moving treadmill belt, infants typically adapted by keeping only one leg in the air at a time (Pang & Yang, 2001). In the event that infants momentarily lost the alternating pattern, they quickly regained it in the step immediately following the disturbance.

A third line of evidence concerns the effects of practice. When parents give their infants daily practice moving their legs in an upright position as part of an experimental training regimen or as part of a cultural belief in infant exercise, infants retain the alternating movements for longer periods (N. A. Zelazo, Zelazo, Cohen, & Zelazo, 1993; P. R. Zelazo, Zelazo, & Kolb, 1972) or display the movements continuously over the 1st year of life (Konner, 1973). Similarly, regular practice stepping on a motorized treadmill results in a higher frequency of alternating steps and more adult-like muscle actions (Vereijken & Thelen, 1997; Yang et al., 1998). A related argument for continuity is that typically developing infants who receive regular practice with stepping movements begin to walk at younger ages compared with infants in control groups who did not receive daily practice and infants in cultures that do not emphasize the exercise of upright postures (Hopkins & Westra, 1990; Keller, 2003; Super, 1976; P. R. Zelazo et al., 1972, 1989). Similarly, children with Down syndrome who receive daily practice walking on a treadmill begin walking independently at younger ages than matched controls (D. A. Ulrich, Ulrich, Angulo-Barroso, & Yun, 2001).

Contextual Factors

The remaining piece to Puzzle 3 concerns why upright steps might normally be masked. Just as nonneural, biomechanical factors may constrain and facilitate movements in real time, the culprit in the developmental course of infants' leg movements may be the decidedly nonneural factor of leg fat. Over the first few months of life, normal gains in leg fat typically outstrip gains in muscle strength (Thelen, 1984b). On this leg-fat account, supine kicking may continue during the same period when upright stepping disappears because supine kicking requires less muscle strength than upright stepping (think of performing bicycling movements with your legs in a supine position compared with marching movements while standing upright). Gravity assists hip flexion while infants are lying down by pulling infants' thighs toward their chests, but gravity works against lifting the legs while infants are standing up by pulling the leg downward (Thelen, Fisher, & Ridley-Johnson,

1984). Accordingly, naturally slimmer infants produce more upright steps than chubbier ones (Thelen et al., 1982). When infants' legs were loaded with small weights to simulate normal gains in leg fat, previously stepping infants stopped stepping (Thelen et al., 1984). Conversely, when infants' legs were submerged in a tank of water to alleviate the effects of gravity, nonstepping infants stepped once again.

Consistent with the leg-fat explanation, nonstepping infants might exhibit steps on a motorized treadmill because the treadmill belt provides the necessary energy to lift the leg against gravity. The treadmill stretches the leg backward and allows it to pop forward like a spring (Thelen, 1986). Alternating steps may predominate over simultaneous leg movements because lifting both legs together requires more work in the abdominal muscles. Regular practice moving the legs in an upright posture may prolong stepping movements beyond the 8-week cutoff and accelerate walking onset before the end of the 1st year by building up the requisite strength for infants to lift one leg through the air and to support their body weight on the other leg. Specificity of training effects provides further evidence that practice builds strength. Training regimens for newborn stepping do not facilitate newborn sitting and vice versa (N. A. Zelazo et al., 1993).

Facial Wiping

Our choice of newborn stepping as an extended case study was not accidental. For nearly a century, infants' alternating leg movements have served as a favored model system for illustrating general principles in maturationist (e.g., McGraw, 1940), learning (e.g., P. R. Zelazo, 1998), core competence (e.g., Forssberg, 1985; Spelke & Newport, 1998), and dynamic systems (e.g., Thelen & Smith, 1994) views of development. The favored status of infants' leg movements stems both from the centrality of walking for human functioning and from the fascinating puzzle of developmental regressions. Our aim here is to illustrate the plausibility of the argument that, at least in principle, factors outside the province of the CNS may sometimes be the critical facilitators of development. Toward that end, we describe a lesser known, but equally fascinating example.

Just as alternating leg movements are a highly patterned response in the behavioral repertoire of human infants, facial wiping is a highly stereotyped response for rats. The animals bring one or both forepaws to their ears and stroke downward toward their nose in bouts of

single or simultaneous limb movements (Berridge, 1990). Under normal circumstances, adult rats exhibit facial wiping during grooming. In an experimental arrangement, a noxious stimulus such as an infusion of quinine or lemon into the mouth elicits facial wiping (Grill & Norgren, 1978). Like the U-shaped trajectory of infants' leg movements, facial wiping also exhibits a developmental regression. Facial wiping to a lemon infusion appears in completely exteriorized fetal rats at 20 to 21 days of gestation (rats have a 21-day gestation). After birth, facial wiping to lemon disappears. The classic limb movements to a noxious lemon infusion reappear 11 days later when rats stand up on their hind legs and wipe their face with their front legs (Smotherman & Robinson, 1989).

Like stepping in human infants, the propensity for facial wiping in rat pups is merely masked; the movements have not actually disappeared. At 19 days of gestation, the age when completely exteriorized fetuses fail to facial wipe to a lemon infusion, partially exteriorized fetuses exhibit wiping movements inside the amnion (Robinson & Smotherman, 1991). What factor might underlie the dramatic difference in behavior caused by the subtle difference in context? Between 19 and 20 days of gestation, fetuses acquire the ability to stabilize their head. For 19-day-olds, the amnion provides an important stabilizing function. The amniotic membranes hold the head steady and help the paws to contact the face.

Why, then, do the movements disappear after birth? In newborn pups, the facial wiping behavior competes for expression with a strong tendency to maintain contact against a surface with their belly and all four feet (Pellis, Pellis, & Teitelbaum, 1991). With forelimbs freed from contact with the ground by neck-deep immersion in water, 1- to 3-day-old rat pups exhibited facial wiping to lemon (Smotherman & Robinson, 1989). Although the urge to keep the body pressed against a contact surface dissipates after a few days, full-blown facial wiping awaits sufficient postural control for rats to stand up on their hind legs at 11 days postbirth. In the meantime, 7- to 9-day-old rat pups compensate for inadequate balance by improvising the necessary support (Robinson & Smotherman, 1992). For example, they support their bodies on their elbows and lower their head for simultaneous wiping between the two forepaws.

Rate-Limiting Factors

The factors involved in unmasking facial wiping in rat pups are reminiscent of the role played by the treadmill,

the tank of water, and the supine position in unmasking alternating leg movements in human infants. The amnion, water tanks, and so on served as external scaffolds that temporarily replaced missing elements and thus promoted the expression of the target behaviors (Smotherman & Robinson, 1996). In a sense, the ability to lift the forelimbs to the face or to move the legs in an alternating pattern resides as much in the scaffolds as in the infants.

Both case studies—alternating leg movements and facial wiping—highlight the epigenetic nature of development (Oyama, 1985). That is, current behavior emerges from the changing interplay between the various components in the organism and the various components in the local environment (Smotherman & Robinson, 1996). New developments might be more than the sum of the component parts and new behavioral forms might arise as the product of spontaneous self-organization.

Given a particular environment, each organismic component must be above some threshold level of developmental readiness to produce the target behavior. Many writers refer to the set of component abilities, processes, propensities, and bodily features as a “confluence of factors” (Bertenthal & Clifton, 1998, p. 87; Freedland & Bertenthal, 1994, p. 26; Spencer & Schöner, 2003, p. 397; Thelen, 1995, p. 83) to emphasize the fluid and changeable nature of the entire behavioral system. Like a developmental chemistry experiment, over time, factors may enter and disappear from the mix and the various combinations and interactions of components may result in new behaviors. At any given point in development, the critical, rate-limiting factor that triggers the system to reorganize into a new configuration might be a psychological function governed by the CNS (e.g., motivation, balance control), or it might be a more peripheral factor such as gravity or leg fat.

Developmental Trajectories

Developmental regressions underscore the importance of describing developmental trajectories, especially in individuals. Motor development and physical development are uniquely suited for such a task because the dependent variables—movements and body growth—can be observed and mapped directly. Historically, research in motor development has always recognized the value of careful, detailed descriptions of individual developmental trajectories. McGraw’s (1935) daily observations of identical twins Jimmy and Johnny are the most famous example. However, other examples abound. Re-

searchers have tracked the course of fetal motility (de-Vries et al., 1982; Robertson, 1990), infants’ eye movements (von Hofsten, 2004), rhythmical stereotypies (Thelen, 1979, 1981a), treadmill-elicited stepping (Thelen & Ulrich, 1991; Vereijken & Thelen, 1997), reaching (Clifton, Muir, Ashmead, & Clarkson, 1993; Corbetta & Bojczyk, 2002; Halverson, 1931; Spencer et al., 2000; Thelen et al., 1993; von Hofsten, 1991), crawling (Adolph, Vereijken, & Denny, 1998; Freedland & Bertenthal, 1994), walking (Bril & Breniere, 1989, 1992, 1993; Shirley, 1931), crawling and walking over slopes (Adolph, 1997), everyday crawling and walking experience (Adolph, 2002; Garciaguirre & Adolph, 2005b), and stair-climbing (Gesell & Thompson, 1929).

What can be gained from so much complex, individualized description? What new understandings might warrant the additional work and expense of microgenetic analyses? Although cross-sectional studies can identify interesting developmental milestones, microgenetic descriptions of individual children may yield a more accurate picture of developmental progress (see Siegler, Chapter 11, this *Handbook*, this volume). The rate and amplitude of change vary across children and sometimes critical features in the shape of the trajectory vary across children (Corbetta & Thelen, 1996). Thus, one argument for microgenetic analyses is that averaging across children and time-based observations can lead to erroneous assumptions about the underlying trajectory (Lampl, Johnson, & Fronville, 2001). Such errors can, in turn, misinform theories about the mechanisms of developmental change and distort the design of subsequent studies to test the putative mechanisms.

A second argument for microgenetic analyses is that based on individual trajectories, researchers can identify possible causes of change (Ledebt, 2000; Thelen & Corbetta, 2002). For example, reaching for small objects shows a zigzag trajectory over the 1st year of life. First, infants reach with two hands for small objects, then one hand, then they revert to the less efficient bimanual reach, then back to one hand (Fagard, 2000). The timing of the zigzag, however, varies across infants. Microgenetic observations of individual children suggested that the reversion to bimanual reaching might stem from an increased coupling between the arms in walking. In the same few weeks when infants reverted to bimanual reaching, they began to walk using the typical “high-guard” position of the arms to help themselves keep balance (Corbetta & Bojczyk, 2002). In subsequent weeks, as the arms gradually lowered and differentiated into a

reciprocal swinging pattern in walking, the arms also redifferentiated into one-handed reaching.

One Step Backward, Two Steps Forward

The path of development is often tortuous and uneven. Sometimes when skill performance reaches asymptote, the only route to forward progress involves a detour. Infants may need to relinquish the accuracy, efficiency, and stability that they have fought so hard to attain with an earlier developing skill in order to make progress with a later developing skill that will eventually enable a higher level of functioning. In terms of both form and function, development can be a process of moving one step backward for every two steps forward (P. H. Miller, 1990; P. H. Miller & Seier, 1994).

The transition from crawling to walking provides a wonderful illustration of uneven developmental progress. After weeks of steady improvement, infants achieve high levels of performance in crawling on hands and knees (Adolph et al., 1998; Freedland & Bertenthal, 1994). Their quadruped gait is fast, beautifully modulated, and highly functional. Ironically, the switch from the earlier developing skill of crawling to the more mature skill of walking requires expert crawlers to cope with an initial decrement in performance. At first, upright walking is slow, variable, and so teeming with errors that infants may fall after every few steps (Shirley, 1931). On some level, infants may be aware that their new upright skill comes with a cost. Newly walking infants sometimes revert from walking to crawling if they want to get somewhere quickly (McGraw, 1935; Zanone et al., 1993). Nonetheless, many researchers have noted that children appear pulled, perhaps by the sheer novelty of the new skill or the motivation for advancement, toward relinquishing the old in favor of the new (e.g., Rosander & von Hofsten, 2000; Shrager & Siegler, 1998; von Hofsten, 2004). New walkers prefer to face locomotor obstacles in their less efficient upright posture than in their more functional and familiar crawling posture (Adolph, 1997). When placed in their old familiar crawling posture at the top of an impossibly steep slope, new walkers sometimes stand themselves up, walk haplessly over the brink, and fall.

Like the developmental change from crawling to walking, the acquisition of locomotion involves an initial decrement in performance. Infants must relinquish the hard-won stability of a stationary posture for a new, more precarious dynamic posture in which they are likely to fall. After infants finally acquire sufficient

arm strength to push up and keep balance on all fours, they may spend weeks practicing their new balancing act, sometimes rocking back and forth rhythmically (Adolph et al., 1998; Gesell & Ames, 1940; Goldfield, 1989; Thelen, 1979), as if aroused and eager to go, but stuck with both hands on the ground. The developmental transition from expert, controlled quadruped to novice, falling-down walker requires infants to give up developmental stability for variability and poor performance. Similarly, after infants finally acquire sufficient strength and control to maintain balance in an upright standing position, they experience an initial decrement in performance when they take their first walking steps a few weeks later.

The real-time process of gait initiation—taking the first step in a walking sequence—literally invites falling, but in this case, falling is deliberate and controlled. Walkers must deliberately induce disequilibrium to shift the body weight onto one foot and to produce the propulsive forces necessary to move the body forward (Breniere & Do, 1991; Breniere, Do, & Bouisset, 1987; Ledebt, Bril, & Breniere, 1998). In adults, gait initiation begins before the swinging foot ever leaves the ground. First, in a preparatory phase that disrupts the equilibrium of the standing posture, the center of foot pressure moves backward toward the heels and sideways, first, slightly away then rapidly toward the standing foot (Breniere & Do, 1986; Breniere et al., 1987; Jian, Winter, Ishac, & Gilchrist, 1993). The change in foot pressure causes the center of mass to accelerate in the opposite direction: forward and toward the swinging foot. Next, in a takeoff phase, the swinging foot lifts from the ground and the total weight of the body is carried by the stance leg. Now, the body is falling forward and the velocity of the center of mass increases exponentially.

By the time that the swinging foot recontacts the ground, the center of gravity is moving at peak progression velocity (Breniere & Do, 1986; Breniere et al., 1987; Jian et al., 1993). At the end of the first step, the velocity is nearly at the steady state velocity of the entire walking sequence. How do walkers manage this? For faster intended walking speeds, adults lean their bodies farther forward by shifting their center of foot pressure farther backward (Breniere et al., 1987). As in sprinting, these actions build up more propulsive forces during the preparatory phase before the walker's foot has left the ground. For slower intended speeds, adults exhibit less forward lean, and foot pressure exhibits a

smaller backward excursion. These findings are remarkable because they indicate an exquisite anticipation of the forces needed for the intended walking speed. Thus, for adults, the real-time process of gait initiation is loosely analogous to the developmental process of moving backward initially to facilitate forward progress eventually. In this case, the initial back step is beautifully coordinated with the size of the forward step.

For infants, the problem of gait initiation is somewhat different: Babies must cope with the two competing necessities of minimizing the disequilibrium inherent in their new upright posture and creating the disequilibrium required to move (Ledebt et al., 1998). In contrast to adults, infants do not initiate gait with a consistent backward and sideways displacement of their center of foot pressure prior to liftoff, and they do not show anticipation of their intended walking speed by building up the appropriate propulsive forces before the end of their first step (Breniere, Bril, & Fontaine, 1989). Instead, in the earliest days after walking onset, infants' strategies for inducing disequilibrium and catching the body appear to be variable and idiosyncratic (Adolph, Vereijken, & Shrout, 2003; McCollum, Holroyd, & Castelfranco, 1995; McGraw, 1945). With a "falling" strategy, infants raise up on tiptoe and allow themselves to fall forward. With a "twisting" strategy, they wind their trunk like a spring and then let fly bringing their swinging leg around using the torque and angular momentum of the trunk. With a "stepping" strategy, they lift the swinging leg by bending the knee and minimize the fall by taking very small forward steps.

Adultlike anticipatory control of gait initiation takes years to acquire (Ledebt et al., 1998). After the first few months of walking, in the preparatory phase of gait initiation, infants apply vertical force with the swinging leg to load the standing leg and unload the swinging leg. They move the swinging leg forward by tilting the stance leg and pelvis sideways (Assaiante, Woollacott, & Amblard, 2000). As infants' bodies begin to accelerate forward during the takeoff phase, the swinging foot reaches out to catch the body and infants simply control the fall as best they can. Even as the foot lifts, the pelvis drops on the side of the swinging leg as if infants' bodies are collapsing downward into the fall (Bril & Breniere, 1993). Both before and after liftoff, infants' legs, pelvis, trunk, and head oscillate more in sideways and front-back directions compared with preschool-age children and adults (Assaiante et al., 2000). At 4 years of age, children finally show a backward shift in the center of

foot pressure and they achieve steady state velocity by the end of their first step, but the size of the backward shift is not yet correlated with walking velocity (Ledebt et al., 1998). At 6 years, the size of the preparatory backward displacement in foot pressure is correlated with walking velocity but is still not at adult levels.

Fits and Starts

In contrast to motor development where research has enjoyed a long history of tracking trajectories in individual children, microgenetic descriptions of physical growth are rare. The typical approach to studying body growth is to collect measurements from large cross-sectional samples or to measure children's bodies longitudinally at quarterly or yearly intervals. Given the high variability between children at the same age and the relative paucity of data points for individual children at different ages, the typical analytic strategy is to average over children and interpolate between observations, mathematically smoothing out any jitter in the growth curve. Thus, as illustrated by the curve shown in Figure 4.3a, body growth is depicted as a smooth continuous function. From birth to adulthood, the standard growth curve has three bends caused by a rapidly decelerating rate of growth over infancy, a relatively slow but constant rate of growth during middle childhood, and the pubertal growth spurt prior to reaching final adult size (e.g., Tanner, 1990).

Microgenetic descriptions of physical growth in individual children provide a very different picture of development. As illustrated in Figure 4.3b, actual growth spurts bear no resemblance to the mathematically smoothed bump on the standard growth curve that represents researchers' traditional view of the adolescent growth spurt. Children's growth is episodic, not continuous (M. L. Johnson, Veldhuis, & Lampl, 1996; Lampl, 1993; Lampl et al., 2001; Lampl & Johnson, 1993; Lampl, Veldhuis, & Johnson, 1992). Brief periods (24 hours) of extremely rapid growth are interspersed with long periods of stasis during which no growth occurs for days or weeks on end. Episodic development is characteristic of changes in height, weight, head circumference, and leg bone growth and of every period of development—fetal (Lampl & Jeanty, 2003), infancy (Lampl, 1993; Lampl & Emde, 1983), middle childhood (Lampl, Ashizawa, Kawabata, & Johnson, 1998; Togo & Togo, 1982), and adolescence (Lampl & Johnson, 1993; Togo & Togo, 1982). When measured daily, infants' height increased by 0.5 to 1.65 cm punctuated by 2- to

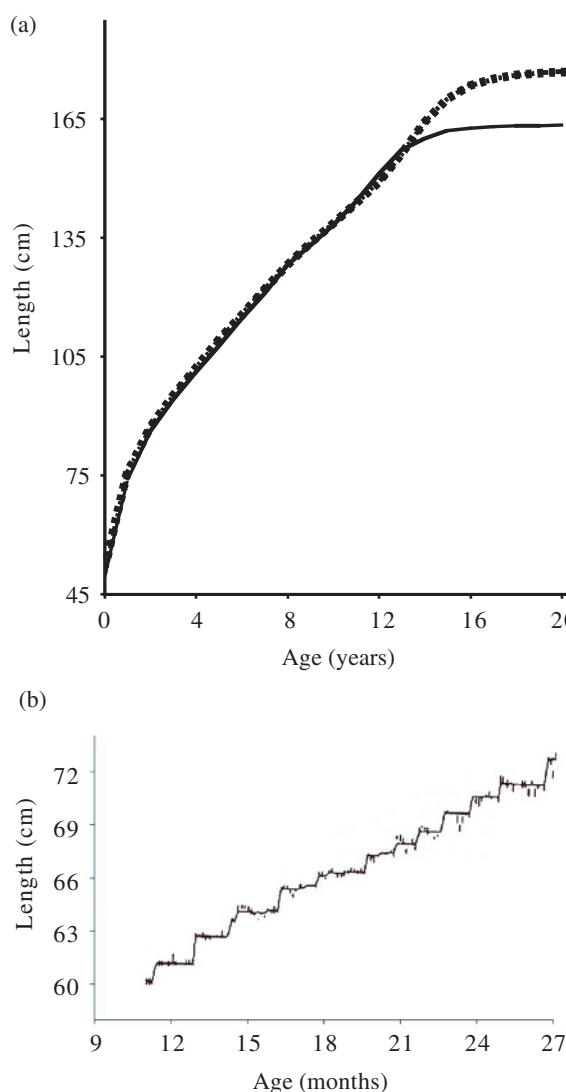

Figure 4.3 Growth curves for height. (a) Standard growth curves from birth to 18 years. Data are mathematically smoothed and averaged over children. Dashed line represents boys. Solid line represents girls. *Source:* From growth charts developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion (2000). (b) Microgenetic episodic growth curve for one exemplar infant. Each vertical line represents daily replicate observations. *Source:* From “Saltation and Stasis: A Model of Human Growth,” by M. Lampl, J. D. Veldhuis, and M. L. Johnson, 1992, *Science*, 258, pp. 801–803. Reprinted with permission.

28-day periods of no growth (Lampl et al., 1992). Sampling at weekly intervals preserved the episodic nature of children’s growth but had the effect of reducing the number of growth spurts, increasing the amplitude of the spurts, and increasing the periods of stasis (e.g., for

infants observed at weekly intervals, height increased by 0.5 to 2.5 cm interspersed by 7- to 63-day periods of no growth). Although episodic growth characterized every child measured, the timing of spurts, the size of the growth increments, and the length of the plateaus showed large intra- and intersubject variability.

Even within a 24-hour period, growth is not continuous. Children appear to grow more at night while lying down than during the day while standing and walking, especially in their weight-bearing extremities (Lampl, 1992; Noonan et al., 2004). For years, pediatricians assumed a link between nighttime growth and nighttime lower leg pains, but there were no data to corroborate speculations about the source of children’s “growing pains.” In a recent tour de force of micromeasurement, researchers collected direct measures of lower leg bone growth at 3-minute intervals over a 3-week period via microtransducers implanted into the tibia bones of 3 free-ranging lambs (Noonan et al., 2004). Video recordings synchronized with the activity of the microtransducers specified the lambs’ activities during periods of growth and stasis. Approximately 90% of all growth occurred while the lambs were lying down. Weight bearing while standing or walking resulted in biomechanical compression of the growth plate cartilage.

Evidence for Developmental Stages

The dramatic example of body growth shows how inadequate sampling intervals can lead researchers to mischaracterize the underlying developmental trajectory. If the sampling interval is too large, findings will be insensitive to important fluctuations in the data. Skills that are indexed with interval data (such as height and weight) will appear continuous regardless of whether the underlying trajectory is episodic or U-shaped. Skills that are indexed with binary data (such as object permanence and conservation of quantities) will look stage-like regardless of whether the actual trajectory is variable. The risk is that erroneous descriptions of development can compromise theorizing about underlying mechanisms. Given the expense of collecting increasingly microscopic observations, researchers need to know how small is small enough to capture the essential shape of change.

To answer this question, Adolph and colleagues (Adolph, Robinson, Young, & Gill-Alvarez, 2005; Young, Webster, Robinson, Adolph, & Kanani, 2003) sampled 32 infant motor skills (rolling, sitting, crawling, cruising, walking, etc.) from 11 infants on a daily basis using a

checklist diary with parents as the informants. The period of observation averaged 13 months per child. Due to missing data and skills, 261 time series were available. Of these, only 42 time series (16%) showed single stage-like developmental transitions. In these cases, infants never demonstrated the skill prior to the onset day and always demonstrated the skill after the onset day. In the other 84% of the time series, trajectories were variable. Skills sputtered in and out of infants' repertoires, with 3 to 72 transitions between skill absence and presence. In these cases, the selection of an onset day is arbitrary because an infant might walk on Monday, but not again until Thursday, and then not again until the following week, and so on. The data argue against the widely held practice of using punctate estimates of onset dates in normative screening tests (e.g., Frankenburg & Dodds, 1967) and in estimates of infants' motor experience (e.g., Adolph et al., 2003; Bril & Ledebt, 1998; Campos et al., 2000).

Most important, the consequence of sampling at intervals larger than a single day was a dramatic loss of sensitivity to detect the variability in the data (Adolph, Robinson, et al., 2005; Young et al., 2003). Sampling at 2- to 30-day intervals was simulated by systematically removing observations, then reconstructing the developmental trajectories based on the reduced number of observations. The resulting data set included the original data (1-day interval) and the sum of the 2- to 30-day simulated intervals by phase multiplied by the original 261 available time series for a total of 129,456 time series. Of these, 109,120 were variable.

Loss of sensitivity followed an inverse power function (visualize a curve with a sharp initial drop-off that slowly tapers toward 0 over an extended tail). For each day that widened the sampling interval, the loss of sensitivity increased at a greater rate. At the simulated sampling frequency of once per week (considered heroic in microgenetic studies of motor skill acquisition), 51% of the variable time series erroneously appeared stagelike. At the simulated rate of once per month, 91% of the variable time series appeared stagelike. In other words, stagelike developmental trajectories may be an artifact of inadequate sampling rather than a true description of the underlying course of development.

Variability

Traditionally, researchers in cognitive and perceptual development viewed variability as error variance to be minimized or stochastic noise to be ignored. Currently,

however, variability is enjoying a sort of renaissance in these areas, where researchers have begun to recognize change in variability as an important marker of learning and development (e.g., Siegler, 1994, 1996; Siegler & Munakata, 1993). For example, while learning new strategies to solve math, matrix completion, and conservation of quantity problems, children show a spike in variability between erroneous and correct ways of thinking (Alibali, 1999; Goldin-Meadow, Alibali, & Church, 1993).

In contrast to the long disregard of variability in cognitive and perceptual development, researchers in motor development and motor learning have a tradition of using measures of real-time variability (e.g., the standard deviation, coefficient of variation, or category counts) as dependent variables to index learning and development in motor skill acquisition (e.g., Adolph et al., 2003; J. E. Clark et al., 1988; Vereijken, van Emmerick, Whiting, & Newell, 1993). The movements of infants and novices are notoriously variable and unreliable, whereas movements of adults and experts are typically smooth and consistent.

Crawling

Prior to crawling on hands and knees, many infants belly crawl with their abdomen resting on the floor for at least part of each cycle. Even excluding solutions wherein infants hitch along sitting, crab on their backs, and log roll, belly crawling may be the most variable, idiosyncratic, and creative of all infants' motor skills (McGraw, 1945). Infants use their arms, legs, chests, bellies, and heads in various combinations, sometimes pushing with only one limb in a girdle and dragging the lame limb behind, sometimes ignoring both arms and scraping along with the cheek on the floor or dragging both legs like a marine, sometimes pushing with first the knee then the foot on one leg, sometimes launching themselves from knees or feet onto the belly, and so on (Adolph et al., 1998; Gesell, 1946; Gesell & Ames, 1940). Even when all four limbs move, patterns of interlimb timing are variable (Adolph et al., 1998; Freedland & Bertenthal, 1994). Infants move ipsilateral limbs together like goose-stepping, move arms and legs on alternate sides of the body together like a trot, lift front then back limbs like a bunny hop, and lift all four limbs into the air at once like a swim. Belly crawling is so variable that infants change the configuration of limbs used for support and propulsion and the timing between limbs from cycle to cycle (Adolph et al., 1998). Variability in belly crawling is all the more striking because infants show a dra-

matic decrease in the variability of interlimb timing within a week or two of crawling on hands and knees (Adolph et al., 1998; Freedland & Bertenthal, 1994).

Reasons for Variability

What can we make of such variability? With the new renaissance of variability in developmental psychology, researchers in motor development have begun to herald variability as a causal agent of change rather than merely a marker or correlate (e.g., Bertenthal, 1999; Goldfield, 1995; Goldfield, Kay, & Warren, 1993). Indeed, Freedland and Bertenthal (1994, p. 31) wrote with regard to belly and hands-knees crawling, "Variability in performance is one of the driving forces for the emergence of new behaviors." Changes in variability around real-time transitions illustrate researchers' shift from describing changes in variability to treating variability as a causal mechanism. In Kelso's (1995) classic task, adults point both index fingers first to the right then to the left. At slow speeds, variability in the coordination between the two fingers is low. As participants try to wiggle their fingers back and forth at faster and faster speeds, variability increases until the fingers shift to an in-out pattern, at which point variability sharply decreases. On some accounts, the loss of stability is the chief mechanism that causes such changes in behavioral patterns (Bertenthal, 1999; Spencer & Schöner, 2003; Zanone et al., 1993). That is, variability is a prerequisite for any change between stable states, whether in real time, over the course of learning, or over development.

A second current conceptualization of behavioral variability concerns its exploratory function. On analogy to the evolutionary process of variability and selection and the neural process of overproduction and pruning, some researchers view variability as providing the fodder for subsequent selection and sculpting based on feedback from ongoing movements (e.g., Bertenthal & Clifton, 1998; Berthier et al., 2005; E. J. Gibson & Pick, 2000; Thelen & Smith, 1994). On this view, variable belly crawling steps (Bertenthal, 1999; Freedland & Bertenthal, 1994), arm flaps (Thelen et al., 1993), leg kicks (Thelen & Fisher, 1983a), and so on could create the raw materials for more efficient movements by generating an information-rich array of possibilities.

Of course, important exploratory functions could arise as a developmental by-product of variability (Adolph, 1997), just as many important physiological and behavioral forms can be evolutionary exaptations—characters that evolved for other uses or no function at all that were co-opted later for their current role (Gould

& Vrba, 1982). However, many researchers portray variability in infants' movements as intentional exploration motivated by a search for information (e.g., Bertenthal & Clifton, 1998; Goldfield, 1995; von Hofsten, 1997). Furthermore, in some cases, variability is viewed as both an active search for alternatives and as an impetus for exploration: Inconsistency in performance impels infants to explore alternative behaviors until they settle on a more efficient solution (Freedland & Bertenthal, 1994; Goldfield, 1995).

Although new views of variability have stimulated thinking and research, some of the proposals are problematic. The problem with imbuing variability in skills like crawling and reaching with intent is that the evidence for intentional exploration and active searching is simply the finding of variability itself. The problem with treating variability as an independent variable, moderator, or mediator—a causal prerequisite for learning and development—is that variability can also serve as a dependent variable for explaining the same phenomena. Natural selection may not be a useful metaphor in every case of behavioral development (just as evolution may include multiple mechanisms such as exaptation and spontaneous mutation) and generalizations from simple laboratory tasks such as finger-wiggling may not always hold true.

Belly crawlers show no evidence of selection or pruning and no evidence of a sudden spike in variability around the transition to crawling on hands and knees (Adolph et al., 1998). Rather, infants showed improvements in speed and proficiency despite unabated variability over weeks of belly crawling, and nearly every infant used an alternating gait pattern to crawl on hands and knees regardless of whether they had previously crawled on their bellies. Without a salient cost to performance, variability may continue unabated (Vereijken & Adolph, 1999). Perhaps the safest conclusion is that development is a many-splendored thing and variability may play multiple roles in the developmental process (see Siegler, Chapter 11, this *Handbook*, this volume). Frequently, changes in variability inform on that process, but sometimes variability may simply reflect noise.

Time, Age, and Experience

Development is about change over time. Thus, a central question for developmental psychologists is how best to conceptualize the passing of time and the factors that accompany it (e.g., Wohlwill, 1970). How should we order repeated observations and assign participants into

groups? The most common solution is to put children's chronological age at the time of testing on the x-axis. Indeed, many researchers do not consider a study to be developmental without comparisons between age groups. The most common alternative is to retain the regularity of days, weeks, months, and so on, but to normalize observations and subject groupings by children's experience, calculated with reference to an estimated day of skill onset (e.g., Adolph et al., 1998; Bertenthal, Campos, & Kermoian, 1994; Bril & Breniere, 1992; Corbetta & Bojczyk, 2002). Thus, instead of comparing individuals at 3 and 6 months of age or comparing groups of 3- and 6-month-olds, researchers might compare children over the first few months of reaching or the first few years of walking. Similar research strategies include retaining the serial order of milestone events (e.g., standers, new walkers, experienced walkers, runners) without retaining the interval spacing (e.g., Sundermier, Woollacott, Roncesvalles, & Jensen, 2001; Witherington et al., 2002) and holding age constant while varying experience with particular motor skills (e.g., Adolph, 2000; Campos et al., 2000). Here, we focus on the development of walking to illustrate some of the issues involved in representing, describing, and explaining change over time.

Improvements in Walking Skill

After 75 years or so of research on the development of walking, researchers have compiled a consistent constellation of related parameters that change with age and experience. Between 10 and 16 months of age, most infants take their first independent walking steps (Adolph et al., 2003; Frankenburg & Dodds, 1967). Initially, infants have such difficulty surmounting the dual problems of balance and propulsion that their walking gait resembles that of Charlie Chaplin. They take small forward steps with their legs splayed wide from side to side (e.g., Adolph et al., 2003; Bril & Breniere, 1992; Burnett & Johnson, 1971; McGraw, 1945; Shirley, 1931). Their hips are externally rotated and their toes point out to the sides to further increase the base of support (e.g., Adolph, 1995; Ledebt, van Wieringen, & Savelsbergh, 2004). They co-contract extensor and flexor muscles in their legs (Okamoto & Goto, 1985) and their excessively bent knees fail to cushion the downward fall at foot contact and fail to extend the leg fully at toe-off (Sutherland, Olshen, Cooper, & Woo, 1980). They spend a relatively long time with both feet on the ground and a relatively short

time with one foot swinging through the air (e.g., Bril & Breniere, 1989, 1991, 1993); as a consequence, overall progression velocity is slow, step frequency is high, and infants land flat-footed or on their toes because there is no time for them to dorsiflex their ankles (McGraw, 1940; Thelen, Bril, & Breniere, 1992). The time and distance of each step is variable and asymmetrical, suggesting that infants are recovering balance from step to step (Adolph et al., 2003; J. E. Clark et al., 1988; J. E. Clark & Phillips, 1987; Ledebt et al., 2004; McGraw & Breeze, 1941). New walkers hold their arms stationary in a high-guard position, with elbows bent, palms turned up, and hands raised above waist level (Ledebt, 2000; McGraw, 1940). Their heads and trunks wobble up and down and from side to side (Bril & Ledebt, 1998; Ledebt, Bril, & Wiener-Vacher, 1995). Most telling, the vertical acceleration of infants' center of gravity is negative at foot contact, meaning that babies are falling downward rather than propelling forward during periods of single leg support (Bril & Breniere, 1993).

Figure 4.4 shows the characteristic time course and direction of improvements in walking skill over infancy and early childhood. The base of support narrows as infants take longer steps with their legs closer together laterally and their toes pointed more straight ahead (e.g., Adolph et al., 2003; Bril & Breniere, 1992). Muscle actions become more reciprocal (Okamoto & Goto, 1985) and steps appear less jarring and variable (e.g., J. E. Clark et al., 1988; Ledebt et al., 2004). As the relative duration of double support decreases and single support increases, walking speed increases and infants land on their heel at foot contact (Bril & Breniere, 1989, 1991, 1993; Thelen et al., 1992). Arms lower toward infants' sides and begin to swing in alternation with leg movements (Ledebt, 2000). Infants stabilize the pitch and roll of their head and trunk (Ledebt et al., 1995) by rigidly locking their upper body parts together "en bloc" (Assaiante, 1998). Eventually, children unlock the rigid coupling between the head and trunk and begin to coordinate the pitch and roll of the head with the reactive up/down and sideways movements of the body caused by each walking step (Assaiante, Thomachot, Aurenty, & Amblard, 1998; Bril & Ledebt, 1998). The size of the negative value of the vertical acceleration of the center of gravity at foot contact slowly decreases until the sign of the function finally becomes positive as in adult walkers (Bril & Breniere, 1993). At this point, when children can "push off" during single leg support,

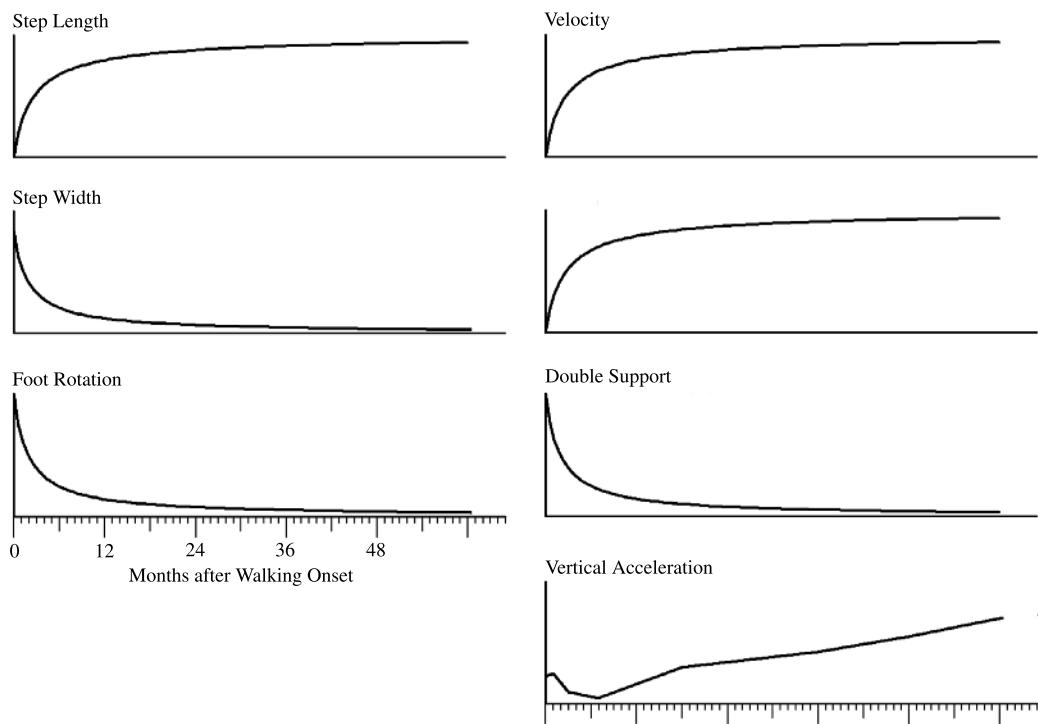

Figure 4.4 The characteristic time course of improvement in several measures of children's walking gait over the first 60 months of independent walking. Step length = Distance between consecutive steps; Step width = Lateral distance between steps; Foot rotation = Absolute value of in/out-toeing from path of progression; Velocity = Overall distance/time; Swing time = Amount of time with one foot moving through the air; Double support = Amount of time that both feet are on the floor; Vertical acceleration of the center of gravity = Rate of change in velocity of the center of gravity along the vertical axis. *Source:* Figure adapted from "Head Coordination as a Means to Assist Sensory Integration in Learning to Walk," by B. Bril and A. Ledebt, 1998, *Neuroscience and Biobehavioral Reviews*, 22, pp. 555–563. Curves for step length, step width, and foot rotation drawn from data presented in "What Changes in Infant Walking and Why," by K. E. Adolph, B. Vereijken, and P. E. Shrout, 2003, *Child Development*, 74, pp. 474–497; curves for velocity, swing time, and double support derived from *Baby Carriage: Infants Walking with Loads*, by J. S. Garciaguirre and K. E. Adolph, 2005b, manuscript submitted for publication; Curve for vertical acceleration drawn from data presented in "Posture and Independent Locomotion in Early Childhood: Learning to Walk or Learning Dynamic Postural Control," by B. Bril and Y. Breniere, 1993, *The Development of Coordination in Infancy*, pp. 337–358. Reprinted with permission.

they have finally mastered control over both balance and disequilibrium.

Since the 1930s, researchers have shared widespread agreement about the proximal cause of the characteristic improvements in walking skill: Infants must acquire sufficient muscle strength to propel their bodies forward while supporting their body weight on one leg and sufficient postural control to maintain balance, especially during periods of single limb support (e.g., Bril & Breniere, 1993; Bril & Ledebt, 1998; McGraw, 1945; Thelen, 1984a). Where most modern and early researchers diverge concerns their assumptions about the

distal source of improvement in the development of walking—the factors that drive increases in muscle strength and balance control. The early pioneers plotted developmental changes in walking skill with infants' age on the x-axis to emphasize the role of neural maturation and body growth in facilitating improvements. In contrast, most modern researchers plot similar graphs with infants' walking experience on the x-axis to emphasize the role of learning and practice.

Given the 6-month range in infants' age at walking onset, normalizing the data to children's walking onset age rather than their birth date facilitates graphical and

statistical comparisons between children (e.g., Bril & Breniere, 1993; Bril & Ledebt, 1998; J. E. Clark et al., 1988; Corbetta & Bojczyk, 2002). Note, for representing and describing change in individual infants, age and experience are equivalent measures. In addition, formal statistical models comparing the respective roles of infants' walking experience, chronological age, and body dimensions show that only walking experience explains unique variance in skill improvement over the first 2 years of life (Adolph et al., 2003; cf., Kingsnorth & Schmuckler, 2000). Over the next several years, developmental milestones are a more sensitive measure of improvements than age (Sundermier et al., 2001).

Moreover, as illustrated in Figure 4.4, for many measures, the development of walking skill resembles the negatively accelerated performance curves found in most motor learning tasks (Schmidt & Lee, 1999): Initial improvements are rapid and dramatic while subsequent improvements are more gradual and subtle. Most researchers identify the elbow in the rate of change at 3 to 6 months after walking onset (e.g., Adolph et al., 2003; Bril & Breniere, 1992, 1993; Bril & Ledebt, 1998; McGraw, 1945). Analogous to motor-learning tasks, the initial phase where the performance curve is steepest may reflect infants' struggle to discover the relevant parameters that allow forward progression and balance. The subsequent period of more gradual change may reflect a process of honing and fine-tuning the values of the gait parameters to maximize the biomechanical efficiency of walking.

Empty Time

Regardless of the relative predictive power of children's chronological age versus their walking experience, neither factor alone or in combination provides an explanation for the improvements in children's walking skill. The widespread use of age and experience as predictor variables in analysis of variance and regression analyses imbues these factors with the causal quality of independent variables (Wohlwill, 1970). However, they are not. Children are not randomly assigned to age or experience groups and each child is (or will be) a member of every group (e.g., in contrast to ethnic and sex groups). Cohort effects and cultural differences are well documented in the development of walking (e.g., Hopkins & Westra, 1990; Super, 1976). In addition, time could just as easily be the dependent measure, as typified by the common use of trials to criterion and time on task as

dependent variables in motor-learning studies (Schmidt & Lee, 1999). Most problematic, the passing of time since infants' birth date or date of walking onset is merely a convenient proxy for age- or experience-related factors that are currently unspecified or difficult to measure. In Wohlwill's (1970) harsh assessment, time itself is conceptually empty. It serves as a "cloak for ignorance" (p. 50).

Rather than relying on age as a crude stand-in for developmental changes in infants' brains and body dimensions, a more optimal research strategy would be to measure the putative causal factors and correlates more directly. For example, the frontal lobes show a temporary surge of electroencephalogram (EEG) activity in the first few weeks of crawling (Bell & Fox, 1996), consistent with an initial overproduction and subsequent pruning in neural connections. The otolith channel of the vestibular-ocular reflex shows a sharp increase in sensitivity to linear accelerations at the time of walking onset (Wiener-Vacher, Ledebt, & Bril, 1996), linking the ability to stabilize gaze while the head moves with the onset of an activity that accelerates the head through space. The natural slimming-down of infants' body proportions is correlated with improvements in walking skill (e.g., Adolph, 1997; Shirley, 1931) and more babyish top-heavy proportions (experimentally induced with lead-weighted shoulder packs or platform shoes) result in decrements to walking skill (Adolph & Avolio, 2000; Garciaguirre & Adolph, 2005a; Schmuckler, 1993; Vereijken, Pedersen, & Storksen, 2005; Yanez, Domakonda, Gill-Alvarez, Adolph, & Vereijken, 2004), suggesting that biomechanical constraints affect strength and balance.

What Infants Experience

Just as age is only a crude stand-in for unspecified developmental changes, the number of days since walking onset is only a proxy for practice and exposure. Researchers rely on locomotor experience as a causal factor in development for a range of psychological domains (e.g., Bertenthal et al., 1994; Campos et al., 2000). However, the construct of locomotor experience is largely unexamined. Ironically, the abundance of laboratory data collected over the past 100 years with infants walking short straight paths on flat ground under conditions of steady state velocity cannot speak to the quantity or content of infants' everyday experiences with balance and locomotion. In everyday life, infants travel along

circuitous paths for large distances over variable ground surfaces with variable walking speeds.

In particular, daily checklist diaries, “step-counters” in infants’ shoes, and video recordings of infants walking in everyday environments reveal large individual differences in the amount of practice that infants acquire with walking and large fluctuations for individuals across situations and days (Adolph, 2002, 2005; Adolph, Robinson, et al., 2005; Chan, Biancaniello, Adolph, & Marin, 2000; Chan, Lu, Marin, & Adolph, 1999; Garciaguirre & Adolph, 2005b). Many infants walk intermittently in the first several weeks after onset, vacillating between days when they walk and days when they do not (Adolph, Robinson, et al., 2005). Within days, walking experience is distributed in bouts of activity interspersed with periods of quiet stance when infants stop to play, manipulate objects, or interact with a caregiver (Garciaguirre & Adolph, 2005b). During trips toward a distant destination (on a city sidewalk with a caregiver), bouts tend to be longer in duration ($M = 18$ s) and contain more consecutive steps ($M = 45$ steps) than during free play where destinations are more transient and caregivers are less likely to encourage infants to walk (M bout length = 5 s, M steps = 11).

Accumulated over the course of a normal waking day, the quantity and variety of infants’ experience is truly massive (e.g., Adolph, 2002, 2005; Adolph et al., 2003). Each day, infants take more than 9,000 steps and travel the distance of more than 29 football fields. They travel over nearly a dozen different indoor and outdoor surfaces varying in friction, rigidity, and texture. They visit nearly every room in their homes and they engage in balance and locomotion in the context of varied activities. Minor inconsequential falls are common, averaging 15 times per hour, but serious falls that cause infants to engage in sustained crying or that result in minor injuries occur less than once per month (Garciaguirre & Adolph, 2005b).

In sum, infants’ everyday walking experiences resemble a type of practice regimen that would be highly conducive to motor learning: massive amounts of variable and distributed practice largely free from aversive consequences for errors (Gentile, 2000; Schmidt & Lee, 1999). However, practice is not doled out evenly across infants and days and researchers have not yet linked the various features of infants’ practice regimen with improvements in walking skill. Thus, to infuse the construct of locomotor experience with conceptually mean-

ingful content, researchers might quantify practice or exposure by putting the number of walking steps, number of walking bouts, distance traveled, duration of time engaged in balance and locomotion, number of surfaces traversed, number of falls, or the like on the x-axis instead of simply counting the number of elapsed days since walking onset.

Movement Is Ubiquitous

Movement is perhaps the most ubiquitous, pervasive, and fundamental of all psychological activity. It is the hallmark of animacy and the essence of agency. Across development, self-initiated movements of the eyes, head, limbs, and body provide the largest source of infants’ perceptual experiences.

Epochs of Movement

As illustrated in the case of walking, the sheer quantity of infants’ experiences with movement is staggering. By the time that infants begin to show visual expectancies in laboratory tasks at 3.5 months of age, they may have performed 3 to 6 million eye movements outside the laboratory and viewed countless examples of occlusion and other visual events (Haith, Hazan, & Goodman, 1988; S. P. Johnson, Slemmer, & Amso, 2004). By the time that children succeed at spatial search tasks at 10 months of age, they have likely accumulated enough crawling steps to travel more than half the length of Manhattan (Adolph, 2005). By the time that infants are 12 months old, they have likely experienced over 110,000 bouts of wiggles, waves, kicks, and flaps of 47 different types of spontaneous rhythmical stereotypies in their legs, arms, heads, and trunks (Thelen, 1979, 1981b). The connectionist notion of “epochs” of experience (Munakata, McClelland, Johnson, & Siegler, 1997) is the appropriate metric for measuring the quantity of infants’ movement.

The vast quantity of experience, however, does not imply an unremitting march. The bursts and bouts of infants’ movements wax and wane with daily sleep/wake cycles and the acquisition of new motor skills. Although newborns are asleep most of the day, they are still moving (e.g., Erkinjuntti, 1988; Fukura & Ishihara, 1997). Sleeping movements include gross movements of the limbs and trunk together, localized movements of one limb, and fast twitches (Fukumoto, Mochizuki, Takeshi, Nomura, & Segawa, 1981). Waking movements are more

frequent and of higher amplitude, shifting from slow, writhing movements due to excessive co-contractions in the first weeks of life to smaller, more graceful, and purling fidgety movements between 8 and 12 weeks of life (Cioni, Ferrari, & Prechtl, 1989; Hadders-Algra & Prechtl, 1992; Hadders-Algra, van Eykern, Klip-Van den Nieuwendijk, & Prechtl, 1992; Prechtl & Hopkins, 1986). Rhythmic stereotypes are apparent from the 1st month of life and are most common when infants are awake and aroused but not crying (Thelen, 1979, 1981b). Peak frequencies of particular stereotypes coincide with the acquisition of new motor skills (e.g., kicking and rocking appear prior to crawling, waving the arms appears prior to reaching, and swaying appears prior to independent standing; Gesell & Thompson, 1934; McGraw, 1945; Spencer et al., 2000; Thelen, 1996).

Movement Is Pervasive in Development

From the very beginning of life, movement is a pervasive feature of development. Fetuses' first spontaneous self-produced movements appear somewhere between 5 and 6 weeks after conception, within a few days after fetuses develop body parts to move (Moore & Persaud, 1993). The earliest movements are tiny, barely discernible head bends and back arches (e.g., DeVries et al., 1982; Nilsson & Hamberger, 1990; Prechtl, 1985). At 6 to 7 weeks postconception, fetuses slowly wave their limbs (DeVries et al., 1982; Sparling & Wilhelm, 1993) and display quick, general startle movements, beginning in the limbs and radiating to the neck and trunk (DeVries et al., 1982). Between 7 and 10 weeks postconception, limb waves and body bends become larger and more rapid and forceful (DeVries et al., 1982). In addition, fetuses begin moving their arms and legs separately from the rest of their bodies, bend their heads up and down, turn their heads from side to side, open their mouths, hiccup, and bring their hands to their faces (DeVries et al., 1982; Sparling, van Tol, & Chescheir, 1999). They begin to execute their first "breathing" movements, moving their diaphragm and abdomen in and out to draw small amounts of amniotic fluid in and out of the lungs (James, Pillai, & Smoleniec, 1995; Pillai & James, 1990).

Starting at 12 weeks after conception, two thirds of fetuses' arm movements are directed toward objects in the uterus—their own faces and bodies, the wall of the uterus, and the umbilical cord (Sparling et al., 1999). Many hand-to-body and hand-to-object movements occur in brief bouts of activity (Sparling et al., 1999),

like fetal versions of Piaget's (1952) primary and secondary circular reactions. By 13 weeks after conception, the fetal movement repertoire has expanded to more than 16 different types of movements including whole body stretching, alternating leg movements, somersaults, yawns, sucking, and swallowing of the amniotic fluid through the nose and mouth (Cosmi, Anceschi, Cosmi, Piazze, & La Torre, 2003; DeVries et al., 1982; Dogtrop, Ubels, & Nijhuis, 1990; James et al., 1995; Kuno et al., 2001; Nilsson & Hamberger, 1990; Pillai & James, 1990). By 16 weeks, fetuses' hands can find their mouths so that they can suck their thumbs (Hepper, Shahidullah, & White, 1991). Fetuses begin moving their eyes even before the lids unfuse at 26 weeks (Dogtrop et al., 1990; Moore & Persaud, 1993; Prechtl & Nijhuis, 1983).

Fetal activities follow a daily rhythm, increasing during the evening and decreasing in early morning (Arduini, Rizzo, & Romanini, 1995). Across weeks of gestation, whole body movements and large movements of the arms and legs peak at 14 to 16 weeks postconception, averaging nearly 60% of each observation, then begin to decrease as fetuses' growing bodies occupy increasingly more space in the uterus (D'Elia, Pighetti, Moccia, & Santangelo, 2001; Kuno et al., 2001). By 37 weeks or so, fetuses are so cramped that their hands are often molded to the shape of their heads with the back of their hands pressed against the uterine wall (Sparling et al., 1999).

Movement Is Fundamental

Movements are not only omnipresent in development, they are literally as basic to life as breathing. Drawing air into the lungs requires movement of the diaphragm and intercostal muscles to expand the chest cavity (Goss, 1973; Marieb, 1995). After infants' first dramatic breaths at birth, breathing movements typically fade into the background of most researchers' awareness. Breathing, however, must be actively controlled when it occurs in conjunction with other movements, as when adults control their breathing movements during meditation, swimming, late stages of labor, and so on.

Like breathing, the seemingly simple acts of swallowing and sucking are often taken for granted. Although fetuses have ample practice exercising the muscles and body parts used for breathing and swallowing, fetuses do not breathe air and the two types of movements do not need to be coordinated (J. L. Miller,

Sonies, & Macedonia, 2003). In contrast, after birth, the anatomy of the body requires that breathing and swallowing movements be staggered in time so that infants do not get gas pains from ingesting air or choke from aspirating milk. Initially, milk and air share the same passage as they enter the body through the pharynx, but milk must divert to the esophagus and air to the trachea.

Sucking also begins prenatally (Humphrey, 1970). After birth, infants suck to feed and they display non-nutritive sucking movements while sleeping or sucking a finger or pacifier (Wolff, 1987). Although sucking is possible while breathing, healthy term infants most frequently stagger non-nutritive sucking and breathing movements with a complex 3:2 ratio of sucks to breaths (Goldfield, Wolff, & Schmidt, 1999a, 1999b).

The sophisticated temporal coordination between breathing, swallowing, and sucking movements is highlighted when infants have problems feeding (Craig & Lee, 1999). When coordination breaks down, breathing is typically the bottleneck (van der Meer, Holden, & van der Weel, *in press*). The need to breathe competes with the need to swallow (Goldfield, 2005). Premature infants are especially at risk for feeding problems, in part because it is difficult for them to regulate their breathing. Thus, they cannot coordinate the sucking, breathing, and swallowing movements required for feeding (Goldfield, 2005). For example, at 32 weeks postconception, preterm infants stop breathing for a few moments before and after each swallow (Mizuno & Ueda, 2003). The pauses allow infants to feed without choking on the milk, but they also result in insufficient amounts of oxygen while feeding. Like full term infants, by 35 weeks postconception, preterm infants can intersperse their swallows between the parts of a breath, swallowing between breathing out and breathing in (Mizuno & Ueda, 2003; van der Meer et al., *in press*).

During nursing, as milk flow increases, so too do sucking and swallowing. Milk accumulates in the mouth after several bursts of sucking, then it is swallowed. Additional swallows clear any residual milk left in the mouth (Newman, Keckley, et al., 2001). In addition to coordinating these movements during nursing, infants also change the ratios of sucking and swallowing to breathing over the course of a feeding session as they become satiated and the intensity of their sucking decreases (Goldfield, Richardson, Saltzman, Lee, & Margerets, 2005). When milk delivery is accommodated to premature infants' irregular breathing patterns (with a

cleverly instrumented bottle system), premature infants can better coordinate breathing, sucking, and swallowing to feed more effectively (Goldfield, 2005).

Summary: Models of Change

How might the details of infant sucking, wiggling, crawling, walking, kicking, and so on pertain to psychological research outside the domain of motor development? At a time when so much of the work in developmental journals consists of developmentally atheoretical descriptions or narrow developmental theories about highly specialized phenomena, an effort to extract general principles of development seems an important and refreshing enterprise (E. J. Gibson, 1994; Siegler & Munakata, 1993; Thelen & Smith, 1994). Indeed, Gesell's most important and enduring legacy may be his example of using the formal structure of infants' movements as a model system for understanding general principles of developmental change. With the case studies in this section, we provided the flavor of a model system approach to motor development by describing how researchers have used changes in the temporal structure and spatial configuration of infants' movements to address some of the big issues that all developmental psychologists must face: Can development create qualitatively new forms? What causes development to emerge? What is the role of variability in performance? How can we determine the shape of a developmental trajectory? How should we understand the passage of time? And, how ubiquitous is the stuff of development?

Thelen and Bates (2003) affirmed in a recent special issue on dynamic systems and connectionism their belief "that there are general principles of development: mechanisms and processes that hold true whatever the content domain" (p. 378). In motor development, Thelen's influential work stands as a testament to the effort to discover such general principles and to construct a unified dynamic systems approach to development (Thelen, 1995; Thelen et al., 2001; Thelen & Smith, 1994, 1998; Thelen & Ulrich, 1991). Dynamic systems may prove to be a grand unifying theory of development or it may not. Our guess is that any single approach may prove to be too limiting or too specious to do justice to the many guises that development takes and to the many issues that are raised by developmental research. However, without the effort to transcend the particulars of a phenomenon or a content domain, researchers will never

establish a science of development. Our aim in this section was to illustrate how a small, clear, specialized model system can be used to investigate large, complex, general issues in development. Moreover, the transparent nature of infants' movements nested over multiple time scales provides a uniquely tractable and generative model system for undertaking the enterprise of developmental science.

MOTOR DEVELOPMENT AS A PERCEPTION-ACTION SYSTEM

In contrast to movements, actions, by definition, imply intentionality and a goal (Pick, 1989; Reed, 1982). Whereas infants' rhythmical leg kicks and arm flaps may be a by-product of arousal or random neural activity, infants' actions on objects and surfaces are intentional and purposeful. Whereas spontaneous movements may serendipitously create functional outcomes, actions are goal-directed from the outset and are expressly performed to serve an immediate function. The speed at which 10-month-olds reach for a ball, for example, depends on whether their goal is to fit the ball into a tube or to toss it into a tub (Claxton, Keen, & McCarty, 2003). Each part of the action anticipates the next part and is geared toward the final destination.

Satisfying goals through action requires animals to detect affordances, select among them, and sometimes create new possibilities for action. Behavior must be flexibly adapted to the local conditions. Povinelli and Cant's (1995) description of primate locomotion through the jungle canopy provides a wonderful example. Long-tailed macaques are so lightweight that they can safely ignore the strength and compliance of the arboreal support surface. They travel along the tops of branches and vines on all fours like squirrels, stepping over small gaps between supports and leaping over large ones. Siamangs are a bit heavier. They circumvent falling by suspending themselves below the canopy and swinging along from arm to arm. They judge the distance between branches and vines in terms of their arm length and the boost provided by a springy branch and the inertia of their swing. Orangutans are so heavy—that the size of a large man—that the strength and the compliance of each branch are of crucial importance. They solve the problem of locomotion through the canopy by distributing their body weight over multiple supports, testing each branch and vine before shifting their

weight, and bridging the gaps between neighboring supports by bending a tapering tree trunk under their weight until grasping a branch on the far side.

Like primate locomotion, the case studies in this section exemplify the issues involved in realizing affordances for action. The starting assumption is that adaptive actions are always goal directed and always embodied and contextually embedded. As described in the previous section, infants walking over a straight, flat path at steady state velocity provide a wonderfully rich paradigm for analyzing the formal structure of gait patterns. However, as frustrated researchers quickly learn when they try to elicit steady state velocity from toddlers over repeated trials, infants usually have different goals in mind: Infants alter their own functional body dimensions by holding their arms out and carrying toys; they stop and start to investigate a detail of the testing walkway; they accelerate to run into their parents' open arms. Thus, researchers who study motor development as a perception-action system focus on infants' ability to achieve their goals by detecting and adapting to changes in their physical propensities and surrounding environments. Researchers vary the available perceptual information by experimentally manipulating infants' functional body dimensions and level of balance control, altering the properties of target objects and surfaces, and providing infants with various types of social support for action.

We begin this section with the prospective, future-oriented nature of goal-directed looking and reaching and describe how even the simplest movements of the eyes, head, trunk, and extremities require infants to anticipate disruptions to a stable postural base. We use infants' responses to challenging ground surfaces to illustrate both flexibility and specificity in learning to detect affordances for action and we describe how exploratory movements provide the perceptual basis for guiding actions. We conclude this section with examples of how tools create new possibilities for action.

Prospective Control

The development of action is basically a matter of increasing prospective control: preparing and guiding actions into the future (von Hofsten, 1993, 1997, 2003, 2004). Time only runs in one direction. Thus, the only part of an action that can be controlled is the part that has not yet happened (von Hofsten, 2003). Reactive responding is only a method of last resort. In the worst

case scenario, actions are irreversible and reactive responses result in dire consequences (trips, slips, collisions, falling from the jungle canopy). In the best case scenario, reactive post hoc corrections cause actions to be jerky and inefficient because of the neural time lag in transmitting information through the body and the mechanical time lag in getting the various body parts to move. Perceptual information links time past with time future by using feedback from just prior movements to anticipate the consequences of future actions and by using updates from recent perceptual events to predict what will happen next. Perception provides a time bubble to continually extend action into the future, like a protective cushion between the body and its surrounds.

Early Action Systems

Infants' looking behaviors are so frequently used to make inferences about perceptual and cognitive processes that developmental psychologists sometimes forget that the visual system is an action system, designed to scan the world and to track objects and events. Without the ability to control eye movements, to keep the fovea on a target, the visual system is functionally useless (von Hofsten, 2003). Like looking, a function of prehension is to bring a highly sensitive information-gathering device—the hands—to external objects. Prehension also functions to bring objects to the eyes for close-up visual inspection. Reciprocally, keeping the hands in view allows vision to aid in steering infants' reaches and grasps.

Indeed, eye and arm movements may be sufficiently coordinated in newborns to jump-start visual-manual exploration and goal-directed reaching. For example, newborns will actively work to keep their hands in the field of view. While lying supine with small weights tied to both wrists, newborns allowed the weight to pull their arm down on the side toward the back of their heads but resisted the weight on the arm toward which their face was turned (van der Meer, van der Weel, & Lee, 1996). Their hand-to-face action did not merely reflect the fencing posture of the asymmetric tonic neck reflex because when view of the hands was occluded, both arms sank. When view of the hand toward the back of infants' head was provided on a video monitor rather than directly, infants resisted the weight on the side opposite to the fencing posture (van der Meer, van der Weel, & Lee, 1995). Similarly, in a dim room, newborns kept their hand positioned in a narrow beam of light (van der Meer, 1997a). Viewing the hand appeared to be inten-

tional and prospective because infants moved their hand when the light beam moved and they slowed down their arm movements before the hand arrived in the light, rather than after they noticed that they could see it.

Moreover, months before infants can reach or grasp, newborns orient toward objects with eyes and arms as if pointing their available "feelers" toward it (von Hofsten, 1982). When strapped securely around the chest into a slightly reclined seat or held by the head to prevent collapsing under the pull of gravity, newborns' flailing arm movements became more directed toward a target object when the target was visually fixated than when they were looking elsewhere (Amiel-Tison & Grenier, 1986; von Hofsten, 1982).

Common Paths to Prospective

On a generous interpretation, infants' earliest actions show the inklings of prospective. For example, by 1 month of age, infants can smoothly pursue a moving target with their eyes (Aslin, 1981; Rosander & von Hofsten, 2000; von Hofsten & Rosander, 1996), indicating an intent to follow the target and the ability to match target velocity with eye velocity. Smooth pursuit anticipates the target's motion by extrapolating from the just seen motions to predict what will happen next (von Hofsten, 1997, 2003). However, neonates' smooth pursuit occurs only in short bursts. As their eyes begin to trail behind the target, they are forced to use jerky, reactive, saccades to catch up (Phillips, Finoccio, Ong, & Fuchs, 1997). The initial saccade may so dramatically undershoot the target that a series of small steps may be required to move the eye to the goal (Aslin & Salapatek, 1975). Moreover, prospective control is fragile in neonates and easily disrupted by demanding tasks and unsupportive contexts (von Hofsten & Rosander, 1997). The target must be quite large and move slowly in predictable sinusoidal motions from side to side for neonates to keep it in sight (von Hofsten & Rosander, 1997). With larger objects infants perform fewer catch-up saccades because less precision is required to keep the target on the fovea (Rosander & von Hofsten, 2002).

As shown in Figure 4.5a, over the ensuing weeks, smooth pursuit comprises an increasing portion of infants' visual tracking and corrective saccades comprise a decreasing portion, with the most rapid improvements between 6 and 14 weeks of age (Richards & Holley, 1999; Rosander & von Hofsten, 2002; von Hofsten & Rosander, 1997). Infants succeed at tracking smaller objects moving at faster speeds (Phillips et al., 1997;

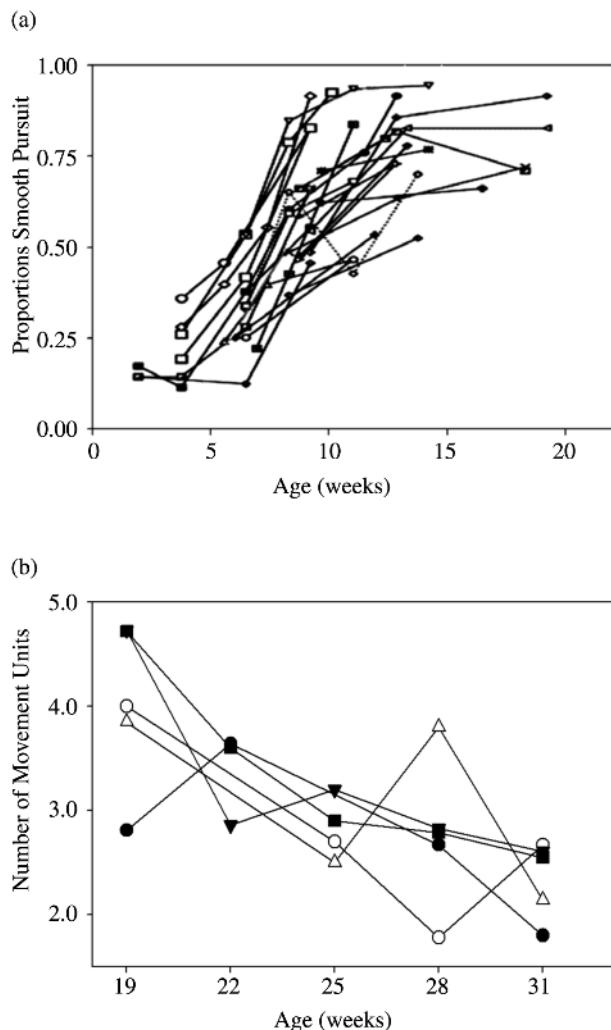

Figure 4.5 Developmental trajectories derived from longitudinal observations of eye and arm movements. (a) Smooth pursuit eye movements. *Source:* From “An Action Perspective on Motor Development,” by C. von Hofsten, 2004, *Trends in Cognitive Sciences*, 8, pp. 266–272. Reprinted with permission. (b) Movement units in reaching. *Source:* From “Structuring of Early Reaching Movements: A Longitudinal Study,” by C. von Hofsten, 1991, *Journal of Motor Behavior*, 23, pp. 280–292. For both looking and reaching, each curve represents a different infant. Note the large individual differences in the rate and amplitude of developmental change.

Richards & Holley, 1999; Rosander & von Hofsten, 2002). By 4 to 5 months, looking is sufficiently predictive for infants to track targets moving behind an occluder (e.g., Rosander & von Hofsten, 2004). Brief exposure to an unoccluded trajectory makes infants’ looking more anticipatory to occluded trajectories so that their eyes wait on the far side of the occluder to

catch the target when it reappears (S. P. Johnson, Amso, & Slemmer, 2003). By 3 months of age, infants can use rules instead of local extrapolation to predict the shifting location of a target (Adler & Haith, 2003; Wentworth, Haith, & Hood, 2002). By 5 months, they successfully track objects that abruptly reverse their direction of motion (von Hofsten & Rosander, 1997). By 6 months, they can use an arbitrary shape cue to anticipate the shifting location of a target (Gilmore & Johnson, 1995).

Infants’ prehensile actions show a similar developmental trajectory to looking. Reaching for stationary objects appears between 12 and 18 weeks (e.g., Berthier & Keen, in press; Clifton et al., 1993) and catching moving objects appears at approximately 18 weeks (von Hofsten, 1979, 1980). Just as infants’ first eye movements are saccadic and lagging rather than smooth and on-target, their first goal-directed reaches and catches are typically jerky and crooked. Initial reaches contain several “movement units,” where infants’ arms speed up and slow down and change directions before the hand finally contacts the toy (e.g., Berthier, Clifton, McCall, & Robin, 1999; Berthier & Keen, in press; Thelen et al., 1993; von Hofsten, 1980, 1983, 1991; von Hofsten & Lindhagen, 1979; Wentworth, Benson, & Haith, 2000). Corrections are more pronounced during faster reaches (Thelen, Corbetta, & Spencer, 1996).

Movement units and direction changes decrease after a few months until infants’ reaches and catches are made up of only two movement units, the first to bring the hand near the target and the second to grasp it (Figure 4.5b). Prospective extrapolations of target motion become increasingly resilient to loss of visual information. By 9 months, infants reach for moving objects on an unobstructed path but inhibit reaching when a barrier blocks the path (Keen, Carrico, Sylvia, & Berthier, 2003). By 11 months, infants catch moving objects as they appear from behind an occluder (van der Meer, van der Weel, & Lee, 1994).

What makes infants’ initial reaches so jerky and crooked? An initial suggestion was that movement units reflect visual corrections for a misaligned arm path (e.g., Bushnell, 1985). However, infants successfully reach for objects in the dark within a week or two of reaching in the light (Clifton et al., 1993), suggesting that they can use proprioceptive information to guide the reach. Indeed, by 5 to 7 months, infants can catch moving objects without sight of their hand by gauging the speed of the glowing object in the dark (Robin,

Berthier, & Clifton, 1996) and by 9 months, they preorient their hands to grasp in the dark (McCarty, Clifton, Ashmead, Lee, & Goubet, 2001). Several alternatives have been proposed. Possibly, the increased precision required to position the hand for grasping may prompt new researchers to plan the action as a series of small steps (Berthier, 1996, 1997; Berthier et al., 2005). Alternatively, some of the movement units might simply reflect unanticipated reactive forces (Berthier et al., 2005; Thelen et al., 1996; von Hofsten, 1997). Or, infants may have little motivation for efficient reaching (Withington, 2005)—the functional penalty for extra movement units is low—and might even use variable arm paths to explore the capabilities of their new action system (Berthier, 1996, 1997; Berthier et al., 2005).

Divergent Developments in Prospective Looking and Prehension

Looking and prehension involve more than the eyes and the arms. Visual tracking requires fine-grained coordination between eye movements and head movements to keep the eyes on the target while the head and body move, especially during locomotion or while being carried (Daniel & Lee, 1990; von Hofsten, 2003). Prehension involves decisions about whether to use one or two arms, which arm to move, and coordinating reaching with grasping—all in relation to the features of the target object.

Prospective control over the components of looking and prehension develop asynchronously. Predictive eye movements do not transfer automatically to predictive head movements and predictive one-armed reaches do not transfer automatically to prospective control of grasping or decisions about whether to use one or two arms. For example, weeks after infants can smoothly track moving objects with their eyes, they begin to make large tracking movements with their heads (von Hofsten, 2004; von Hofsten & Rosander, 1997). However, infants have difficulty suppressing the vestibular-ocular reaction and initially their heads lag so far behind the target that they must put their eyes ahead of the target to keep it in view. The functional consequence of discord between eyes and head is a decrease in tracking precision.

Similarly, the components of prehension develop asynchronously. For many weeks after infants can smoothly transport their hand to an object, they misalign their hand position vis-à-vis the object's orientation (Wentworth et al., 2000; Withington, 2005) and fail to adjust their hand opening to the object's size (Fagard,

2000; von Hofsten & Ronnqvist, 1988). Infants reach with their feet a full month before they reach with their hands (Galloway & Thelen, 2004). At the same age when infants show skilled reaches when one object is presented at midline, they respond haphazardly with one- and two-armed reaches to variations in object size (Corbetta, Thelen, & Johnson 2000; Fagard, 2000). Although infants may cross the midline of their bodies for two-armed reaches to large objects (van Hof, van der Kamp, & Savelsbergh, 2002), they fail to reach across midline when two objects are presented simultaneously (McCarty & Keen, 2005).

Like the developmental dissociations between the components of looking and prehension, prospective tracking and reaching for moving objects behind occluders appear at different ages. In general, infants demonstrate prospective control of looking before reaching. Their heads and eyes are on the target object when it reappears from behind the occluder while their hands seem lost or lag behind (Jonsson & von Hofsten, 2003; Spelke & von Hofsten, 2001; von Hofsten, Vishton, Spelke, Feng, & Rosander, 1998). By 11 months of age, infants can also intercept the occluded object with their hands (van der Meer et al., 1994).

Centrality of Posture

Maintaining balance is not optional. Actions require a stable postural base. Moreover, simply maintaining balance is usually not an end in itself (Riley, Stoffregen, Grocki, & Turvey, 1999). Rather, infants and adults maintain various postures to set up the necessary conditions for looking around, handling objects, holding conversations, or going somewhere (Stoffregen, Smart, Bardy, & Pagulayan, 1999).

Nested Actions

One reason for discrepant developments in the various components of looking and prehension is that actions are nested within other actions. Visual tracking with the eyes is nested within visual tracking with the head. Grasping with the hands and fingers is nested within reaching with the arms. Both looking and prehension—like all other actions—are embedded, in turn, within the most basic action of all: posture (Bernstein, 1967; E. J. Gibson & Pick, 2000; Reed, 1982, 1989).

Accordingly, one reason that newborns could demonstrate the inklings of prospective looking and reaching is that researchers eliminated the need for infants to

maintain the stable postural base required for action: Experimenters strapped infants around the chest into reclined seats or cradle-boards, supported their heads with side cushions, or held infants' heads in their hands. Without the supporting scaffolds provided by the experimenters, young infants would not have been able to turn their heads to track or extend their arms to reach (Spencer et al., 2000; von Hofsten, 2003). By 4 to 6 months of age, infants exploit the features of a normal high chair to create a stable base for reaching by using the back of the chair and the edge of the tray to help support their trunks (van der Fits, Otten, Klip, van Eykern, & Hadders-Algra, 1999). Even with the benefit of supports, posture exerts effects on reaching through gravity. At 3 to 4 months, infants reach more frequently while strapped sitting into a special seat than while lying supine, where the entire body is supported by the cot, because less muscle torque in the arms is required to fight gravity in an upright posture (Savelsbergh & van der Kamp, 1994).

Unsupported reaching awaits infants' ability to provide a stable postural base for themselves (Bertenthal & von Hofsten, 1998; Spencer et al., 2000). Reaching freely from a prone posture appears at approximately 5 months when infants can prop up their chest with one arm and reach with the other without tipping (Bly, 1994; McGraw, 1945). Reaching freely from a sitting posture appears between 6 and 8 months when infants can keep their heads balanced between their shoulders and maintain equilibrium in the trunk with their legs outstretched along the floor in a "V" (van der Fits et al., 1999). When infants first achieve propped sitting in a tripod position (propped on the arms between the outstretched legs), postural requirements compete with action goals. For example, new sitters reach with only one hand and avoid leaning forward because if they lift the supporting arm or disrupt the fragile equilibrium of the posture, they are likely to fall (Rochat, 1992; Rochat & Goubet, 1995).

Anticipatory Postural Adjustments

Establishing a stable postural base for actions requires infants to control balance prospectively (von Hofsten, 1993, 1997, 2003, 2004). Moving one part of the body to look, reach, or locomote creates disequilibrium by displacing the location of the entire body's center of gravity. Moreover, movements of the head or limbs create reactive forces on body parts far removed because all of the body is mechanically linked (Gahery & Massion, 1981). Lifting an arm requires forces to be directed for-

ward and upward. As a consequence, destabilizing forces of equal magnitude act in the opposite direction on the trunk. To prevent movement-induced disequilibrium from reverberating through the body, infants must anticipate postural disruptions and deal with them prospectively. In anticipation of the arms moving upward, adults activate neck and trunk muscles to stabilize the torso prior to activating arm and shoulder muscles to lift the arm. Or, adults shift the center of gravity backward prior to its being displaced forward. Without such prospective corrections to posture, the entire action can be disrupted and induce loss of balance and a fall.

Before 15 to 18 months of age, infants in a sitting posture rarely show anticipatory muscle activations of the trunk and neck to prepare for a reach (van der Fits & Hadders-Algra, 1998; van der Fits et al., 1999; von Hofsten, 1993). Instead, infants tend to activate arm, neck, and trunk muscles simultaneously. However, infants show other evidence of prospective control of balance during reaching. While strapped loosely around the waist in an infant seat, some 5-month-olds increased their reaching space by leaning forward (Yonas & Hartman, 1993). Attempts to reach decreased with increasing object distance, but infants who leaned attempted reaches at farther distances than the infants who did not lean. When balance constraints were altered with small wrist weights, 6-month-olds were less likely to stretch forward to reach than when they were not weighted (Rochat, Goubet, & Senders, 1999). Between 8 and 10 months of age, infants leaned forward in anticipation of raising their arm to reach for distant objects, suggesting that they perceived the additional stretch provided by their trunks and used the leaning posture to set up the framework for action (McKenzie, Skouteris, Day, Hartman, & Yonas, 1993).

As in a sitting posture, consistent anticipatory muscle activations in a standing posture appear between 15 and 17 months of age (Witherington et al., 2002). Lifting an object or pulling a weight with the arms causes a forward displacement of the center of mass. Adults' calf muscles anticipate the disruption by firing just prior to activation of the arm muscles. In a clever adaptation of the adult paradigm, infants were encouraged to pull open a small weighted drawer (Witherington et al., 2002). Anticipatory postural adjustments became more frequent, consistent, and finely timed between 10 and 17 months. After 3 months of walking experience, 80% of the trials involved anticipatory activation of the leg muscles.

Some researchers have argued for age-related, developmental stages in the acquisition of a stable postural base for action (Assaiante & Amblard, 1995), with increasing levels of control through sitting, standing, and walking stages. However, other researchers argue that the changes are likely to be related to expertise, regardless of the period of development (B. Bril, personal communication, December 15, 2004). Novice adults sitting on a unicycle or standing while wearing Rollerblades are in the same precarious position as novice infants trying to sit and reach or stay upright and walk.

Perceiving Affordances

Affordances are possibilities for action. As described below, infants must learn to discriminate actions that are possible from those that are not. In some cases, infants' learning is impressively flexible and transfers to novel situations. But, in other cases, learning is surprisingly specific and fails to transfer beyond the particulars of the training context. Together, flexibility and specificity of learning provide important insights into what it is that infants learn in the development of adaptive motor action.

The Actor-Environment Fit

Affordances reflect the objective state of affairs regarding infants' physical capabilities and the behaviorally relevant features of the environment (J. J. Gibson, 1979; Warren, 1984). Actions are possible or not, regardless of whether infants perceive, misperceive, or take advantage of the possibilities. Because affordances are relational, the facts of embodiment must be taken with reference to the properties of the environment and vice versa. For example, walking is possible only when infants have sufficient strength, postural control, and endurance relative to the length of the path, obstacles along the way, and the slant, rigidity, and texture of the ground surface.

In fact, bodily propensities and environmental properties are so intimately connected for supporting motor actions that changes in a single factor on either side of the affordance relationship alter the probability of successful performance. Researchers have experimentally manipulated possibilities for locomotion by loading infants with weights, extending their leg length with platform shoes, and dressing them in roller skates or rubber- and Teflon-soled shoes to alter their body dimensions and level of postural control. (An alternative

approach is to treat naturally occurring changes in infants' bodies and skills as predictors.) To alter possibilities for locomotion by manipulating environmental properties, researchers have varied the slant, friction, and rigidity of the ground surface, created gaps in the path, terminated the path in a cliff, blocked the path with overhead or underfoot barriers, varied the height of stair risers and pedestals, varied the width of bridges spanning a precipice, and varied the substance and extent of handrails used for manual support (for reviews, see Adolph, 1997, 2002, 2005; Adolph & Berger, 2005; Adolph et al., 1993b).

Following Warren, Mark, and colleagues' (Mark & Vogele, 1987; Warren & Whang, 1987) elegant psychophysical approach to describing affordances in adults, researchers have used a psychophysical staircase procedure to describe the probability of successful motor performance in infants (e.g., Adolph, 1995, 1997, 2000; Adolph & Avolio, 2000; Corbetta, Thelen, & Johnson, 2000; Mondschein, Adolph, & Tamis-LeMonda, 2000; Schmuckler, 1996; Tamis-LeMonda & Adolph, 2005). The staircase procedure is a classic method in psychophysics for estimating a perceptual threshold using a minimal number of trials (Cornsweet, 1962). When estimating a perceptual threshold, researchers plot the function spanning the increments where the observer's accuracy is 1.0 to those where the observer guesses at 0.50 chance levels. To describe an affordance, researchers estimate a "motor threshold" along a function spanning the increments where success rates are 1.0 to those where success rates drop to 0. (The success rate is the number of successful attempts to perform the target action divided by the sum of successful plus failed attempts. Trials where infants refuse to attempt the action do not enter the calculations.) Coarser estimates require approximately 15 to 20 well-placed trials per infant; more precise estimates require upward of 40 trials per infant.

Like many psychophysical functions, the curves that characterize the transition from possible to impossible actions are generally steep S-shaped functions with long extended tails. As a consequence, most actions are either possible or impossible for a wide range of situations and have a shifting probability of success under a narrow range of increments. To illustrate, for a typical 14-month-old on a sloping walkway covered in rubber, the probability of walking successfully may be close to 1.0 on slopes from 0° to 18°, close to 0 on slopes from 28° to 90°, and show a sharply decreasing function on slopes

from 18° to 28° that encompasses the motor threshold (Adolph, 1995; Adolph & Avolio, 2000); see dashed curve in Figure 4.6a. For the same infant on a walkway covered in slippery vinyl, the entire function shifts leftward along the x-axis; see solid curve in Figure 4.6a. The probability of walking successfully may be close to 1.0 on slopes from 0° to 6° , close to 0 on slopes from 16° to 90° , and show a sharply decreasing function on slopes from 6° to 16° (Adolph, Eppler, Joh, Shrout, & Lo, 2005; Lo, Avolio, Massop, & Adolph, 1999).

Typically, infants show a wide range in motor thresholds even when tested at the same age. For example, the range for 14-month-olds walking down carpeted slopes is 4° to 28° (Adolph, 1995; Adolph & Avolio, 2000). The size of infants' motor thresholds reflects their level of locomotor skill, duration of locomotor experience, age, body dimensions, and the specifics of the task (e.g., Adolph, 2002; Kingsnorth & Schmuckler, 2000; van der Meer, 1997b). In contrast to older children and adults where body dimensions are frequently the critical determinant of affordances for locomotion (Konczak, Meeuwson, & Cress, 1992; van der Meer, 1997b; Warren, 1984; Warren & Whang, 1987), with infants, skill and experience are generally the strongest predictors because between-subject variability is due more to differences in infants' strength and balance than to the geometry of their bodies.

Learning to Perceive Affordances

The critical question for understanding the adaptive control of action is whether affordances are perceived—whether infants can select appropriate actions to meet their goals by detecting affordances (or lack of them) prospectively (see Adolph et al., 1993b for a review; E. J. Gibson, 1982; E. J. Gibson & Pick, 2000; E. J. Gibson & Schmuckler, 1989). In essence, the perceptual problem is to determine whether a potential future action lies on one of the tails of the affordance function or along the inflection of the curve. Because the location of the affordance function along the x-axis varies with changes in local conditions (e.g., whether the slope is covered in carpet or slippery vinyl, whether the infant is carrying a load), to solve the perceptual problem, infants would need to continually update information about the current status of their own action systems relative to environmental conditions.

For human infants and other altricial animals, determining the current state of affairs is no easy feat. The problem of perceiving affordances is complicated by

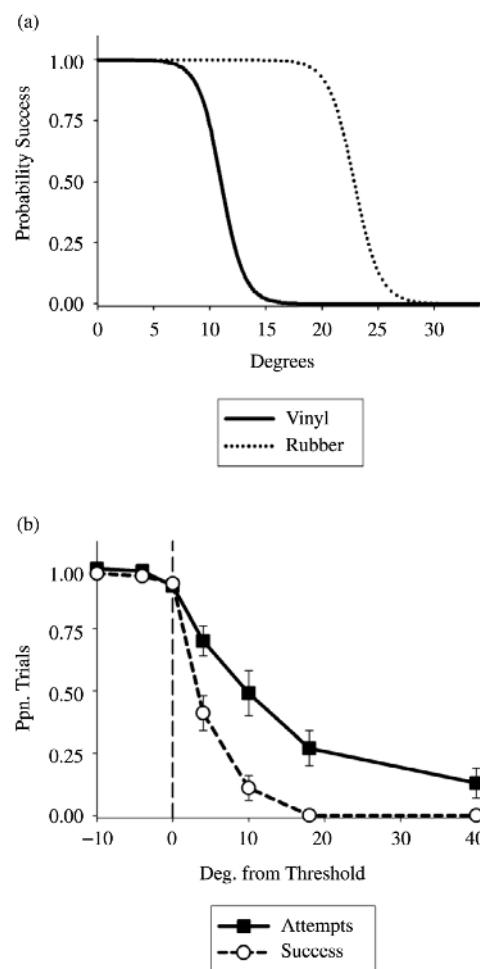

Figure 4.6 (a) Fitted curves showing the probability of walking successfully down high-friction rubber (dashed curve) and slippery vinyl (solid curve) covered slopes for a typical 14-month-old infant. *Source:* From *Walking Down Slippery Slopes: How Infants Use Slant and Friction Information*, by K. E. Adolph, M. A. Eppler, A. S. Joh, P. E. Shrout, and T. Lo, 2005, manuscript submitted for publication. (b) Actual (dashed curve) and perceived (solid curve) possibilities for walking down carpet covered slopes for a sample of 14-month-old infants. Success rate = (Successes)/(Successes + Failures). Attempt rate = (Successes + Failures)/(Successes + Failures + Refusals). Error bars represent standard errors. Data are normalized to each infant's motor threshold (represented by 0 on the x-axis). Positive numbers on the x-axis denote slopes steeper than infants' motor thresholds; negative numbers denote slopes shallower than infants' motor thresholds. Perfect perceptual judgments would be evidenced if the curves were superimposed. Parallel curves show that infants scaled their responses to their own skill levels. *Source:* From "Walking Infants Adapt Locomotion to Changing Body Dimensions" by K. E. Adolph and A. M. Avolio, 2000, *Journal of Experimental Psychology: Human Perception and Performance*, 26, pp. 1148–1166. Reprinted with permission.

rapid, large-scale developmental changes in infants' bodies, skills, and environments. As described earlier in this chapter, infants' bodies grow in sudden overnight spurts; reaching, sitting, crawling, and walking skills improve most dramatically over the first few months after onset; and the environments to which infants are exposed are continually expanding. Moreover, in contrast to many other altricial animals, human infants spend prolonged periods—months—coping with objects and navigating surfaces after achieving each postural milestone in development. Typically, infants sit independently at approximately 6 months of age, crawl at 8 months, cruise (move sideways in an upright posture) at 10 months, and walk at 12 months (Frankenburg & Dodds, 1967). Given the changeable nature of the actor-environment fit, several authors have proposed that infants must learn to detect possibilities for action (e.g., Adolph, 2005; Campos et al., 2000; E. J. Gibson & Pick, 2000).

The classic paradigm for studying infants' perception of affordances is the "visual cliff" (E. J. Gibson & Walk, 1960; Walk, 1966; Walk & Gibson, 1961). As illustrated in Figure 4.7a, crawling infants or other animals are placed on a narrow, 30-cm center board dividing a large glass-covered table. The glass is carefully lighted from beneath so that it is invisible from infants' vantage point. On one side of the table, a patterned ground surface lies 0.6 cm beneath the glass. On the other side, the ground surface is 102 cm below the safety glass. Although locomotion is possible in either direction over the sturdy safety glass, visually, the "shallow" side specifies safe passage and the "deep" side specifies an impossibly large drop-off. With babies, caregivers beckon to their infants from first one side and then the other, with 1 or 2 trials per side. With other animals, the experimenters place them on the center board to descend to the shallow or deep side on their own.

Dozens of experiments have yielded fascinating but conflicting findings regarding the roles of locomotor experience and fear in infants' avoidance of the apparent drop-off. The earliest studies showed that precocial animals such as chicks, kids, lambs, and piglets avoid the deep side of the visual cliff from their first days of life (E. J. Gibson & Walk, 1960; Walk & Gibson, 1961). If forcibly placed onto the safety glass, the animals brace their legs, bleat, tremble, and back up as if afraid of being unsupported in mid-air. Some altricial animals, such as kittens, rabbits, puppies, and monkeys, venture off the centerboard onto the deep side when they are newly locomotor or if they are prevented from acquiring

visual feedback from their own locomotor activities by rearing them in the dark or in a "kitty carousel" (Held & Hein, 1963; Walk & Gibson, 1961). However, rats, also an altricial species, do not require visual experience with locomotion to avoid the drop-off (Walk, Gibson, & Tighe, 1957).

With human infants, a frequently cited cross-sectional study found that crawling experience predicted avoidance responses (Bertenthal & Campos, 1984; Bertenthal, Campos, & Barrett, 1984). At the very same age at testing—7.5 to 8.5 months of age—only 35% of inexperienced crawlers ($M = 11$ days of crawling experience) avoided the apparent drop-off compared with 65% of more experienced infants ($M = 41$ days of crawling experience). However, other cross-sectional experiments controlling for crawling experience or test age found opposite results, where experience predicted crossing onto the deep side rather than avoidance (Richards & Rader, 1981, 1983). Longitudinal data are inconclusive because infants learn from repeated testing that the safety glass provides support for locomotion (Titzer, 1995). Avoidance attenuated in some experienced crawlers, and other infants used a compromise strategy of detouring along the wooden wall at the edge of the table (Campos, Hiatt, Ramsay, Henderson, & Svejda, 1978; Eppler, Satterwhite, Wendt, & Bruce, 1997).

In some cases, locomotor experience appears to be posture-specific: The same crawlers who avoided the drop-off when tested on their hands and knees crossed over the cliff when tested moments later in an upright posture in a wheeled baby-walker (Rader, Bausano, & Richards, 1980). In other cases, locomotor experience appears to generalize across postures: 12-month-old walkers avoided the apparent drop-off after only 2 weeks of walking experience appended to their several weeks of crawling experience (Witherington, Campos, Anderson, Lejeune, & Seah, 2005).

Findings are equally discrepant with regard to the role of fear. Seven-month-olds showed accelerated heart rate—a measure associated with wariness or fear—when they were lowered toward the deep side of the visual cliff after only 1 week of crawling experience or 40 hours of upright locomotor experience wheeling around in a mechanical baby-walker (Bertenthal et al., 1984; Campos, Bertenthal, & Kermoian, 1992). However, crawling experience was not related to heart rate in 9- and 12-month-olds and the 9-month-olds showed cardiac deceleration—a measure associated with interest—to placement on the deep side (Richards & Rader, 1983).

Caregivers (shown in a, not shown in b-f) stand at the far side of each apparatus and encourage infants to cross. Plexiglas ensures infants' safety on the visual cliff. An experimenter (shown in b-f) ensures infants' safety on the other obstacles.

Infants fussed slightly while lowered toward both the shallow and deep sides of the table but they also displayed positive vocalizations during placement on the deep side (Richards & Rader, 1983). Mothers' fearful facial expressions produced higher rates of avoidance in 12-month-old crawlers on a 30-cm drop-off than did mothers' joyful expressions, but the infants' own facial expressions were positive or neutral—not negative or fearful—on the trials when they avoided the drop-off (Sorce, Emde, Campos, & Klinnert, 1985).

Albeit the most famous test paradigm, the visual cliff is not optimal. The discrepant findings may result from methodological problems stemming from the use of the safety glass, the procedure of starting infants on the center board, the fixed dimensions of the cliff, and the practice of testing each infant in only 1 or 2 trials. Due to the safety glass, visual and haptic information are in conflict. The drop-off looks risky but feels safe and is, in fact, perfectly safe as infants discover over repeated trials. Similarly, when the visual cliff was modified by replacing the drop-off with a deformable waterbed (agitated from below to create ripples), 14- to 15-month-old walkers refused to walk when they could feel the rippling surface, but walked over the waterbed when it was covered with safety glass (E. J. Gibson et al., 1987).

Moreover, placing infants on the narrow center board gives them little room to maneuver; sometimes avoidant infants accidentally move onto the deep side or start onto the glass and then retreat (Campos et al., 1978; E. J. Gibson & Walk, 1960). The fixed dimensions on the visual cliff preclude researchers from assessing whether perception is scaled to action and from testing the accuracy of infants' perceptual judgments. The heights of the shallow and deep sides in the standard arrangement lie far on the tails of the affordance function, rather than along the inflection of the curve. Finally, data from a single trial per infant per condition are less stable than data from a single forced-choice trial (E. J. Gibson et al., 1987), and both procedures are more vulnerable to errant responses than methods that involve multiple trials per infant at each increment.

Specificity of Learning

Perception of affordances, like any perceptual judgment, involves observers' sensitivity to the signal and observers' response criterion. Both factors are highly influenced by the vicissitudes of single trials, especially with infant and animal subjects. To circumvent the methodological problems on the visual cliff, researchers

have devised testing arrangements involving slopes, gaps, and barriers where perceptual information was concordant with the actual affordance, errors in judgment had actual consequences, mobile infants began on a runway several steps prior to the obstacle, and the dimensions of the test apparatus were adjustable. Most important, each infant contributed multiple trials at each stimulus increment (e.g., Adolph, 1995, 1997, 2000; Adolph & Avolio, 2000; Schmuckler, 1996; for examples with older children, see Plumert, 1995, 1997; Plumert, Kearney, & Cremer, 2004; Pufall & Dunbar, 1992; van der Meer, 1997b).

Following Warren, Mark, and others' work with adults (e.g., Mark, 1987; Warren, 1984; Warren & Whang, 1987), researchers assessed the correspondence between infants' perceptual judgments and the actual possibilities for action. Because infants are preverbal, perceptual judgments were determined based on an attempt rate: The number of successful plus failed attempts to perform the target action divided by the sum of successful attempts, failed attempts, and refusals to attempt the action. (The inverse avoidance rate yields the same information.) As shown in Figure 4.6b, decreasing attempt rates relative to the motor threshold provide evidence that perception is scaled to action. A close correspondence between attempt rates and the actual probability of success indicates that perceptual judgments are accurate.

Several experiments used the psychophysical procedure to examine infants' perception of affordances for crawling and walking over slopes (for reviews, see Adolph, 2002, 2005; Adolph & Eppler, 2002). For each infant, researchers compared the correspondence between infants' perceptual judgments and the actual probability of success. As illustrated in Figure 4.7b, flat starting and landing platforms flanked an adjustable slope (0° to 90°). Rather than safety glass, an experimenter followed alongside infants to ensure their safety. Infants received easy baseline trials after each failure or refusal to renew their motivation to crawl or walk; parents stood at the end of the landing platform, encouraging infants to descend and applauding their efforts after each trial. The procedure biased infants toward using a liberal response criterion (meaning a higher false alarm rate) and thus provided a conservative test of infants' ability to detect affordances and respond adaptively.

Both cross-sectional (Figure 4.8a) and longitudinal data (Figure 4.8b) suggest that infants learn to perceive affordances for locomotion through everyday crawling

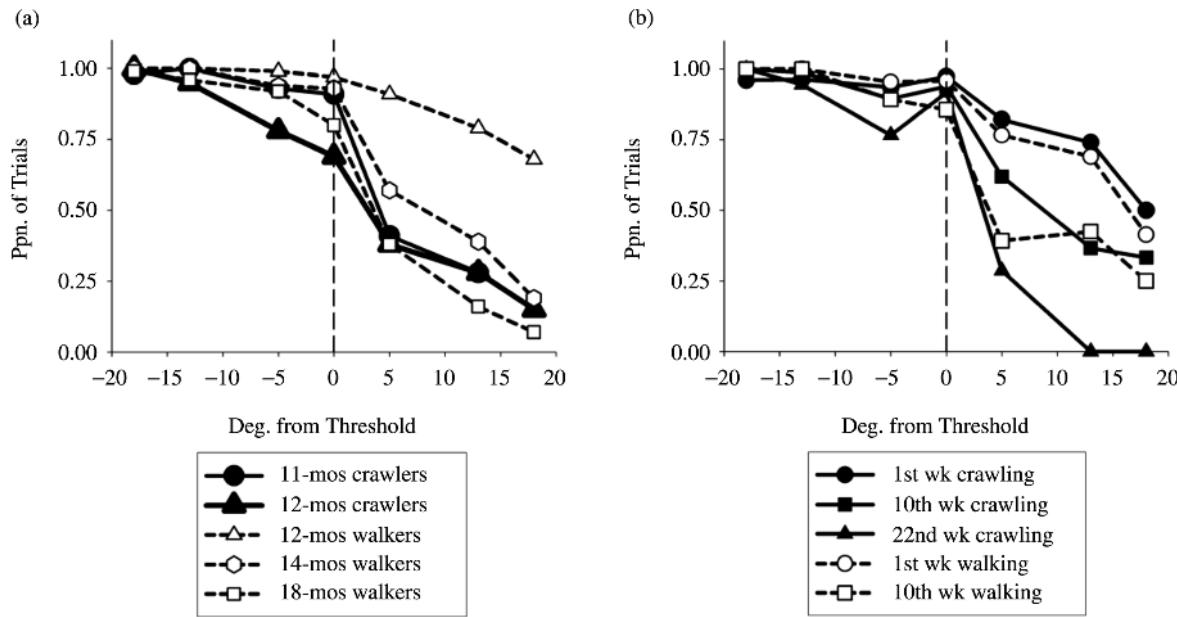

Figure 4.8 Perceptual judgments indexed by infants' attempts to crawl (solid curves) and walk (dashed curves) down slopes. (a) Cross-sectional data. *Source:* From “A Psychophysical Assessment of Toddlers’ Ability to Cope with Slopes,” by K. E. Adolph, 1995, *Journal of Experimental Psychology: Human Perception and Performance*, 21, pp. 734–750; “Walking Infants Adapt Locomotion to Changing Body Dimensions,” by K. E. Adolph and A. M. Lobo, and S. E. Berger, October 2005, paper presented to the Cognitive Development Society, San Diego, CA; Gender Bias in Mothers’ Expectations about Infant Crawling,” by E. R. Mondschein, K. E. Adolph, and C. S. Tamis-LeMonda, 2000, *Journal of Experimental Child Psychology*, 77, pp. 304–316. (b) Longitudinal data. *Source:* From “Learning in the Development of Infant Locomotion,” by K. E. Adolph, 1997, *Monographs of the Society for Research in Child Development*, 62(3, Serial No. 251). Attempt rate = (Successes + Failures)/(Successes + Failures + Refusals). Data are normalized to each infant’s motor threshold (represented by 0 on the x-axis). Negative numbers on the x-axis represent safe slopes shallower than infants’ motor thresholds. Positive numbers represent risky slopes steeper than infants’ motor thresholds. Note that perceptual errors (attempts on risky slopes) depend on infants’ motor experience within a posture, not on their age or the locomotor posture per se.

and walking experience. Moreover, learning appears to be specific to crawling and walking postures. In their first weeks of both crawling and walking, infants attempted slopes far beyond their ability and required rescue by the experimenter. Over weeks of crawling and walking, false alarms steadily decreased. Perceptual judgments gradually honed in to infants’ actual ability until attempts to descend closely matched the probability of success. The decrease in errors reflects remarkable behavioral flexibility because infants’ motor thresholds changed from week to week.

There was no evidence of transfer between crawling and walking postures. Infants tested repeatedly over weeks of crawling and walking showed no sign of savings in the transition from quadruped to upright postures, and infants in control groups matched for age and experience behaved similarly to infants tested repeatedly. Learning

was so posture-specific that new walkers avoided descent of an impossibly steep 36° slope in their experienced crawling posture but plunged down the same hill moments later when tested in their inexperienced walking posture (Adolph, 1997). Twelve-month-old crawlers avoided a 50° slope; 12-month-old walkers stepped blithely over the brink (Adolph, Joh, Ishak, Lobo, Berger, 2005). As Campos and colleagues (2000) wrote, “The mapping between vision and posture that results from crawling experience will need to be remapped as the infant acquires new motor skills such as standing and walking. . . . In fact, remapping is likely to occur with the acquisition of every new motor skill in a continuously coevolving perception-action cycle” (p. 174).

Posture-specific learning is not limited to crawling and walking postures or to locomotion over slopes. In a modern twist on the classic visual cliff, Adolph (2000)

used the psychophysical procedure to test 9.5-month-old infants' perception of affordances at the edge of a real 76-cm drop-off in sitting and crawling postures (Figure 4.7c to 4.7d). The apparatus was adjustable; the precipice lay below a 0- to 90-cm gap in the surface of support. The largest 90-cm gap was the size of the visual cliff. Caregivers encouraged their infants to lean forward over the gap to retrieve a toy. When tested in their experienced sitting posture ($M = 104$ days), infants perceived precisely how far forward they could lean without falling into the precipice; they matched the probability of attempting with the probability of success. However, when facing the gaps in their inexperienced crawling posture ($M = 45$ days), the same infants fell into impossibly large gaps. Nearly half of the sample in each of two experiments crawled over the brink of a 90-cm gap on multiple trials.

Similarly, infants showed specificity of learning between sitting and crawling postures when tested with barriers in their path. Over longitudinal observations, sitting infants reached around a barrier to retrieve a target object several weeks before they demonstrated the ability to crawl around the barrier (Lockman, 1984). When tested cross-sectionally, 10- and 12-month-olds were more successful at retrieving objects from behind a barrier when they were tested in a sitting position than when they had to execute the detour by crawling (Lockman & Adams, 2001). When the task was to learn a location based on repeated trips to mothers' hiding place, experienced crawlers fared better than younger novice crawlers and better than older novice walkers (Clearfield, 2004). Younger crawlers attempted locomotion over a rippling waterbed on hands and knees but older walkers refused to step onto the waterbed or switched from their typical upright posture to quadruped (E. J. Gibson et al., 1987).

Infants may even show posture-specific learning between two upright postures: cruising and walking (Adolph, 2005; Adolph & Berger, 2005; Leo, Chiu, & Adolph, 2000). Like walking, cruising involves an upright posture. However, in contrast to walking, cruising infants move sideways and cling to a handrail or furniture for support. Using the psychophysical procedure, 11-month-old cruising infants were tested in two conditions. The handrail condition was relevant for maintaining balance with the arms in cruising: a solid floor with an adjustable gap (0 to 90 cm) in a handrail. The floor condition was relevant for maintaining balance with the legs in walking: a solid handrail with an adjustable gap

(0 to 90 cm) in the floor. Infants correctly gauged how far they could stretch their arms to cruise over the gap in the handrail but the same infants erred when judging how far they could stretch their legs to cruise over the gap in the floor beneath their feet. New walkers erred in both conditions, failing to judge how far they could travel between manual supports in the handrail and stepping into impossibly large gaps in the floor.

What Infants Learn

What might infants learn that would lead to posture-specific perception of affordances? Several possibilities can be eliminated. In the slopes and gaps experiments where perceptual errors caused infants to fall, babies were not learning that the experimenter would catch them. Although the experimenter did rescue them as they fell, infants in longitudinal studies became more cautious over sessions, not more reckless; and in cross-sectional studies, the same infants who were caught dozens of times in their inexperienced posture avoided the obstacle when tested in their experienced posture.

Learning fear of heights is a frequently cited explanation (e.g., Campos et al., 2000). However, external manifestations of fear are not required for mediating an adaptive avoidance response, and it is unlikely that fear would wax and wane with changes in body postures. As on the visual cliff, crawling and walking infants in both cross-sectional and longitudinal studies showed primarily positive and neutral facial expressions and vocalizations, not fearful expressions or crying, as they avoided impossibly steep slopes (Adolph & Avolio, 1999; Fraisse, Couet, Bellanca, & Adolph, 2001; Stergiou, Adolph, Alibali, Avolio, & Cenedella, 1997). When infants' mothers provided them with encouraging and discouraging social messages, 18-month-olds only deferred to their mothers' unsolicited advice when the probability of success was uncertain (0.50 as determined by the psychophysical procedure). Moreover, they displayed primarily positive facial expressions and vocalizations at every increment regardless of whether they walked or avoided (Karasik et al., 2004; Tamis-LeMonda, Adolph, Lobo, Karasik, & Dimitropoulou, 2005).

Perhaps the most commonsense explanation is that infants learn that drop-offs, steep slopes, and the like are dangerous. However, the finding of posture-specific learning belies the notion that infants might learn to use particular facts about the environment to guide their actions, even when those facts hold true. Infants always require a sturdy floor to support their bodies. A 50° slope

and 90-cm gap are risky for every infant in every posture. The location of a hidden object is the same whether infants are sitting, crawling, or walking.

Similarly, the finding of flexibility within postures belies the notion that infants learn static facts about their physical propensities. In the longitudinal slopes study, experienced infants updated their perceptual judgments to reflect naturally occurring improvements in their crawling or walking skill (Adolph, 1997). In a cross-sectional experiment, when infants' bodies were made more top-heavy and their balance more precarious by loading them with lead-weighted shoulder packs, infants recalibrated their perception of affordances from trial to trial (Adolph & Avolio, 2000). They correctly treated the same degree of slant as risky while wearing lead-weighted shoulder packs and as safe while wearing feather-weighted packs.

Along the same lines, infants do not learn simple stimulus-response (S-R) associations or fixed patterns of responding to particular environmental conditions. Rather, variety of responding is a common feature in studies where infants encounter obstacles to locomotion (e.g., Berger, 2004; Berger & Adolph, 2003). Experienced walkers displayed alternative locomotor strategies for coping with risky slopes: crawling down on hands and knees, sliding headfirst prone in a Superman position, backing down feet first, sliding in a sitting position, holding onto the experimenter for support, and avoiding traversal entirely by remaining on the starting platform (e.g., Adolph, 1995, 1997). Individual infants used multiple strategies at the same increment of slope within the same test session.

What, then, do infants learn that promotes flexible transfer across changes in bodies and skills but not across postural milestones? Since Thorndike's (1906; Thorndike & Woodworth, 1901) classic theory of identical elements, researchers in motor skill acquisition have assumed that transfer depends on the extent to which elements of the training context are similar to elements of the performance context (Adams, 1987; J. R. Anderson & Singley, 1993). In our view, given the novelty and variability of motor actions, the notion of identical elements in simple association learning is far too static and narrow to account for learning to perceive affordances (Adolph & Eppler, 2002).

Harlow's (1949, 1959; Harlow & Kuenne, 1949) notion of "learning sets" represented a try at something broader than simple association learning. His idea was that learners might acquire a set of exploratory procedures and strategies for figuring out solutions to novel

problems within a circumscribed problem space (Stevenson, 1972). This set of information-gathering behaviors and heuristic strategies allows learners to solve novel problems of a certain type. The scope of transfer should be limited only to the boundary of the problem space. Rather than learning particular solutions, facts, or cue-consequence associations, learners are, in Harlow's words, "learning to learn."

In Harlow's classic learning set paradigm, monkeys acquired a "win-stay/lose-shift" rule that would allow them to solve new instances of discrimination problems. But, solving novel problems in the circumscribed space of discrimination problems is a far cry from solving novel problems in the world of everyday motor actions. A fixed rule cannot provide the necessary flexibility to cope with a varying body, a varying environment, and moment-to-moment variations in biomechanical constraints.

Learning to learn in the context of controlling everyday motor actions requires something even bigger, something akin to the information-gathering procedures and strategies of Harlow's learning sets, but more flexible than a rule. As suggested in the next section, infants assemble a repertoire of exploratory behaviors to generate the requisite perceptual information to specify affordances (Adolph & Eppler, 2002). Once infants can both generate and detect information about their physical capabilities and environmental properties, they are equipped to perceive possibilities for action. To the extent that each postural control system functions as a separate perception-action system (i.e., a distinct problem space), perceptual information will fail to transfer between postural milestones in development (Adolph, 2002, 2005).

The Perception-Action Loop

Perception and action are linked together in a continuously evolving loop (J. J. Gibson, 1979; von Hofsten, 2003). The textbook image of a motionless eyeball waiting to receive perceptual information is overly simplistic. In real life, eye, head, limb, and body movements bring the perceptual systems to the available information; "We don't simply see, we look" (E. J. Gibson, 1988, p. 5). The traditional distinction between perception and motor control is largely artificial. Every movement is accompanied by perceptual feedback, and many types of visual, haptic, vestibular, and proprioceptive information do not exist without movement (J. J. Gibson, 1979). Reciprocally, prospective control of action relies on perceptual information. Perceptual feedback from

ongoing movements creates the potential for feed-forward control. Thus, the perception-action loop can guide future actions rather than merely elicit them.

Over time, the loop comes to reflect developmental changes in infants' perception-action systems, and experience refines infants' actions toward more optimal function (E. J. Gibson, 1988; von Hofsten, 2003). Improvements in eye/head, manual, and postural control help infants glean visual information about external events and spurs their attention to the properties of objects and surfaces (Eppler, 1995; Needham, Barrett, & Peterman, 2002). Reciprocally, interesting visual displays motivate infants to seek information through looking. Feedback from interactions with objects and experiences with stance and locomotion facilitates improvements in prehension and locomotion.

For example, even the quiet touch of an infant's hand resting on a stable surface provides information (and support) for postural stability. Infants in the early stages of upright balance used a manual support reactively to control their postural sway; they altered downward forces on the supporting handrail after their bodies began to sway (Barela, Jeka, & Clark, 1999; Metcalfe & Clark, 2000). More experienced walkers stabilized posture prospectively by changing the amount of downward force prior to body sway. Over the 4-month period between pulling themselves upright and acquiring 1.5 months of walking experience, the amount of vertical force applied to the handrail decreased by 50%.

Sensitivity to Perceptual Information

What is required to detect affordances? Perceptual information is a necessary but not a sufficient condition for perceiving possibilities for action. Without the appropriate information, infants have no basis for selecting or modifying actions and prospective control is doomed to fail: Walkers will trip over an obstacle in their path if they do not see it. Even with information available, infants must know where to direct their attention and be able to distinguish the relevant information structures. To illustrate with a classic (and hilarious) example of perceptual learning, both naive and expert adults looked at the same pairs of chick genitals, but only the experts could reliably differentiate their sex (Biederman & Shiffrar, 1987; E. J. Gibson, 1969). In short, prospective control will fail without both the appropriate exploratory behaviors to generate the crucial information and the perceptual expertise to tell the difference.

In the laboratory, experimenters can simply make information available to infants and measure their reac-

tions. Differential responding would provide evidence for perceptual sensitivity. In the case of locomotion, insensitivity to visual information for depth, rigidity, slant, and self-motion is surely not responsible for perceptual errors at the edge of a cliff, waterbed, and steep slope. Infants show sensitivity to visual information about properties of surfaces and about the equilibrium of their own bodies long before they are independently mobile and even before they can sit up, reach, or fully control their heads. Newborns respond differentially to visual information for a drop-off versus solid ground, deformable versus rigid surfaces, and to surfaces slanting to different degrees in depth (e.g., Campos, Langer, & Krowitz, 1970; E. J. Gibson & Walker, 1984; Slater & Morison, 1985).

Prelocomotor infants also are sensitive to visual information for self-motion. Newborns pushed their heads backward in response to optic flow displayed on monitors along the sides of their heads (Jouen, 1988; Jouen, Lepecq, Gappen, & Bertenthal, 2000). Remarkably, the speed and amplitude of their head movements were related to the velocity of the optic flow. Infants 3 to 4 months old distinguished a looming obstacle from an approaching aperture, indicating sensitivity to visual information about collision and safe passage (Gibson, 1982; Schmuckler & Li, 1998). Infants 3 to 6 months old even showed crude sensitivity to visual information for the direction of heading ($> 22^\circ$) based solely on patterns of optic flow (Gilmore, Baker, & Grobman, 2004; Gilmore & Rettke, 2003).

The standard apparatus for testing sensitivity to visual information for self-motion is a "moving room" (e.g., Lee & Lishman, 1975; Lishman & Lee, 1973). Infants sit or stand on the stationary floor while the walls and ceiling in a mini-room around them swing forward and backward. Movement of the room in one direction simulates the optic flow that would result from a body sway in the opposite direction. Although the moving room puts visual and muscle-joint information into conflict (infants see that they are moving but feel that they are stationary), the sensation of induced sway is very compelling. To compensate for perceived disequilibrium, sitting infants sway their heads and torsos and standing or walking infants sway, step, stagger, and fall in the direction of the room movement (e.g., Bertenthal & Bai, 1989; Butterworth & Hicks, 1977; Lee & Aronson, 1974). Adults differentiate two kinds of flow structure, primarily using lamellar flow from movement of the side walls (optic texture elements stream in parallel along the sides of the path) to control their posture while

reserving radial flow from the front wall (optic texture elements stream outward from a central point of expansion) to guide their direction of heading (e.g., Stoffregen, 1985, 1986; Warren, Kay, & Yilmaz, 1996). Moreover, adults functionally differentiate the velocity of the flow, primarily using sway frequencies less than 0.5 Hz to control balance (Stoffregen, 1986; van Asten, Gielen, & van der Gon, 1988).

With age and experience, infants show more modulated behavioral responses to induced self-motion, increased functional differentiation of optic flow structures, and a tighter coupling between their sway responses and the timing and amplitude of room movements. In an upright position, younger children (< 24 months) were literally bowled over in the moving room, but older children (2 to 6 years) and adults responded with smaller, more modulated postural sways (e.g., Schmuckler, 1997; Stoffregen, Schmuckler, & Gibson, 1987; Wann, Mon-Williams, & Rushton, 1998). Seated 9-month-olds showed functional differentiation of optic flow structure by producing directionally appropriate sways in response to whole room and side wall movement; 7-month-olds responded appropriately to whole room movement; but 5-month-olds responded indiscriminately (Bertenthal & Bai, 1989). Greater attention to the functional significance of optic flow structures in the older infants may have been facilitated by experience with locomotion; 8-month-olds with locomotor experience showed more postural responses to side wall movements than did precrawling infants of the same age (Campos et al., 2000; Higgins, Campos, & Kermoian, 1996). Similarly, standing and walking infants (12 to 24 months of age) displayed more staggers and falls to whole room and side wall movements than to front wall movements (Stoffregen et al., 1987). The dual task of steering while maintaining balance in a “moving hallway” caused more postural disruptions than walking along an open path (1- to 5-year-olds), and younger, less experienced walkers were more aversely affected (Schmuckler & Gibson, 1989).

Continuously oscillating movements of the whole room entrained sitting and standing infants’ postural responses so that they swayed back and forth like puppets in accordance with the room movements (Barela, Godoi, Freitas, & Polastri, 2000; Delorme, Frigon, & Lagace, 1989). The timing and amplitude of sway responses in older, more experienced sitters (9- and 13-month-olds) were more tightly linked to the frequency and amplitude of the continuously oscillating visual flow than the

sways of younger, less experienced sitters (5- and 7-month-olds; Bertenthal, Rose, & Bai, 1997). Unlike adults, sitting 9-month-olds and standing 3- to 6-year-olds swayed in response to continuous room oscillations from 0.2 to 0.8 Hz (Bertenthal, Boker, & Xu, 2000; Schmuckler, 1997). However, like adults, sitting infants showed a linear decrease in the correlation between the swaying movements of their heads and the driving frequency of the room.

Information-Generating Behaviors

Outside the laboratory, disruptions to posture are generally self-induced by infants’ prior movements, not externally imposed by moving the surrounding room. There is no experimenter to distill perceptual information and present it to infants for their reactions. Instead, infants must do much of the information gathering for themselves. Even then, the availability of perceptual information does not guarantee that it will be detected.

To examine information gathering, researchers observe the exploratory behaviors of freely moving infants as they approach various obstacles in their path. Walking infants hesitated longer and engaged in more visual scanning and touching at the edge of a rippling waterbed (agitated from beneath) compared with the brink of a rigid surface (E. J. Gibson et al., 1987). Both crawling and walking infants—at all levels of age and experience—exhibited longer latencies and more looking and touching as they approached risky slopes compared with safe ones (Adolph, 1995, 1997; Adolph & Avolio, 2000; Adolph, Eppler, & Gibson, 1993a). Walkers generated visual and mechanical information by standing with their feet straddling the brink and rocking back and forth over their ankles. Crawlers leaned forward with both hands on the slope and rocked over their wrists (drawn in Figure 4.7b).

Sitting, crawling, and cruising infants generated information about the size of a gap in the floor by stretching their arm (or leg in the case of cruisers) out over the precipice and then retracting it (Adolph, 2000; Leo et al., 2000). Figure 4.7c to 4.7d illustrates examples. Cruisers explored the size of a gap in the handrail by stretching and retracting their arms over the gap. Similarly, walkers explored possibilities for crossing a deep precipice via a narrow bridge by peering into the gap, dipping their foot into the gap, touching the bridge with their feet, and holding onto a support pole while stretching out a foot to see how far they could walk onto the bridge before having to let go (see Figure 4.7e; Berger &

Adolph, 2003; Berger, Adolph, & Lobo, 2005). Across studies, latency, looking, and touching were elevated on risky increments compared with safe ones.

On waterbeds, slopes, gaps, bridges, and the visual cliff, infants of all ages produced another kind of information-generating behavior: social expressions (e.g., Fraisse et al., 2001; Karasik et al., 2004; Richards & Rader, 1983; Sorce et al., 1985; Stergiou et al., 1997; Tamis-LeMonda & Adolph, 2005). Most infants vocalized (primarily babbles, open vowels, calls, and grunts rather than whimpers and cries; few words) and older infants also used manual gestures (e.g., arms outstretched toward their parents, pointing). Like perceptual exploration, infants' social expressions were most frequent at risky increments. Researchers instructed caregivers about how to respond so as to manipulate or control for their social messages. However, under more natural conditions, presumably caregivers would respond with sensible and individually tailored social information in the form of encouragement or prohibition.

The Real-Time Loop

Largely absent from the infant and adult literatures on perceptually guided locomotion is a mechanistic account of the real-time, perception-action loop. What prompts infants in the ongoing course of locomotion to shift their attention to an obstacle, engage in concerted looking and touching, vocalize, look toward a caregiver, and so on? Given that infants' exploratory behaviors are not random or indiscriminate, one thing must lead to another. The loop must spiral along from moment to moment until infants select a different action and begin again.

We offer two suggestions. First, not all information gathering need be deliberate (Adolph, 1997). Some types of information can arise serendipitously as a consequence of ongoing movements. Optic flow, for example, arises as a by-product of locomotion. With the eyes parked in front of the walker's face, both radial flow for steering and lamellar flow for balance become instantly available (Patla, 1998). New walkers, however, have a problem. Tipping their heads downward to look at the ground near their feet throws their bodies off-balance (hence, toddlers' "Frankenstein" gait). Thus, visual scanning of the near ground is likely to be deliberate.

In contrast, newly crawling infants tend to point their faces downward, perhaps because lifting the head requires more balance and neck strength. For them, visual information about the ground near their hands is cheaply available. Moreover, new crawlers frequently move in

bursts punctuated by bouts of rocking. Such movements create torque around infants' wrists and shoulders and shear force between their hands and the ground—all useful types of mechanical information (especially if they occur at the edge of a slope, waterbed, foam pit, or slippery surface) arising as a happy by-product of poor crawling skill.

Like looking and touching, social information gathering need not be deliberate. Individual animals (or entire species) can co-opt happenstance forms in adaptive ways. Young infants might vocalize without the intent to communicate and thereby serendipitously elicit useful social information from their caregivers. A similar notion of communicative exaptations is well documented in the animal literature. For example, rat pups emit ultrasonic vocalizations when they are separated from the nest. Although the squeaks serve a communicative function by prompting dams to return pups to the nest, pups are not deliberately calling to their mothers for help. The cause is simply a physiological response to rapid body cooling (Blumberg & Sokoloff, 2001, 2003). In the course of locomotion, rodents emit ultrasonic squeaks, horses wheeze, and dogs bark due to the compression of the thorax as their forelimbs hit the ground (Blumberg, 1992). Human infants 9 to 13 months old emitted grunts as a consequence of physical effort while crawling, moving from standing to squatting positions, and trying to lift the lid on a bottle (McCune, Vhiman, Roug-Hellichius, Delery, & Gogate, 1996). In the case of perceptually guided locomotion, infants' vocalizations might arise as a by-product of arousal caused by the first sight of a large drop-off or steep slope; or, infants' noises might stem from the physical exertion of mustering a crawling burst. Either way, an acoustic by-product of an underlying physiological maneuver does not preclude the listener from hearing a useful communicative signal. Regardless of infants' initial intent, caregivers respond and are likely to precipitate a sort of "conversation" about the wisdom of attempting traversal.

A second suggestion for the precipitating events in a real-time perception-action loop concerns the role of visual information from a distance. Variations in the geometric layout of the terrain—cliffs, slopes, gaps, barriers, passageways, elevations, and so on—are specified by a host of visual depth cues. In addition to optical expansion and contraction, infants are sensitive to motion parallax, accretion and deletion of texture, stereoscopic information, convergence, and several pictorial depth cues (for review, see Kellman & Arterberry,

2000). Thus, the real-time sequence of information gathering is likely to begin with visual information about the surface layout (Adolph, Eppler, Marin, Weise, & Clearfield, 2000). When the ground surface appears relatively flat and continuous (as in the baseline trials or control condition in most experiments), infants crawl or walk without hesitation or breaking stride. When infants detect depth information for a change in the layout, like adults, they may be prompted to modify their gait (Mohagheghi, Moraes, & Patla, 2004; Patla, 1991; Patla, Prentice, Robinson, & Neufeld, 1991) and to engage in more concerted looking and touching.

In most cases, reliance on visual depth cues is highly efficient. However, when the ground is deformable or slippery, visual information from a distance may fail to elicit the appropriate exploratory behaviors (Adolph, Eppler, et al., 2005; Joh & Adolph, in press; Lo et al., 1999; Marigold & Patla, 2002). Adults may rely on erroneous intuitions about the predictive relationship between deformable surfaces and rounded contours and between slippery surfaces and shine (Joh, Adolph, Campbell, & Eppler, in press). For example, more than 300 participants (15- to 39-month-old children and adults) walked straight into a large foam pit and fell. Apparently, the rounded edges and irregular surface of the foam blocks were not adequate to specify deformability. (Note, in the Gibson et al., 1987, waterbed experiments, event information for deformability was created by a researcher agitating the surface from underneath.)

Creating New Affordances for Action

Possibilities for action are not always constrained by infants' immature bodies and limited skills. Happily, infants live in a world that is populated by caregivers who are willing to lend a helping hand, a world that abounds with objects and surfaces that can be incorporated as tools into an action plan. Although researchers typically do not consider social interaction and cognition to be central to the perception-action approach, social supports and tools can expand affordances for action and even create new possibilities for action.

Parents' Role in Promoting Action

The development of action is not a lonely enterprise. Infants typically acquire new motor skills in a supportive social context (Tamis-LeMonda & Adolph, 2005). Before infants can exploit affordances for action on their

own, caregivers create affordances for them. Caregivers scaffold prewalkers into walking infants simply by offering them a finger to hold onto for support. Similarly, in recent clever experimental manipulations, researchers have promoted new actions at earlier ages than if infants had to discover them on their own. For example, 3-month-olds who normally lack the motor skill to handle objects manually wore "sticky mittens" with Velcro-covered palms as they played with Velcro-edged toys (Needham et al., 2002). After the training, infants could pick up the toys and explore them as well as 5-month-olds who acquired their manual skills naturally. Seven-month-old prelocomotor infants learned to move around the room using a powered-mobility-device—a joystick controlled, battery operated buggy (D. I. Anderson et al., 2001; Campos et al., 2000).

Differences in child-rearing practices highlight parents' role in providing opportunities for action. Parents promote action by organizing and constraining the circumstances surrounding infants' developing skills (Reed & Bril, 1996). Caregivers decide whether infants are on the floor (Adolph, 2002; Campos et al., 2000), whether they have access to stairs (Berger, Theuring, & Adolph, 2005), and whether they sleep on their stomachs or on their backs (Davis, Moon, Sachs, & Ottolini, 1998; Dewey, Fleming, Golding, & Team, 1998). In some cultures, caregivers carry newborns as if they were a fragile carton of eggs and protect them from intense stimulation. In others, they throw newborns into the air and catch them, and stretch and massage their limbs (Bril & Sabatier, 1986; Hopkins & Westra, 1988, 1989, 1990; Super, 1976). Some cultures encourage new skills verbally. Others "train" infants, for example, by propping 3- to 4-month-olds in a special hole in the ground to promote sitting (Hopkins & Westra, 1988, 1989, 1990; Super, 1976) and jumping infants up and down to promote walking (Keller, 2003). As a consequence of the variation in child-rearing practices, infants acquire their sitting, crawling, walking, and stair-climbing at different rates—at later ages for children with fewer opportunities and less practice.

Tools Expand Possibilities for Action

Implementing a tool allows infants to create new affordances for action by themselves. When infants' current physical abilities are inadequate for achieving a goal, tools can improve the actor-environment fit (Bongers, Smitsman, & Michaels, 2003). Tool use requires infants to (1) perceive a gap between their own motor abilities

and a desired goal, (2) realize that an object or environmental support can serve as an alternative means to bridge the gap, and (3) implement the tool successfully (Berger & Adolph, 2003). Although most researchers focus on the cognitive skills required by the second step (Chen & Siegler, 2000; Piaget, 1954), perceptual-motor skills are central to all three steps (Lockman, 2000). The first step to successful tool use involves perceiving (lack of) affordances for action—understanding that a desired object is too far out of reach or that the intended action is blocked by an obstacle (Berger et al., 2005). Developmentally, perceiving impediments to action appears before a concerted search for alternative means and both may appear prior to a search that incorporates an external object or environmental support (McCarty, Clifton, & Collard, 2001; Piaget, 1952; Willatts, 1984).

The means-ends problem solving that is so critical for the second step to tool use may have its roots in the perceptual-motor activity of relating objects to surfaces through actions (Lockman, 2000). For example, 8-month-olds relate objects to surfaces according to their respective material properties (Lockman, 2005). They perform banging actions with solid objects on solid tabletops but not when the object or surface is soft. Eventually, physical limitations cease to prevent infants from achieving their goals. By 10 months, infants show evidence of the second step to successful tool use. They extend their reaching abilities using sticks, hooks, rakes, and rings to drag over distant objects and show evidence of means/ends analysis by choosing an appropriate tool for a job (Bates, Carlson-Luden, & Bretherton, 1980; Brown, 1990; Chen & Siegler, 2000; Leeuwen, Smitsman, & Leeuwen, 1994). Similarly, in Köhler's (1925) famous work on tool use in chimps, the animals pieced sticks together to retrieve an object beyond their reach.

The third step involves the biomechanics of tool use (Berger & Adolph, 2003; Berger et al., 2005). Beyond knowing that a tool is necessary for task completion and that certain items make appropriate tools, successful implementation of a tool requires knowing how to use it. Infants' early action patterns may serve as the rudimentary foundations for later tool implementation (Lockman, 2000). Sliding objects back and forth over a surface may be an early precursor for writing and scribbling, and banging a hard object on a solid surface may prefigure hammering (Greer & Lockman, 1998).

Before 12 months of age, infants have difficulty planning an implementation strategy. Instead, they must correct their actions after they have already begun to use

the tool. For example, 9- to 12-month-olds grab a spoon by the bowl- instead of the handle-end or hold it with the bowl-end pointing away from their mouth (McCarty, Clifton, & Collard, 1999, 2001). To correct, they must awkwardly rotate their hands or switch hands to get the bowl in their mouth. When experimenters highlighted the orientation of a spoon's handle by repeatedly presenting it pointing in the same direction, 12-month-olds used the most effective radial grasp (McCarty & Keen, 2005). By 18 months of age, infants know which end of a spoon to grasp, how to grasp it, and how to plan the implementation so that they reach for the tool with the appropriate hand orientation instead of resorting to post hoc corrections (McCarty et al., 1999, 2001). Eighteen-month-olds can even adjust their typical tool-use strategies to cope with novel situations. Infants modified their grasp orientation, the location of their grip along the handle of the spoon, and the angle at which they held the spoon when they had to retrieve food through a narrow opening in a lid or when they had to use a spoon with a bent handle to scoop food from a bowl (Achard & von Hofsten, 2002; Steenbergen, van der Kamp, Smitsman, & Carson, 1997).

Tools are not limited to hand-held objects. Tool use can involve the whole body in action (Berger & Adolph, 2003). Köhler's (1925) chimpanzees used poles to vault themselves into the air to retrieve bananas that were hanging from the ceiling. McGraw's (1935) twins, Jimmy and Johnny, stacked boxes on top of each other to climb to a toy suspended high out of reach. Similarly, in a series of experiments involving whole-body tool use (Figure 4.7e to 4.7f), 16-month-old walking infants recognized that handrails could augment their balance for crossing narrow bridges (Berger & Adolph, 2003; Berger et al., 2005). When no handrail was available, infants refused to cross narrow bridges altogether. On wide bridges, infants ran straight across regardless of whether a handrail was available. Moreover, infants used wooden but not wobbly handrails for crossing narrow bridges, suggesting that they took the material composition of the handrail into account for determining its effectiveness as a tool (Berger et al., 2005).

Summary: Getting into the Act

Historically, developmental psychology has acquired a sort of split personality: Are we movement scientists, perception psychologists, cognitive psychologists, social psychologists, and language acquisition researchers? Or,

are we developmental psychologists? And if so, development of what? The fractionation of psychology into separate content domains has created a field of developmental psychologists who do not study common phenomena or even speak a common language. Research on motor development holds some promise for helping to forge a shared developmental science.

Perhaps the most far-ranging consequence of a perception-action approach to motor development is that motor skills have become relevant to developmental psychologists who would not normally worry about motor control. Rather than a simple response measure for making inferences about the workings of the mind, motor actions are now viewed as both a facilitator and beneficiary of psychological functions. On one side of the perception-action loop, researchers—like Piaget before them—study the effects of developing motor actions on perception, cognition, language, and social interaction (e.g., Biringen, Emde, Campos, & Applebaum, 1995; Campos et al., 2000; Needham et al., 2002; Sommerville & Woodward, 2005; Sommerville, Woodward, & Needham, in press). On the other side of the loop, researchers study the mental representations viewed as integral to motor actions (e.g., Gilmore & Johnson, 1995; S. P. Johnson et al., 2003, 2004; Munakata et al., 1997; Shinskey & Munakata, 2003; Spelke & von Hofsten, 2001; Spencer & Schöner, 2003). In short, researchers from a range of backgrounds are “getting into the act.”

In looking back over a career spanning 70 years, E. J. Gibson (1994) said in a keynote address to the American Psychological Society that nothing is so exciting as the search for encompassing principles. She offered ideas such as prospectivity and flexibility as a starting place for a grand unified theory of psychology, and she urged younger researchers to continue to search. In that spirit, we close with a final suggestion: The perception-action approach can serve as a model system for the study of developmental psychology. Research from the perception-action approach illustrates the utility and feasibility of studying infants, with all their many body parts and psychological functions, everything continually changing, embedded in a rich and varied physical environment populated by other people. Bridging the traditional divisions between content areas is certainly possible and may be the best bet for understanding how movements, learning, development—any kind of psychological change—occurs in the real-time processes of a moving and perceiving animal.

Since the chapter on infant cognition in the fifth edition of this *Handbook* was published (Haith & Benson, 1998), infant cognition has continued to grow, develop, and become a more complex field of study. In this chapter, we discuss some of these changes, and throughout, we expand on and extend Haith and Benson's treatment of the topic. We begin by defining *infant cognition* and then present our perspective—a constructivist, domain-general, information-processing approach—on the development of cognition during infancy. Subsequently, we discuss some of the newer and more popular research methods used in the field, considering both their advantages and disadvantages. Finally, we present recent findings across various topic

Preparation of this manuscript was facilitated by NIH Grant, HD-23397, awarded to L. B. Cohen and by NIH grant #P20 RR017702 from the COBRE Program of the National Center for Research Resource to Cara H. Cashon.

We wish to thank Miye N. Cohen and Jennifer Balkan for their careful reading of this manuscript and their many helpful editorial suggestions.

areas. To present a comprehensive picture of the current state of our field, we limit most of our discussion to recent research and theory.

WHAT IS INFANT COGNITION?

It is appropriate to begin this chapter with the difficult task of defining infant cognition. Deciding which areas of study to include and exclude is an obstacle in arriving at a clear definition. Consider the continuum in Figure 5.1. It represents roughly a continuum from implicit to explicit processes, or from lower level to higher level brain structures. Depending, in all likelihood, on one's research perspective, there are several ways to partition the continuum. Most researchers working on infant sensory processes would assume their work has close ties to infant perception, but much looser ties to infant cognition and language (see Version A). On the other hand, most researchers on infant language acquisition would see close ties to aspects of infant cognition (e.g., categorization), but much looser ties to infant sensation and perception

Version A

Version B

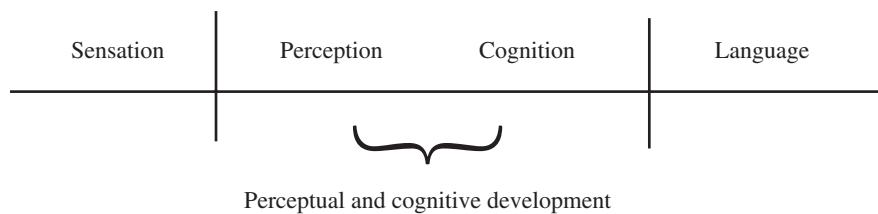

Figure 5.1 Possible ways of categorizing traditional areas with infant development. Adapted from “An Information-Processing Approach to Infant Perception and Cognition” (pp. 277–300), by L. B. Cohen, in *The Development of Sensory, Motor, and Cognitive Capacities in Early Infancy*, F. Simion and G. Butterworth (Eds.), 1998, East Sussex, England: Psychology Press. Reprinted with permission.

(also shown in Version A). In contrast, many of those who study infant perception or cognition find it difficult to distinguish perception from cognition, yet find the ties to infant sensation or infant language to be more distant (see Version B).

Our constructivist information-processing view (Cohen, Chaput, & Cashon, 2002) places us closer to Version B. We believe inserting an artificial boundary between infant perception and infant cognition can be detrimental when attempting to understand the underlying processes of developmental change. Consider object individuation, the ability to understand that one object is independent of another object even when their surfaces may be touching (Needham & Baillargeon, 1997). This ability depends on both the infant’s differentiating the objects’ surface characteristics, such as color, shape, and pattern, and the infant’s perceiving object unity in understanding that the visible parts of a partially occluded moving object are really part of the same object (Cohen & Cashon, 2001b). Differentiating surface characteristics and recognizing object unity are assumed to involve perceptual processes, but understanding of object individuation is generally assumed to be cognitive. Thus, it is our position that imposing an artificial divid-

ing line between cognition and perception may mask the true nature of infant development.

Whether a sharp distinction exists between infant perception and infant cognition is a contentious issue. Not all researchers agree that one should consider these topics as falling on a continuum from perception to cognition. Some who take a more nativist “core knowledge” approach (Baillargeon, 1994; Carey, 2000; Spelke, 1998) emphasize the infant’s supposed thoughtful cognitive decision making over more passive automatic perceptual processes. Others (e.g., Gibson, 2000) suppose infant perception and cognition can be subsumed under “direct perception” without resorting to mental representations (cognition). Consider the multiple interpretations of how infants perceive a simple launching event. Object A moves across a screen until it contacts Object B. Object B then moves the remaining distance across the screen. At one age, infants respond to this scene as a causal event with Object A being the agent and Object B being the patient. To some, this response indicates the infant’s “core knowledge” (Carey, 2000; Leslie, 1982) or a basic conceptual unit (Mandler, 1992). Yet, at an earlier age infants respond to Objects A and B as two independently moving objects. They

respond to perceptual changes in the movement and location of each object. Furthermore, the age at which infants first respond to the event as causal depends, in part, on surface characteristics of the objects. So where does one draw the line between infant perception and cognition and at what age?

Answering this question becomes more difficult when we consider the various research methods used to study infant cognition. In the previous *Handbook* chapter on infant cognition, Haith and Benson (1998) raise the same issue about the indistinct definitional boundary between perception and cognition. They believe that certain cases represent perceptual processing, such as when an infant reacts to a static property of an object such as its color, shape, or form. However, they also believe there are cases of cognitive processing, such as when infants react to a functional property of an object or two interacting objects in a dynamic event. They note that the problem may be exacerbated by the use of perceptual paradigms, such as visual habituation, to address cognitive issues. Mandler (1992, 2000b) makes a similar point about research on infant categorization. She argues that habituation or other visual attention paradigms tap into perceptual categories, whereas manual exploration or imitation paradigms tap into conceptual categories.

We take a more neutral stance in defining paradigms as either perceptual or conceptual. We believe that the paradigm used does not necessarily elicit one type of processing over another. Findings by several researchers provide support for this view. Oakes, Coppage, and Dingel (1997), Oakes, Madole, and Cohen (1991), and Younger and Fearing (1998) all showed that the results from a manual exploration task with three-dimensional objects were similar to those from visual habituation tasks involving two-dimensional pictures. Furthermore, there is some evidence that infants can attend to more conceptual information that goes beyond surface perceptual features in visual paradigms as well as object manipulation paradigms. Madole, Oakes, and Cohen (1993) were able to use visual habituation to examine infants' understanding of functional as well as visual properties of objects. Thus, the type of paradigm does not limit the mode of processing used by the infant, and there is evidence that a variety of tasks can elicit both perceptual and cognitive processes.

We prefer to use the more neutral term of *infant information processing* instead of drawing a sharp distinction between infant perception and cognition. Thus, we

define infant cognition loosely as the set of processes by which infants organize and interpret information provided by their environment. These processes may be implicit and automatic or explicit and intentional. The information may be unimodal or multimodal and may be static (e.g., a two-dimensional visual pattern) or dynamic (e.g., a causal event whose items interact and change over space and time). Such a broad definition obviously overlaps other areas of study such as early perceptual development and early language acquisition. We view this overlap as a strength rather than a weakness in that it allows investigating commonalities in processing across seemingly disparate areas using various paradigms or methods.

To be both comprehensive and up to date, this chapter presents different points of view about infant cognition and its development. However, we are not completely neutral with respect to these views. It is important to emphasize both infants' competencies and their inadequacies. We also emphasize developmental change and try to show how such changes are consistent with the information-processing principles outlined here.

Our Perspective: A Constructivist Information-Processing Approach

Perception and cognition entail infants processing and reacting to different types of information in their environment. Furthermore, this information may be unimodal or multimodal; it may or may not involve overt motor activity; but it is always relational. Infants are not simply processing raw sensory inputs; they are processing one or more relationships among those inputs, and those relationships determine our tendency to label the processing as perceptual or cognitive. An information-processing approach attempts to identify those relations and show how they change and become more complex and abstract with development.

Our examination of developmental changes in varied areas, from simple angle perception to the understanding of causal events, has led us to propose a set of six information-processing principles that are domain general. We describe them briefly here (for a more complete explanation plus a computational model applying these principles, see Cohen, Chaput, and Cashon, 2002):

1. Infants are endowed with an innate information-processing system that allows them to access low-level featural information, such as color, form,

sound, movement, texture, and so on, with a propensity to process the relations among these features in the environment.

2. Infants form higher units of information from the relationships (e.g., correlational and causal) among lower level units.
3. Higher units serve as components for yet higher units. In other words, the learning system is both constructive and hierarchical.
4. Infants have a bias to process information using the highest formed units, usually the most adaptive strategy. However, the lower-level units are still potentially available and may be accessed if the context requires it.
5. If the system becomes overloaded, infants will regress to a lower level of processing and attempt to incorporate the additional information.
6. This learning system is domain general and may be the mechanism by which we all acquire proficiency or expertise in some domain. It just happens that the most relevant domain for developing infants is the immediate physical and social world impinging on them.

The Relation of This Chapter to Previous Handbook Chapters on Infant Cognition

Approximately 15 years elapsed between the *Handbook* chapters written by Harris (1983) and by Haith and Benson (1998). Whereas the Harris chapter reflected the importance and influence of grand theories, such as those of Piaget and Gibson, Haith and Benson provided a comprehensive report of the major empirical and theoretical changes that had occurred subsequently in the field. Their focus was on the growth of “mini theories” (used to explain a single, relatively constrained ability rather than all of cognitive development), the emergence of nativist explanations (or the assumed precocity of infants), the use of perceptual paradigms to assess cognitive abilities, and the de-emphasis of developmental change.

Since the 1998 *Handbook* chapter, the field of infant cognition has seen some things change and some stay the same. The trend toward minitheories continues. The grand theories described so well by Harris are still mentioned in current research literature but they tend to be cited more as historical views or as foils than as specific predictors of particular types of infant behavior.

The tendency to report an infant’s precocity also continues; however that view is beginning to be challenged.

For some, the emphasis remains on when an ability emerges, rather than on how the ability is acquired or on how it becomes more refined with development. As Haith and Benson (1998) note (see also Horowitz, 1995), in many studies of infant cognition, age may not even be a factor in the design. If it is reported, the purpose is just to demonstrate that at one age infants can do something they cannot do at an earlier age. This approach can lead to some strange contradictions when comparing results from different laboratories that presumably are studying the same topic. We see an example in the section on object individuation, in which age of acquisition appears to range from 4 months to 12 months.

A problem with these studies is the assumption that an infant’s ability is dichotomous: Either the infant has it or does not have it. When examining developmental changes in most cognitive abilities more closely, one often finds that (a) developmental change occurs gradually over time; (b) change is often situation or task specific; (c) change does not always produce improvement—in some cases infants’ development may, at least superficially, appear to regress to a simpler way of processing; and (d) change may appear stagelike but the underlying process may be gradual and continuous. A reemphasis on developmental change and progressions can lead to valuable information regarding issues such as the viability of innate modules or core abilities. At the very least, such information raises questions about what may be changing over age and how central those changes are to understanding an infant’s cognitive ability. A similar point was made by Fischer and Bidell (1991).

Once the importance of developmental change is acknowledged, the most critical question becomes the mechanisms of change. We know from plotting such changes by age that the answer is not always simple or obvious. As noted, in some cases older infants actually appear to do more poorly than younger infants (e.g., Madole & Cohen, 1995). We also know these changes are not tightly tied to particular ages but tend to be domain and task specific. Not only are today’s researchers interested in describing age differences, but also in uncovering how those changes occur and how one might design models that simulate those changes. A recent trend in the field has been to investigate actual mechanisms of change. Researchers study these underlying mechanisms by using a convergence of methods including connectionist modeling and neurophysiological techniques, as well as more sophisticated and creative behavioral measures and experimental designs.

METHODOLOGICAL ISSUES

An obvious challenge for any investigator of infant cognition is to use a method that will indicate what infants are perceiving or understanding about objects and events in their environment. The most obvious and direct technique, of course, would be to ask the infant, but in most cases it is highly unlikely one would receive a meaningful response. As a result, researchers have turned to more indirect methods. These methods have evolved considerably over the past 40 years, and the most popular ones have usually involved some assessment of infant visual attention.

Habituation and Related Paradigms

For over 30 years, two related paradigms, visual habituation and novelty preference, have been the most popular methods for assessing infant cognitive ability. Their popularity stems from their ease of administration, the availability of the necessary equipment and software, and the apparent simplicity of their underlying assumptions. Both paradigms are based on the assumption that infants will tend to prefer (look longer at) something novel over something familiar. In a typical habituation experiment, infants are repeatedly shown the same stimulus until their looking time drops to some predetermined criterion (usually 50% of the initial looking time). In a subsequent test phase, novel and familiar stimuli are presented on successive trials and an infant who can discriminate the difference should look longer at the novel stimulus. In the related novelty preference paradigm, infants are familiarized with one stimulus for some preset amount of time and then are tested with simultaneous presentations of a novel and familiar stimulus. If infants can discriminate between the two, they should look a greater proportion of the time at the novel stimulus.

Both paradigms were originally used in the 1960s and 1970s to examine infant attention and perceptual discrimination (e.g., Fantz, 1964). The paradigms have been modified several times since then to investigate cognitive processes. The first adaptation occurred in the 1970s to examine infant visual memory. Delays were inserted between the end of habituation (or familiarization) and the test phase. These studies showed (a) the two paradigms produced similar results; (b) 5-month-old infants could retain briefly presented visual

information for at least 2 weeks, and (c) this memory (probably most akin to a type of recognition memory) was relatively immune to the effects of interference (Cohen & Gelber, 1975).

A second popular adaptation was introduced in the late 1970s and early 1980s to study infant categorization. Instead of habituating or familiarizing infants to a single stimulus, infants were presented with a sequence of stimuli, all of which were members of the same category (e.g., stuffed animals, dogs, faces). In the test phase, one of these familiar stimuli was presented along with a new exemplar from the old category and a novel noncategory item. Categorization was inferred when the infants responded to the new category exemplar in the same way as to the familiar test stimulus.

A third adaptation that also first appeared in the 1980s has been called the *switch* design (Cohen, 1988). It allows investigators to examine how and when infants come to associate or bind together different pieces of information. In the habituation phase, infants are presented with two stimuli, each of which has two attributes or aspects (e.g., Object A performing Function 1 and Object B performing Function 2). In the test phase, infants are shown three test stimuli. One of these is familiar, so that researchers can acquire a baseline for looking time to a familiar stimulus, and another is a novel stimulus. These novel and familiar markers are important—as Hunter and Ames (1988) showed and as others have subsequently confirmed (Roder, Bushnell, & Saserville, 2000; Shilling, 2000). Incomplete familiarization (particularly when relatively young infants receive complex stimuli) can actually lead to longer looking time to the familiar than to the novel test stimulus. Thus, having a familiar test trial is particularly important in providing evidence that infants have in fact habituated and do not have a familiarity preference. In addition to a familiar and a novel stimulus, infants are also shown a switched stimulus. The switched stimulus is constructed from two familiar components, but in a novel combination (e.g., Object A performing Function 2). The question is whether the infants respond to the switched stimulus as novel or as familiar. Because the individual aspects of this stimulus are familiar, if infants respond to the new combination as novel, it is inferred that they are sensitive to the association between, or binding of, the components. Since the 1980s, the switched design has become an invaluable tool in furthering our understanding of infants' featural versus re-

lational processing, allowing researchers to look beyond discrimination abilities and preference tests to how infants actually process the input.

Another adaptation of a traditional habituation experiment is called the *violation-of-expectation* paradigm. In these studies, the perceptual novelty of an event is pitted against the impossibility of the event. Instead of the experimenter knowing *a priori* which test stimulus will be more novel or unexpected for the infant, the infant must indicate to the experimenter which stimulus is more novel or unexpected. In an early use of this paradigm, infants were first habituated to a screen that rotated up and then down 180 degrees, at the front of an empty stage. In the test, an object was placed on the stage behind the screen so that it would block the screen's rotation. Then the screen either rotated 112 degrees (a physically possible event) or 180 degrees, a physically impossible event (Baillargeon, Spelke, & Wasserman, 1985). According to the investigators, the 112-degree rotation should be more novel, but the 180-degree rotation should be more unexpected. Infants tended to look longer at the 180-degree screen rotation, and it was inferred that infants had the knowledge or understanding necessary to view the event as unexpected or surprising. A frequently overlooked potential problem with this type of design is that the surprising or unexpected test event is also the more familiar one. If infants had a familiarity preference at the time of the test phase, longer looking at the unexpected test event would become uninterpretable since a familiarity preference would produce the same result as looking longer at the unexpected, impossible event. Thus, results can be difficult to interpret if careful steps are not taken to ensure that infants have a preference for novelty over familiarity during the test phase (a basic assumption in habituation studies).

Furthermore, as is the case in many violation-of-expectation experiments, relatively young infants are shown long, complex events that often include one or more real moving objects as well as noise and are presented over a large visual field. According to Hunter and Ames (1988), these are optimal conditions for producing a familiarity preference rather than a novelty preference. Familiarity preferences can arise if infants are not fully habituated; for example, a situation where infants never meet a habituation criterion or a stimulus is shown for a fixed number of trials rather than to criterion. Thus, problems in interpreting

the data can arise when nonhabituated, who would be most likely to show a familiarity preference, are included with habituated in an analysis. Some researchers do not attempt to habituate infants but give infants only a brief warm-up trial or two before presenting the test trials. This practice further increases the chances of a familiarity preference. We are not claiming that all violation-of-expectation results can be explained by familiarity preferences, but care and proper controls must be included to ensure that results are not due to familiarity preferences.

Although measures of infant visual attention continue to provide a viable and popular means for assessing infant cognitive ability, they have drawbacks. A valid criticism, expressed by Haith and Benson (1998), is that even though looking time is a continuous variable, an infant's response to novelty (or to a violation of their expectation for that matter) leads to a dichotomous conclusion. Infants either do or do not respond differently to a novel stimulus, or they do or do not notice the impossibility of an event. In fact, there is usually no good evidence that an individual infant will actually respond in a graded fashion to different degrees of novelty. Furthermore, not all measures of infant visual attention are equal. A number of investigators have reported that only a portion of an infant's look actually involves focused rather than casual attention to the stimulus (Ruff, 1986; Ruff & Rothbart, 1996). Focused attention seems to be the measure most closely associated with information processing. Numerous investigators have reported that infants are more resistant to a distracter stimulus when engaged in sustained attention. Sustained attention and resistance to distraction also seem to be associated with a decrease in heart rate (Hunter & Richards, 2003; Oakes, Tellinghuisen, & Tjebkes, 2000).

Whether one uses total fixation time or focused fixation time, infant looking is still passive and is usually interpreted in an all-or-none manner. A difference in looking indicates that infants prefer novelty or can discriminate between two stimuli. Haith and Benson (1998) note that a more direct tie exists between these attentional measures and novelty, familiarity, and salience than between these measures and more cognitive processes such as belief, reasoning, and inference. Some would argue that inference is being tapped in many looking-time studies, particularly those that involve objects that disappear and then reappear from

behind an occluder. But Mandler (1992, 1993, 2000a) who claims a major distinction between infant perception and infant cognition argues that visual attention and habituation measures assess primarily perceptual, not cognitive processing. She believes an accurate assessment of early cognitive processing requires tasks such as object exploration, sequential touching, and imitation that involve more active manipulation and interaction on the part of the infant.

Object Exploration and Sequential Touching

Ruff (1986) was among the first in studying infants' active exploration of objects to examine infant attention and its development. In these studies, infants were given objects one at a time and then allowed to manipulate and examine them. "Examining" was defined as focused looking in the presence or absence of manipulation. Ruff found that examining could be used as an indicator of active information processing as early as 6 or 7 months of age. Subsequent research has shown active examining to be a function of the complexity of the objects being examined as well as distracting stimuli (Oakes et al., 2000). It also seems to be an effective way to investigate infant categorization (Mandler & McDonough, 1993; Oakes et al., 1991).

Another more active technique for investigating infant categorization is the sequential touching paradigm (e.g., Rakison & Butterworth, 1998b). In this paradigm, objects from two categories (e.g., animals and vehicles) are randomly placed on a table in front of the infant. The sequential order by which the infant examines the objects is recorded. Any deviation from randomness (usually greater than chance runs of touching objects from the same category) is taken as evidence that the infant is responding on the basis of a category. Although both object exploration and sequential touching are measures requiring more active participation by the infant, it is not clear that their use brings us closer to examining cognitive processes such as belief, reasoning, or inference. Recent studies of infant imitation do seem to be a move in that direction, however.

Deferred Imitation

The development of young infant's imitation was a cornerstone of Piaget's theory of sensorimotor development (Harris, 1983). Early imitation also has been a signifi-

cant area of research and debate (Anisfeld et al., 2001) since Meltzoff and Moore's (1977) classic report that neonates will imitate an adult's tongue protrusion as well as other facial gestures. Imitation is a more active response than simply looking, and in cases such as those reported by Meltzoff and Moore, the infants appear to be doing more than just attempting to reproduce the stimulation they received from the model. There must be some translation of the visual stimulation they received into a particular motor output, labeled by Meltzoff and Moore as *active intermodal matching*. Furthermore, it must involve more than recognition memory given that infants as young as 6 weeks of age demonstrate imitation even after a 24-hour delay and may even be using their imitative response for identifying and communicating with the model (Meltzoff & Moore, 1994).

Although the mechanism underlying newborn imitation continues to be debated, in this chapter we emphasize how imitation is now being used as a tool to examine other cognitive phenomena. Mandler and McDonough (1996) used what they called *generalized imitation* to examine infant's concept knowledge. A model produced an action, such as pretending to feed a toy dog out of a cup, and they examined whether infants' imitation would generalize to animals other than the dog, but not to nonanimals such as vehicles. By 11 to 14 months of age, infants' imitation did generalize to other animals, and one interpretation would be that the infants were making an inference based on common concept or category membership.

Deferred imitation (imitation after a delay) is an excellent paradigm for investigating infant long-term recall memory. To imitate after a delay, the infant must do more than just recognize that a particular event is novel or familiar; the infant has to recall a past event and attempt to reproduce it. Numerous experimenters (e.g., Bauer, Wiebe, Carver, Waters, & Nelson, 2003) have used a deferred imitation paradigm (or a modified version called *elicited imitation*) to investigate an infant's ability to recall sequences of past events and the developmental changes in that ability. They found that in some cases infants as young as 9 months of age can remember and reproduce a sequence of 2 or 3 complex events for as long as 1 month (Bauer et al., 2003; Carver, Bauer, & Nelson, 2000; see also Barr and Hayne, 2000; or Bauer, Chapter 9, this *Handbook*, this volume).

INFANTS' UNDERSTANDING OF OBJECTS

Considerable research on infant cognition has examined and continues to examine what infants understand about the existence and nature of physical objects. In this section, we review three of the most studied topics in this area. We begin with a hallmark of infant cognitive achievement, at least from a Piagetian point of view, an infant's understanding of an object's permanence. We then turn to the issue of object unity. How and when does an infant perceive two visible parts of a partially occluded object as a single unified object? Finally, we consider the related question of object individuation. How and when does an infant understand that a particular object is a unique entity, independent of and different from another object?

Object Permanence

For more than half a century, developmental researchers have been examining object permanence. In 1954, Piaget described a constructive developmental process by which infants progress through 6 distinct stages during the first 2 years of life, the sensorimotor period. This progression begins in Stage 1 with newborns simply looking reflexively at an object placed in their visual field and ends at Stage 6 with 18- to 24-month-old infants solving invisible displacement problems in which one object serves as a symbol for a second object that is hidden from view (Harris, 1983, 1987). Few would dispute that more research time and effort have been devoted to investigating some aspect of infants' developing understanding of objects and their permanence than any other topic falling within the rubric of infant cognition. The previous *Handbook* chapters by Harris (1983) and Haith and Benson (1998) provide thorough reviews of the object permanence literature through the mid-1990s. Therefore, in the present section we concentrate on research and theory of the past 10 years. Since the types of research questions and studies have changed over the years, we first provide a brief summary of the object permanence literature as a whole, divided into discrete phases.

Phase 1: Demonstration and Modification

When one examines this immense body of research from the broad perspective of 40 to 50 years, a certain evolu-

tionary change appears in the topics being examined and the methods used to examine them. During the first phase, from the 1960s through the mid 1980s, both large-scale and small-scale studies attempted to standardize, but remain true to, the original tasks described by Piaget. A 14-item standardized test was developed of Piaget type object permanence tasks to tap individual differences in infant performance across all 6 stages (Uzgiris & Hunt, 1975). More typically, restricted studies were concentrated on infants' performance during a single stage. Usually a small toy or other attractive object was hidden under an opaque box or cloth in front of an infant, and the infant was given an opportunity to reach for and retrieve the object. Many variations in this task were used to assess performance at different stages. If the object were only partially hidden, it would be a test of Stage 3 performance. If it were totally hidden, it would be a test of Stage 4 performance, and if it were hidden several times in one location before being hidden in a second location, it would be a test of the A, not B, error with success indicative of performance at Stage 5.

Other variations were used, such as replacement of the opaque box with a transparent one (Diamond, 1981), changing the spatial location of the toy after it was hidden (Sophian, 1984; Wishart & Bower, 1982), delaying the time interval between hiding and retrieval, or the use of three rather than two hiding places (Sophian & Wellman, 1983). These variations were employed to examine possible mechanisms underlying both correct and incorrect behavior. In general, these studies tended to support the basic developmental sequence proposed by Piaget even though researchers disagreed to some extent over the exact ages the transitions from one stage to another occurred and the mechanisms responsible for these changes. Harris (1983) discusses many of these Phase 1 research findings, as well as the theoretical issues generated by them. Readers are encouraged to examine his chapter in the fourth edition of the *Handbook* for a more thorough review.

Phase 2: Refutation and Rejection

The second phase of research on object permanence can be traced back at least to Bower (1974, 1977, 1979), but it became most prevalent in the 1980s and 1990s. Researchers of this era have argued that infants are much more precocious than Piaget believed. They proposed that infants have certain core or innate knowledge about objects that is present early in life, if not at birth. They

introduced new simplified tasks that relied more on an infant looking at an object than having to reach for the object. A new variation of the habituation procedure, called the *violation-of-expectation* paradigm, was developed and used to uncover this precocious ability. In this procedure, an object often would be made to completely disappear behind an occluder and then reappear in either a predictable or unpredictable (often impossible) manner. Longer looking at the unpredictable event was considered an indication first, that the infant had inferred that the object continued to exist behind the occluder and, second, that whatever happened behind the occluder in an unpredictable event was impossible and unexpected. These cleverly designed studies also often pitted a response to novelty against a response to impossibility.

We have already noted an example of this type of study (Baillargeon, 1987; Baillargeon et al., 1985). Researchers first habituated infants to a screen that rotated 180 degrees, up and then down from a horizontal surface. In a subsequent test, an object was placed behind the screen and its view was obstructed as the screen rotated upward. Infants were then shown a possible event in which the screen rotated 112 degrees before stopping (when it presumably hit the object) versus an impossible event in which the screen continued to rotate the full 180 degrees (as in habituation) despite the apparent presence of the object. Infants as young as 3.5 months of age looked longer at the impossible 180-degree test event than at the possible 112-degree event. Baillargeon concluded that these results indicate infants much younger than those predicted by Piaget have mastered the equivalent of Stage 4 object permanence since they must have inferred the presence of the block even though it was totally occluded by the moving screen.

Many researchers using a version of this violation-of-expectation paradigm have reached similar conclusions. In one version, a car rolled down a ramp behind an occluder and reappeared at the other side even though it should have been stopped by an obstacle in its path behind the occluder (Baillargeon, 1986), or a ball was dropped behind an occluder presumably onto a solid table only to reappear under the table when the occluder was removed (Spelke, Breinlinger, Macomber, & Jacobson, 1992), or a rabbit was moved from left to right behind an occluder and either appeared (as it should) or failed to appear in a window in the center of the occluder (Baillargeon & Graber, 1987). In each case, infants much younger than 8 months of age looked longer at the surprising or impossible event, which according to

the authors supported their nativist view that infants at birth or shortly thereafter are equipped with certain core principles about physical objects, such as continuity of motion and solidity, which produce a much more sophisticated understanding of object permanence than had previously been believed. Both Haith and Benson (1998) and Fischer and Bidell (1991) review this research along with some contentious issues, such as how important it is, according to some views, for infants to demonstrate their understanding of object permanence through some physical action. As was the case for Phase 1 research on object permanence, we encourage readers to review either of these chapters for a synopsis of this Phase 2 research, which purports to refute the developmental views of Piaget (1954).

Phase 3: Rebuttal and Recent Evidence

The material covered in Phase 3 falls into two broad categories. The first is an empirical counterattack to some of the nativist studies presented in Phase 2. The second is a new set of theoretical proposals designed to bridge the gap between the evidence in Phase 1 and Phase 2.

Recent Empirical Evidence. Some of the studies demonstrating infant precocity have been questioned on methodological grounds. For the rotating screen example, Rivera, Wakeley, and Langer (1999) noted that infants should have a preference for 180-degree events since these events contain more movement. They also argued that if infants were actually looking longer because of the impossibility of the event, no prior habituation should be necessary. They tested 5.5-month-old infants on Baillargeon's tasks but without the habituation phase and found that infants looked longer at a 180-degree rotation than at a 112-degree rotation, no matter whether the event included a block. As both Bogartz (Bogartz & Shinskey, 1998; Bogartz, Shinskey, & Speaker, 1997) and we noted earlier, the violation-of-expectation paradigm may, on occasion, be subject to a certain artifact. Whenever responses based on novelty are contrasted with responses based on impossibility, an infant's preference for familiarity will be confounded with the infant's preference for impossibility.

Recently, the journal *Infancy* published a collection of studies all providing evidence that infants' responses in studies similar to the original rotation studies by Baillargeon et al. (1985), and Baillargeon (1987) could be accounted for by a preference for familiarity rather than impossibility. A potential problem with the original

studies is that even though Baillargeon had used a version of a habituation paradigm, she grouped together both habituators and nonhabituation in her tests. If the habituators had shown no effect, but the nonhabituation had shown a familiarity effect, she would have obtained the results she reported.

This collection of studies was followed by a series of invited commentaries as well as a rebuttal by the authors of the three original articles. (We encourage readers having an interest in this topic to read the entire set of articles and commentaries.) In her commentary, Baillargeon (2000) presented a rebuttal that included the point that these three studies did not accurately replicate all aspects of her procedure. But, perhaps her most significant argument was the listing of 30 other reports, all of which supported her conclusion that infants between 2.5 and 7.5 months of age can represent fully hidden objects (in other words, have the equivalent of Stage 4 object permanence). Furthermore, not all these studies used her version of the violation-of-expectation design, and most, but not all, were conducted in her laboratory. One of them (Baillargeon and Graber's 1987 rabbit-in-the-window experiment) has already been criticized by Bogartz and Shinsky (1998) on grounds similar to those discussed in relation to the rotating-screen experiment.

But let us consider in detail another example mentioned by Baillargeon in her list of 30. This study by Wynn (1992) presented a series of experiments not conducted in Baillargeon's laboratory. Wynn did not habituate infants; she only gave them a series of test trials. She did not even report a direct test of object permanence, but claimed to show that 5-month-old infants can add and subtract. She also must have assumed that infants at this age are able to represent hidden objects, since the objects they were supposed to count were placed on a stage behind an occluding screen. She also used a version of the violation-of-expectation paradigm since, on some trials, the screen was lowered to reveal the wrong number of objects and infants looked longer on these trials than on trials with the correct number of objects.

Recently Cohen and Marks (2002) examined Wynn's procedure and discovered that even though no habituation trials were used, in both addition and subtraction conditions a possible violation-of-expectation was confounded with familiarity. When it was assumed that infants expected to see one object but instead saw two objects, the presence of two objects was also more familiar than the presence of one object. Likewise, when it

was assumed that infants expected to see two objects but instead saw one object, it was now more familiar than two objects. Cohen and Marks conducted a series of experiments confirming this familiarity effect. In one of these experiments, infants responded in the same way as in the Wynn study even when no objects were added or subtracted. Let us examine that experiment from the point of view of object permanence. In a sense, this study can be viewed as a straightforward example of an object permanence study, using a violation-of-expectation paradigm. Five-month-old infants were shown a series of trials in which either one or two objects were placed on a stage, a screen was then raised occluding the object or objects, and then lowered again after a two-second pause to reveal either the same number of objects or a different number of objects. In some cases, the screen was lowered to reveal no objects on the stage. In other cases, it revealed one, two, or three objects on the stage. If infants at 5 months of age have achieved object permanence, they should unquestionably look longer when the screen reveals the incorrect number. Instead, the infants looked longer when they saw the correct number because, given the paradigm that was used, that number was more familiar. As Hunter and Ames noted, familiarity preferences tend to occur most when the stimuli are complex and the infants are young and have had limited exposure to the stimuli, all conditions that fit both Cohen and Marks' (2002) and Wynn's (1992) experiments.

Another issue raised by the violation-of-expectation studies is why investigators find such advanced levels of object permanence in young infants compared with the findings from standard Piagetian types of tasks. An important difference between these two paradigms is that the violation-of-expectation studies require only looking, whereas standard object permanence studies require both manual search and often removal of an obstacle to obtain the desired object. Haith and Benson (1998) have argued that manual search is a necessary condition to access information infants have about their own effect on objects or the spatial location of objects with respect to themselves, both of which are characteristics of object permanence according to Piaget (1954). Others (Baillargeon, Graber, DeVos, & Black, 1990; Diamond, 1991), however, argue that young infants actually know that an object continues to exist when it cannot be seen, but they have a motor or a means-end deficit that prevents them from actually reaching for the object or removing the occluder. Support for this

means-end deficit position comes from studies by Clifton, Rochat, Litovsky, and Perris (1991) and Hood and Willatts (1986), who found that young infants will reach for objects in the dark even when they do not reach for objects occluded by some barrier in the light. Bertier et al. (2001) also conducted a series of studies that attempted to disassociate visual tracking from reaching. They used a task similar to the violation-of-expectation study reported earlier by Spelke et al. (1992), in which she claimed infants as young as 2.5 months were surprised when a ball rolled behind an occluder and apparently went through one barrier (a wall) to stop at a second barrier (but see Cohen, 1995, for contrary evidence). Bertier et al. recorded 6.5- to 9.5-month-old infants' tracking and reaching for a ball that rolled behind an occluder. On some trials, the experimenter placed a barrier behind the occluder and found that the presence of the barrier tended to disrupt tracking more than reaching. However, this disruption only occurred when the infants could see the top of the barrier above the occluder. Bertier et al. concluded that their tracking results supported Spelke et al. but that reaching was quite difficult for these infants and may have interfered with their integration of visual information and spatiotemporal reasoning.

Several studies have compared results with transparent versus opaque barriers and found infants retrieved visible toys more often than ones that cannot be seen (Munakata, 1997; Shinskey, 2002; Shinskey, Bogartz, & Poirier, 2000; Shinskey & Munakata, 2001, 2003). In one study (Shinskey, 2002), 6-month-old infants were more likely to retrieve an object visible in water than hidden in milk. Since retrieval of the object in either liquid requires the same motor behavior, the only difference between the water task and the milk task was that in the latter, the object could not be seen. If the infants truly had achieved Stage 4 object permanence, the failure to see the object should have not been a problem.

What conclusions should be reached regarding the argument about young infants' understanding of object permanence? The evidence obviously is mixed and has been used to justify both a nativist position that infants as young as 2 or 3 months of age can represent fully hidden objects as well as the more traditional view that they must be 8 or 9 months of age before they can do so. The argument between these two positions is misguided for three reasons. First, the dichotomy is usually cast in either-or terms, when in all likelihood the process of ac-

quiring a representation of completely hidden objects is a gradual process that develops over age. This point has also been made by Fischer and Bidell (1991). Second, each argument is based on selective use of only the portion of evidence that supports a particular position rather than making an attempt to integrate all the relevant evidence into a more comprehensive explanation. Spelke (1998) has argued eloquently for a nativist position. Her paper along with Haith's (1998) counterargument should be required readings in developmental psychology. Although we agree more with Haith than with Spelke, we endorse Spelke's guideline that "all theories of early cognitive development must encompass all the relevant data" (p. 192). Third, the dichotomy distracts us from understanding the mechanisms underlying the representation of an object and its development. We may or may not believe, along with Piaget, or Fischer and Bidell (1991), that the motor action of reaching for the object is an essential aspect of that representation. But our theoretical goal should be to discover the nature of that representation, how it is acquired, and how it changes over the first 2 years of life.

Recent Theoretical Proposals. Recently two theoretical papers have appeared that should receive special attention because they attempt to explain the discrepancy between performance on looking tasks and reaching tasks, and both attribute the discrepancy to changes in the underlying representation. Melzoff and Moore (1998) assume that from birth infants have the ability to form representations of objects and events that persist over time and can be accessed even when the objects are absent. These representations (or memories) include both spatiotemporal information (locations and trajectories) and specific item information (perceptual features and functions) that combine to determine an object's identity. Object identity, however, is very different from object permanence. It allows an infant to predict where and when an object can be seen, and to identify the object when it reappears, but not to assume that the object continues to exist when unseen. Melzoff and Moore believe this representation of object identity is sufficient to explain most of the violation-of-expectation results, but that an additional type of representation, one of the object's existence and changes in movement while behind an occluder, is necessary for true object permanence. They assume this latter type of representation develops later than object identity.

Munakata and Stedron (2002) propose a similar solution. They assume that different types of memory or different strengths of memory may be responsible for the difference in performance on violation-of-expectation versus manual search tasks. They acknowledge Meltzoff and Moore's distinction between identity and permanence but suggest that active versus latent memory may also be a factor with active memories of hidden objects required for search tasks and latent memories sufficient for violation-of-expectation tasks. They also assume that infants gradually acquire the ability to remember hidden objects, and different strengths of memory may also be necessary for different types of task. Munakata and Stedron showed that connectionist models that included these memory systems were able to successfully simulate performance on a variety of tasks from violation-of-expectation, to simple reaching for objects behind occluders, to Stage 4 error problems in which an infant will return to a previous hiding place even though the object has been clearly hidden in a new location.

Our constructivist information-processing perspective is compatible with the theoretical positions of either Meltzoff and Moore (1998) or Munakata and Stedron (2002), who both advocate developmental changes in infant representation or memory. Meltzoff and Moore, in particular, were explicit about the tasks that should require only object identity and the one that requires object permanence. These tasks are reproduced schematically in Figure 5.2.

They reported a series of experiments by Moore, Borton, and Darby (1978), who found based on these tasks

that 5-month-olds were responsive to both an object's features and its trajectory (the object's identity), but only 9-month-olds were successful on the object permanence task.

Our approach would make a similar distinction but go a step further. We would argue that an understanding of object identity requires an integration of featural information with movement and trajectory information. By 5 months of age, as Moore et al. (1978) found, infants should have little trouble with this integration. But, younger infants could well respond to feature and trajectory information independently. We would predict that infants' understanding of objects should be a constructive process that undergoes a number of hierarchical integrations. According to this view, object permanence should develop later than 5 months of age since it represents a higher form of processing involving the integration of identity information from two objects (the object of interest and the occluder) as well as spatial relationship information between these two objects.

Other Areas Related to Object Permanence

Two additional areas of infant research, the perception of object unity and the understanding of object individuation, received their original impetus from the study of object permanence. Although at one time, they could have been categorized as subtopics within the area of object permanence, each of them has generated enough recent research (and controversy) to have become a significant topic for consideration in its own right.

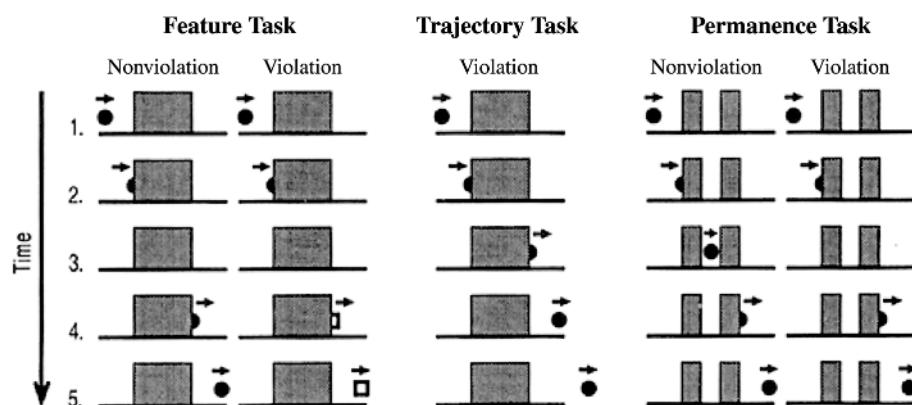

Figure 5.2 Schematic diagram of Feature, Trajectory, and Object Permanence tasks. *Source:* From "Object Representation, Identity, and the Paradox of Early Permanence: Steps toward a New Framework," by A. N. Meltzoff and M. K. Moore, 1998, *Infant Behavior and Development*, 21, p. 208. Reprinted with permission.

Object Unity

The object permanence events we have considered so far include only those in which an object is totally occluded for a period of time by a cover or some other object. The ability to represent that object when fully occluded is characteristic of Stage 4 in Piaget's 6-stage sequence. Infants at Stage 3, by contrast, should be able to represent partially occluded objects. The research on object unity represents the most systematic effort to discover the nature of that representation.

The classic studies in this area were reported by Kellman and Spelke (1983) and, in fact, were among the first to use a version of the violation-of-expectation.

In their initial study, 4-month-old infants were habituated to a rod moving back and forth behind a box that occluded the middle portion of the rod. In the tests, the occluder was removed and the infants saw for the first time either the entire rod including the invisible center portion or just the upper and lower portions of the rod that had been visible during habituation. If the infants had just processed the visible portions of the rod during habituation, they should look longer at the complete rod since it would be novel, but if they had perceived or inferred the existence of the entire rod, they should look longer at the two separate rod pieces. Kellman and Spelke (1983) found their infants did in fact look longer at the separate pieces. Several control studies have also been reported that indicate the common motion of the upper and lower portions of the rod played a major role in specifying object unity (see Kellman, 1993, 1996). A factor of particular interest is that the perceptual similarity between the shape, color, texture, and so on of the upper and lower portions did not seem to be significant until the infants were 7 months of age. Yet, infants at 4 months certainly can distinguish between shapes, colors, and textures. Thus this finding is consistent with our notion that infants will process featural and motion properties of an object independently before they are able to integrate the two.

Many aspects of the original Kellman and Spelke (1983) events have been examined including whether the event was three-dimensional or two-dimensional (Johnson & Nanez, 1995), whether the top and bottom portions were relatable (P. J. Kellman & Shipley, 1991), whether as the rod moved there was accretion and deletion of background texture (Johnson & Aslin, 1996), or even the effect of rotation of an object about its vertical axis rather than its translation (its movement from left

to right; Johnson, Cohen, Marks, & Johnson, 2003). The present chapter cannot cover all this evidence, but for the interested reader, more comprehensive reviews can be found in Johnson (2000) and in Kellman and Arterberry (Chapter 3, this *Handbook*, this volume).

The issue we would like to address more fully is the presence or absence of age differences. Kellman and Spelke (1983) suggested that the perception of unity is innate. They claimed infants are born with a tendency to experience objects as coherent and unified. Thus from their view, one would predict that infants younger than 4 months of age should respond in these tasks much like the 4-month-olds.

That does not appear to be the case. Two-month-old infants will respond in terms of object unity, but only under restricted conditions such as when a greater portion of the rod is visible (Johnson & Aslin, 1998). Even more significant are the results reported with neonates. In a series of studies, Slater and colleagues (Slater, Johnson, Brown, & Badenoch, 1996; Slater, Johnson, Kellman, & Spelke, 1994; Slater et al., 1990) found that newborns look longer at the complete rod, not the broken rod. If one uses the same logic as in the Kellman and Spelke (1983) study with 4-month-olds, newborns must be processing the visible portion of the rod as separate pieces, not as a whole. Thus there appears to be a developmental trend from processing independent parts to integrating those parts into a unified whole, just as predicted by our constructivist information-processing view.

Finally, Eizenman and Bertenthal (1998) reported a developmental change between 4 and 6 months of age. They used a translating rod and found that 4-month-olds, as in previous studies, looked longer at the pieces than at the complete rod. When the rod rotated (around the z axis, as a propeller), however, 4-month-olds looked longer at the complete rod (like the behavior of younger infants), but 6-month-olds looked longer at the pieces. Furthermore, when the event was made more complex by having the rod oscillate rather than just rotate, the 6-month-olds looked longer at the complete rod. If one assumes that a rotating rod (with its changing orientations and angles with respect to the occluder) contains more complex information than a translating rod, and that an oscillating rod contains more complex information than a rotating rod, then these data also fit the constructivist information-processing view quite well. Recall that information-processing principle 5 stated that if the system becomes overloaded, infants

will tend to fall back to a lower level of processing. That is exactly what seems to have happened to the 4-month-olds with the rotating rod and to the 6-month-olds with the oscillating rod.

Object Individuation

Even when an object is completely visible, it does not follow that the infant regards it as a distinct three-dimensional entity that moves as a whole. Perception of the number and nature of distinct objects present in an event is termed *object individuation*. For example, how does an infant know that an object that moves from one location to another location is the same object? Does it matter if the object in the second location is the same color, shape, size, and texture as the object in the first location? Most investigators agree that an understanding of object individuation requires, at a minimum, certain spatiotemporal criteria, including that an object cannot be in two places at the same time, two objects cannot occupy the same space, and objects travel on spatiotemporally connected paths (Xu, 2003). Some investigators (e.g., Leslie & Kaldy, 2001; Leslie, Xu, Tremoulet, & Scholl, 1998) also make a distinction between object individuation, which allows infants to determine the number of distinct objects, and object identification, which allows them to distinguish between objects based on their featural differences.

The most important question is how one should assess infants for object individuation. Many of those who investigate this topic tend to make certain additional assumptions. They likely assume that by 5 months of age, if not earlier, infants have the equivalent of Stage 4 object permanence and that the most appropriate way to assess object individuation is to use some version of the violation-of-expectation paradigm. As noted, both of these assumptions remain open to debate. To make matters a bit more complicated, most violation-of-expectation studies no longer begin with a complete habituation phase, so familiarity preferences are more likely to occur.

Putting those matters aside, the most contentious issue seems to be the earliest age at which infants demonstrate their understanding of object individuation. That issue, in turn, hinges on whether use of featural information is considered to be a necessary condition. As with object unity, this area has taken on a life of its own, and so many studies have now been reported that it is impossible to summarize them all. For readers interested in obtaining more information, we recommend two

recent chapters with moderately different points of view (Wilcox, Schweinle, & Chapa, 2003; Xu, 2003).

The types of events used to demonstrate object individuation are variations of those shown in Figure 5.2. Spelke et al. (1995) habituated infants to an event similar to the permanence task shown in the right side of the figure. Two screens were presented, and in one condition (like the violation condition in Figure 5.2) infants saw one object repeatedly appear and disappear behind the first screen. An identical looking object appeared and disappeared behind the second screen, but no object was seen between the two screens. In the test phase, the screens were removed to reveal either one or two objects. The investigators assumed that if the infants could individuate objects, this event would specify two different objects since they never saw an object move between the two screens; therefore the infants should look longer at one object than at two objects. In a second condition, like the nonviolation condition shown in Figure 5.2, infants saw the object travel between the two screens and therefore if they could individuate objects, they should look longer at two objects in the test than at one object. Some evidence for individuation was obtained at 4 months of age. Infants did look longer at one object than at two objects in the violation condition, but they did not look longer at two objects than at one object in the non-violation condition. Xu and Carey (1996) found that 10-month-old infants looked longer at two objects in the nonviolation condition. It is thus a bit unclear whether there was evidence for individuation at 4 months of age or only at 10 months of age. Whatever conclusion one reaches, infants did not have to use featural information because the two objects shown were identical.

Other studies have been reported that more closely resemble the Feature Task shown on the left side of Figure 5.2. In one type of experiment conducted by Xu and Carey (1996), infants were shown a single screen with one object (a ball) appearing and disappearing from the left side of the screen and a different object (a toy duck) appearing and disappearing from the right side of the screen. In the test, the screen was removed to reveal the two different objects, the expected outcome, or a single object, an unexpected outcome. Twelve-month-old infants, but not younger ones, looked longer at the unexpected outcome. Wilcox and Baillargeon (1998) obtained similar results. They presented infants with either the nonviolation or the violation version of the Feature Task and then removed the screen to reveal a single object. Infants at 11.5 months of age, but not

younger, looked longer at the single object in the violation condition, presumably because they expected to see both objects.

From these and other results, Xu (2003) concluded that infants younger than 12 months of age base object individuation almost entirely on spatiotemporal information. At 12 months of age and older, infants incorporate perceptual property (featural) information and respond to objects at a “kind,” that is, category level. Wilcox et al. (2003) take issue with this conclusion and argue that the age at which evidence for individuation can be found depends on the type and complexity of the task. They point to evidence using simpler tasks (event monitoring rather than event matching) that indicates infants as young as 4.5 months of age are sensitive to at least some featural information. Xu (2003) counters by arguing that these tasks show that the infants are sensitive to featural information but not necessarily object individuation.

On the surface, the debate between these two groups seems to be over the earliest age that infants display object individuation. But it actually appears to be centered more on what the minimal necessary conditions are to label infants’ behavior as indicative of object individuation. Regardless of which position is taken, the evidence seems to be clear that infants can process spatiotemporal information about an object’s movement and featural information such as the object’s size, shape, color, and texture independently, prior to their being able to integrate those two types of information (see Cohen & Cashon, 2001b, for a more complete presentation of this point). The evidence provided by Wilcox et al. (2003) that more complex events delay the appearance of object individuation is consistent with the view that an overload of information can cause infants to regress to an earlier mode of processing.

INFANTS’ UNDERSTANDING OF EVENTS

An event can be defined as a dynamic change in one or more objects over space and time. Technically, most of the objects shown to infants in the studies described in the previous section on object knowledge have been presented in the context of an event. In those studies, the emphasis is on the location, unity, or continued existence of a single object. In this section, we consider events that involve multiple objects and the relation between them. The type of event receiving the most extensive investigation over the past 20 years is a simple

causal event in which two objects collide. The question most often investigated is whether infants perceive or understand that the second object’s movement was caused by the first object (Cohen, Amsel, Redford, & Casasola, 1998). We examine research on infants’ understanding of these simple causal events first and then consider their understanding of more complex events.

Simple Causal Events

Philosophical debate over the origin of our understanding of causality dates back, at least, to Hume (1777/1993) and Kant (1794/1982). Hume assumed the notion of causality was acquired through experience, whereas Kant assumed it was innate. For Piaget (1954), an understanding of causality is also a function of experience but develops through several stages and is tied intimately to the infant’s actions. According to Piaget, infants at first have no notion of causality. It emerges gradually through their learning that they can have an effect on the people and objects around them, strengthening a sense of power over their environment. Later, as infants gain object permanence and come to distinguish themselves from external physical objects, they learn to differentiate between psychological causality, in which they act as the agent, and physical causality, which is based on the interaction of external objects with one another independent of the infants’ own actions.

Research on infants’ perception of causality has been described in review articles (Cohen et al., 1998; Oakes & Cohen, 1994), including the chapter by Haith and Benson in the fifth edition of the *Handbook* (1998). As we have done with other topics, we do not dwell on studies that have already been summarized in previous reviews. Instead we note the most important points of these early studies and give greater emphasis to recent research.

A few researchers, beginning with Ball (1973) used an occluding screen to examine infants’ perception of causality. In Ball’s study, and in later ones (Lucksinger, Cohen, & Madole, 1992; Oakes, 1994; Van de Walle, Woodward, & Phillips, 1994), the actual contact (or lack of contact) between two simple objects was hidden and infants had to infer from the timing of the moving objects whether a causal collision had taken place. As Cohen et al. (1998) note in their review, the evidence for infants less than 10 months of age inferring causality when the collision takes place behind an occluder is equivocal.

The evidence is more definitive for visible collisions. Based on Michotte’s (1963) seminal research on adults’

perception of simple causal events, Leslie (1982, 1984, 1986, 1988; Leslie & Kaldy, 2001; Leslie & Keeble, 1987) reported findings from several experiments on 6-month-old infants' reactions to simple launching events such as those shown in Figure 5.3. These studies and subsequent ones from other laboratories (Cohen & Amsel, 1998; Cohen & Oakes, 1993; Desrochers, 1999; Lecuyer & Bourcier, 1994; Oakes & Cohen, 1990) suggest that by around 6 months of age, infants have at least a basic understanding of a simple, causal launching event.

The logic behind most of these studies is fairly simple. Infants are habituated to one type of event and then tested on one or more modifications of that event. If in-

fants are processing an event in terms of its perceptual characteristics, that is, the spatial and temporal information composing the event, the difference between a delayed launching and a no-collision event should be greater than the difference between a direct launching event and *either* a delayed launching or no-collision event. This is so because the delayed launching and no-collision events differ from one another on both spatial and temporal dimensions. In contrast, the direct launching event differs from the delayed and no-collision events on only one dimension, temporal and spatial respectively. On the other hand, if infants are processing the events on some causality dimension, then the delayed and no-collision events are both noncausal and should be

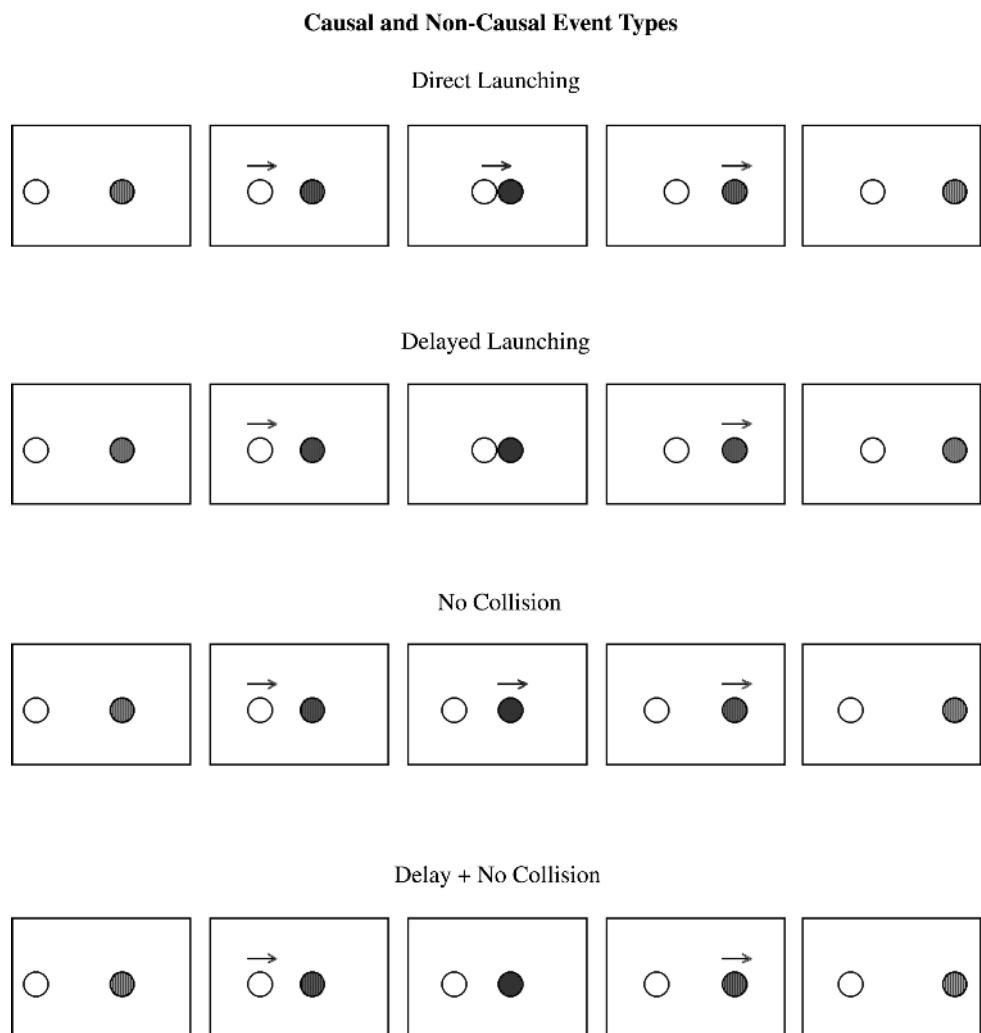

Figure 5.3 Four types of launching events used in studies of infant causal perception. Adapted from "A Constructivist Model of Infant Cognition," by L. B. Cohen, H. H. Chaput, and C. H. Cashon, 2002, *Cognitive Development*, 17, p. 1332. Reprinted with permission.

treated similarly, but both should be quite different from the direct launching since it is a causal event.

In one set of studies, Leslie (1984) habituated 6.5-month-old infants to one of the events shown in Figure 5.3 and then tested them with one of the other events. Infants dishabituated more to a change from a causal to a noncausal event than to a change from one noncausal to another noncausal event. As noted, this pattern is indicative of responding in terms of causality. In another study (Leslie & Keeble, 1987), infants were habituated either to a direct launching or a delayed launching event and then tested on the same event in the reverse direction. Infants dishabituated more to the reversal of the direct launching than to the delayed launching, presumably because the former was also a reversal of the agent and patient. Leslie (1986) assumed from these data that infants were responding on the basis of an innate causal module that can serve as the basis of future development but is not the product of previous development.

Named a *spatiotemporal continuity gradient* by Leslie (1986), the product of this innate causal module is sensitive to the spatial and temporal information in a launching event and produces a gradient of causality, with a direct launching event at one end, no-collision and delay events in the middle, and the no-collision plus delay event at the other end. Some researchers, such as Carey (2000), accept Leslie's assumption of an innate causal module and believe it represents a type of core knowledge present early in life. Others, such as Mandler (2000a), accept the idea of an abstract causal module. She considers it to be an "image schema," but believes it develops early in infancy as a function of the infant's "perceptual analysis" of environmental events. In either case, this module is activated automatically by the spatiotemporal characteristics of the event and should be insensitive to other factors, such as the type of objects engaging in the event.

In contrast, our constructive information-processing approach assumes that an infant's understanding of causal events will be a slow constructive process characterized by an integration of information at several different levels and temporary regression periods when the system becomes overloaded. We believe this approach represents a more accurate developmental picture than either the one proposed by Leslie or the one proposed by Mandler.

Consider first the issue of innateness. Leslie (1984) demonstrated some degree of causal perception or understanding by 6.5 months of age. Cohen and Amsel

(1998) replicated Leslie's result with 6.25-month-old infants but also tested infants at 4 and at 5.5 months of age. Four-month-olds responded only to the continuous movement in an event and 5.5-month-olds responded to the spatial and temporal differences between these moving objects, but not the causality. The failure of younger infants to perceive the causality of such events has been reported recently by others as well. Belanger and Desrochers (2001) replicated Leslie's positive results for causal perception at 6 months. However, Desrochers (1999) did not find infants responding to causality at 3.5 months. Belanger and Desrochers reported also that in an entrainment version of a causal event (in which the first object continues to push the second object after the collision), even the 6-month-olds did not respond in terms of causality.

This developmental evidence seems to be more consistent with the constructive information-processing account than with the presence of an innate module. However, a person who claims existence of an innate module might answer that innateness does not imply presence at birth. Perhaps the module somehow becomes activated at 6 months of age. Partially in response to this criticism, Cohen, Chaput, and Cashon (2002) developed a connectionist model, called "CLA" (Constructive Learning Architecture), that follows the six information-processing principles mentioned earlier. CLA is a hierarchical neural network model that is unsupervised and self-organized. It uses Hebbian learning to organize the highest level in the model from the correlational information provided by lower levels. When processing simple launching events, it works with only two sets of inputs, the spatial distance between the two objects at any point in time and the movement or nonmovement of each object integrated over a very short period. These two inputs form separate Layer 1 maps, one for the spatial changes that take place during the course of an entire event and the other for the changes in movements of the two objects during the course of that event.

With training (learning), correlational information between these two Layer 1 maps project to a single Layer 2 map, whose overall activation becomes related to the degree of causality of each event. In fact, once the network has learned, it evaluates simple events in terms of a causality continuum similar to Leslie's spatiotemporal continuity gradient. Thus, the CLA connectionist network actually learns causality from the simple perceptual features, spatial distance and movement, both of

which should be readily available to a young infant. Learning takes place from the bottom up, with Layer 1 maps organizing before the Layer 2 map forms, consistent with the hierarchical information-processing view described earlier. Once the model "learned," we simulated an information overload by introducing some random variation in the events the model had succeeded in classifying as causal or noncausal. The result was that the model regressed to processing the events at the lower Layer 1 levels in an attempt to reorganize itself, just as the information-processing principles would predict. In other words, CLA learned causality simply from being exposed to causal and noncausal events. So, at the very least, the success of CLA provides an example that the notion of causality need not be innate, but instead can be learned through experience with simple causal and noncausal events and the ability to detect correlations among simple features in those events.

Another prediction generated by an innate module approach relates to the type of objects involved in these causal and noncausal events. According to either the modular or image schema viewpoint, the type of object should not matter; it is the spatiotemporal relations that determine whether the event is causal or noncausal. However, some research indicates that the type of object does matter. Oakes and Cohen (1990) replicated Leslie (1984) by showing the same launching type events using complex, realistic moving toys, rather than moving squares or circles. They found that rather than responding in terms of causality, 6-month-olds now focused on the individual objects. Ten-month-olds, in contrast, did respond in terms of causality. Apparently the complexity of the realistic toys overloaded the 6-month-olds, forcing them back to a simpler way of processing, but did not have this effect on the 10-month-olds.

Cohen and Oakes (1993) also used realistic toys when presenting launching events to 10-month-olds, but in this case the actual toys changed from trial to trial. Because the objects changed but the type of event did not, the task was essentially an event category task. Again, from modular or image schema points of view, changing the specific objects used from trial to trial should be irrelevant and causal perception should not be affected. From our constructive information-processing point of view, however, the task demands of the category task should definitely produce complications in perceiving causality. In support of our viewpoint, Cohen and Oakes found that the 10-month-olds no longer processed the events as causal. Instead, they regressed to process-

ing the events in terms of the independent spatial and temporal differences between them.

Complex Causal Chains

The constructive information-processing approach makes another prediction. According to its principles, not only can higher units of information be formed from the relationships among lower units, but these higher units can also serve as components in yet higher units. Apprehending the causal relation between two moving toys in a launching event certainly represents the formation of a higher unit produced from two lower units. The question to be addressed next is whether that simple causal event can serve as a single element in an even higher unit.

Cohen, Rundell, Spellman, and Cashon (1999) showed 10- and 15-month-old infants complex event sequences called "causal chains." In these events (see Figure 5.4), one moving toy hit a second toy that moved to a house. When the second toy made contact with the house, a dog's head abruptly emerged from under the roof of the house (similar to a jack-in-the-box) coinciding with a "boing" sound. Each collision was also accompanied by an appropriate noise. Although this causal chain event is obviously much more complex than the simple launching events mentioned earlier, the first half of the event is exactly the same type of simple causal event, with realistic toys, used earlier by Oakes and Cohen (1990) and by Cohen and Oakes (1993).

In this causal chain study, one half of the infants at each age were habituated to an event in which the first two toys were involved in a direct launching. That event is illustrated in Figure 5.4. For the other half of the infants, the first two toys were involved in a delayed launching. A 2-second delay occurred between contact of the first toy and movement of the second toy. All infants continued to see the same type of event in the test that they had seen during habituation (beginning with either a direct or delayed launching), but on one test trial the first toy was replaced by a novel toy, and on another test trial the second toy was replaced by a novel toy. The authors reasoned that if the causal agent in the event sequence was the most important object to the infant, then replacing that object should produce more dishabituation than replacing the other object. In the direct launching event, the first object should be the most important since it is the agent; it causes the second object to hit the house and the dog's head to pop up. In

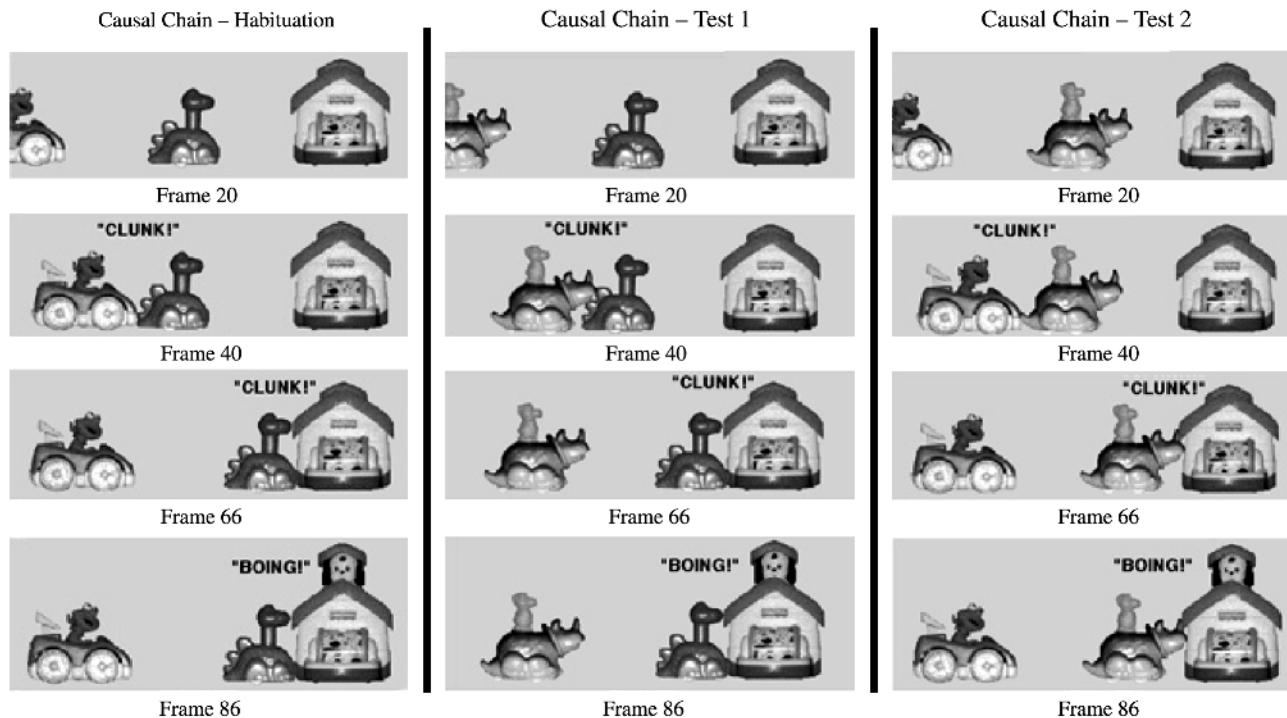

Figure 5.4 Selected frames from events in infant causal chain experiments. *Source:* From “Infants’ Perception of Causal Chains,” by L. B. Cohen, L. J. Rundell, B. A. Spellman, and C. H. Cashon, 1999, *Psychological Science*, 10, p. 414.

contrast, the second object is the most important in the delayed launching event. Its self-initiated movement makes it the agent that collides with the house causing the dog’s head to pop up.

If infants were processing the entire event sequence as a unified causal event, they should have dishabituated more when the first object was replaced if it was involved in a direct launching, but should have dishabituated more when the second object was replaced if it was involved in a delayed launching.

That is exactly the pattern of results obtained with 15-month-old infants. Ten-month-olds, however, responded most to a change in the first object regardless of its relationship (direct launching versus delayed launching) with the second object. The 10-month-olds were apparently overloaded by this complex event sequence involving numerous objects and actions. It is interesting to note though that they did not respond randomly to the change in first and second object. They responded systematically to a change in the first object regardless of whether it was involved in a direct or delayed launching. That type of responding suggests that these 10-month-old infants had indeed regressed to a simpler way of processing (e.g., attending only to the

first object that moved), as would be predicted by an overload explanation.

In a final set of causal chain studies, Cohen, Cashon, and Rundell (2004) presented 15- and 18-month-old infants with the same causal chain events, but in the context of a category task. During habituation, each infant saw two sequences, one that began with a direct launching and one that began with a delayed launching. For both sequences, the same toy was used as the causal agent of the final outcome. During habituation, infants were presented with a direct event in which Toy A launches Toy B, which immediately moves to the dog house making the dog appear. These same infants were also presented with a delay event in which Toy B hits Toy A, and after a 2-second pause, Toy A then moves to the dog house to make the dog appear. Thus, in both of these events, Toy A can be considered the causal agent of the dog’s appearance. In the test, the roles of the two toys were switched, such that Toy B rather than Toy A was now the agent for the first time. The 18-month-olds, but not the 15-month-olds, noticed the switch in agent, as indexed by longer looking at the test event with the switched agent. To do so, they had to coordinate information about the order of movement of the toys along

with the type of event in which the toys were involved (direct versus delayed launching). The 15-month-olds apparently could not respond to these complex events in terms of agency. A subsequent control study indicated that they were sensitive to the order of movement of the toys and to the type of event in which the toys appeared, but could not correlate these two types of information to respond in terms of agency.

Complex Event Sequences

The events described so far have progressed from simple launching episodes in which two squares or circles collide with one another, to the same type of event with more realistic toys, and then to causal chains that involve two separate collisions. More complex causal events are possible, as are other types of event sequences or scenarios in which multiple events occur sequentially. Our constructive information-processing framework, like most other approaches, predicts that infants should be able to process two sequential events before they can process three or four such events. It also predicts that pairs of events that have some logical or necessary tie between them should have greater potential of being grouped together into a single higher-order unit than two arbitrarily grouped, independent events.

Some violation-of-expectation studies qualify as showing infants multiple event sequences. Earlier, we noted one of the more spectacular by Wynn (1992), who claimed that 5-month-old infants can add and subtract. In her addition condition, infants first saw one toy object on a stage; next a screen came up to occlude the object and a hand carrying a second identical object moved behind the screen and reappeared without the object; finally the screen was lowered to reveal either two objects on the stage (a possible event) or only one object on the stage (an impossible event). The infants looked longer at one object, the impossible event. A similar procedure was used in the subtraction condition except that first the infants initially saw two objects on the stage; then the hand went behind the screen and removed one object; and finally, the screen was lowered to reveal one or two objects. In this condition the infants looked longer at two objects, once again the impossible event.

For 5-month-old infants to have actually added and subtracted in these situations, they had to know more than that $1 + 1 = 2$ and $2 - 1 = 1$. They also had to process and integrate information from three separate events—the initial opening of a curtain to reveal either one or two

objects on a stage; the raising of an occluder along with the action of the hand first going behind it either with or without an object, and then reappearing either without or with an object; and finally the lowering of the occluder again to reveal one or two objects. The infants would not only have to integrate these three separate events but would also have to make an inference about what action was taking place behind the occluder.

From our information-processing point of view, this should be an impossibly complex task for 5-month-old infants. As noted in our discussion of the object concept, evidence suggests a simpler explanation of the infants' performance (Cohen, 2002; Cohen & Marks, 2002). An analysis of the actual sequence of events shown to infants indicated that in the addition task, each infant actually saw one item on the stage nine times and two items only three times. Similarly in the subtraction event, each infant saw two items nine times and one item three times. If the infants had a preference for familiarity, which is likely given their relatively young age and the complexity of the events, they should look longer at what appears to be impossible events, that is one item in the addition task and two items in the subtraction task.

As already mentioned, in an experiment designed to test this familiarity hypothesis, Cohen and Marks (2002) replicated the Wynn procedure but without the hand coming in to add or subtract anything. Infants looked longer when the more familiar number of items was on the stage. That is, they looked longer at what would have been an impossible event, but since the hand did not add or subtract any items, no addition or subtraction of items occurred. Thus, one can interpret the behavior of the 5-month-olds in the Wynn (1992) task as a consequence of repetitions of a single event along with a familiarity preference, not a consequence of the integration of three events plus knowledge of addition and subtraction.

Paradigms that use either habituation or violation-of-expectation procedures, and measure only looking-times to understand how infants process complex event sequences, have several inherent limitations in addition to those mentioned in our discussion of methodological issues. One is that a sequence of events often lasts more than a minute and infants must look continuously the entire time to obtain the necessary information, which is difficult, if not impossible for many of them to do. A second is that looking-time paradigms tap only recognition memory, but if infants have to reconstruct events that are not currently being experienced, a measure of

recall memory may be more appropriate. A third is that visual-looking paradigms tap only all-or-none discriminations, whereas paradigms that require more active motor behavior by infants tap their understanding of more graded cognitive and functional information. Mandler (2003) makes a similar point in her distinction between infants' acquisition of perceptual categories versus cognitive concepts.

For these and other reasons related to explicit versus implicit memory (Bauer, Burch, & Kleinknecht, 2002; Meltzoff, 1990, 1995), investigators have turned to a different paradigm, elicited-imitation (Bauer & Mandler, 1992), to study how infants process and remember multiple event sequences.

In a typical experiment, infants see a model perform a sequence of two or three events and the infants' imitation of those events is assessed both immediately and after a delay that might range from a week to several months (Bauer, Chapter 9, this *Handbook*, this volume; Bauer, Hertsgaard, & Wewerka, 1995). In some sequences, the events are considered to be enabling (contingent on one another). The events must necessarily occur in a specific order, such as in the following sequence involved in making a gong: (a) putting a stick horizontally on a frame, (b) hanging a metal plate on the stick, and (c) hitting the plate with a hammer. In other sequences, the order of events is arbitrary, such as in the following making-a-hat sequence: (a) putting a balloon on top of a cone, (b) placing a band around the cone, and (c) placing a sticker on the face of the cone. Investigators tend to measure both the number and order of infants' imitative responses. In general, the older the infants, the more likely they will imitate multiple events. They also tend to model enabling sequences at an earlier age than arbitrary ones. Recent studies on elicited imitation have provided valuable insights into both the development of infant long-term declarative memory and regions of the brain that are involved in such memory (Bauer, Chapter 9, this *Handbook*, this volume).

One of the more interesting findings is the increase with age in number of events remembered and modeled (Barr, Dowden, & Hayne, 1996). Six-month-old infants seem limited to one event. Approximately 50% of 9-month-old infants imitate more than one event (Carver & Bauer, 1999), and by 14 or 15 months, infants have little difficulty recalling temporally ordered sequences. These age differences are similar to those reported earlier for remembering single causal events versus causal chains.

The developmental progression in performance on these imitation tasks from processing one sequence to processing multiple sequences would be predicted by the constructive information-processing principles presented earlier. However, a stronger prediction would pertain to how infants at different ages organize the multiple events they experience. Very little research has been reported on infants' organization of event sequences. In one creative approach to the topic, Baldwin, Baird, Saylor, and Clark (2001) familiarized 10- to 11-month-old infants to a videotape of a woman performing more than one action. Infants might see a woman noticing a towel on the kitchen floor, reaching for and grasping it, and then placing it on a towel rack. Two types of tests were presented in which a 1.5 s pause was inserted in the action. In the "Interrupting" test, the pause was inserted during the middle of an action, whereas in the "Completing" test the pause was inserted between two actions. The infants looked longer at the "Interrupting" test suggesting that the infants had parsed the video movie into discrete actions. The authors also note, however, that it is unclear from this study at what level of description the infants are organizing the video. For example, they could be responding to separate independent events such as picking up the towel and placing a towel in the rack. Or they could be responding to events at a more global level, such as putting the towel away or cleaning up the kitchen. By manipulating the order of the specific events as well as the location of pauses, it should be possible to gain a better understanding of how such event sequences are processed by infants at different ages. We would predict that at an early age infants should be sensitive to the disruption of a specific event, but not necessarily to the event order. At a later age, infants should be sensitive to a disruption in the order of events, particularly when the events are enabling, or when the order suggests a unified goal or intension.

INFANT CATEGORIZATION

Over the past 25 years, one of the most prolific areas of research in infant cognition has been infant categorization. The popularity of this area results in part from an understanding of categorization's fundamental importance for learning and development and in part from the evolution of research paradigms to examine categoriza-

tion in infants. The importance of the ability to categorize is obvious. Imagine if infants, children, or even adults, for that matter, could not group objects or events into categories and make inferences about new objects or events based on their presumed membership in those categories. Given that no two experiences are identical, we could not learn from past experience or generalize what we have learned to new experiences. Oakes and Madole (2003) make the case for infant categorization a bit more conservatively: “the ability to categorize may be especially important in infancy, when an enormous amount of new information is encountered every day. By forming groups of similar objects, infants can effectively reduce the amount of information they must process, learn and remember” (p. 132).

Categorization Paradigms

Realizing the necessity of early categorization is not the same as understanding its origins in infancy. Several paradigms have been used to examine infant categorization. These include (a) a version of habituation and the switch design (Younger, 2003; Younger & Cohen, 1986); (b) an object-examination task that is similar to the habituation one except that infants get to inspect real three-dimensional toys (Oakes et al., 1991); (c) a sequential touching task, in which toys from two categories are placed on a table and infants’ touching of the toys is examined to see if the sequence of touches occurs in a systematic order (Rakison & Butterworth, 1998a, 1998b); and (d) deferred imitation, in which infants see a model do something with one toy category member (such as helping it to drink from a cup) and then imitation of the model’s action is assessed with either a new member from the same category or a member from a different category (Mandler & McDonough, 1996, 1998). These paradigms vary in the ages for which they are appropriate and in how active the infants must be to demonstrate categorization. According to some theorists, the paradigms also differ in whether they are assumed to apply to perceptual categorization, to more abstract concept formation, or to both perceptual categorization and concept formation (Mandler, 2000a, 2003). But all the paradigms are based on the minimal assumption that the demonstration of infant categorization requires infants to treat discriminably different stimuli in an equivalent manner (Cohen & Younger, 1983; Quinn, 2003).

As with previous portions of this chapter, we treat the current section on infant categorization as an extension and update of the material presented by Haith and Benson (1998). We do not reproduce their excellent review of the infant categorization literature and recommend it to interested readers. Although we mention some of the most relevant older literature, we concentrate on more recent empirical work on infant categorization and its theoretical implications.

Feature Correlations and Categorization

An important distinction is the one between *demonstration* studies that simply describe categories to which an infant attends and *process* studies that attempt to explain the mechanism by which infants acquire categories (Oakes & Madole, 2003; Younger & Cohen, 1985). Most models of infant categorization assume that each category exemplar can be described in terms of a set of features. These features may be perceptual (e.g., form, color, texture), functional (e.g., what they can do or be used for), and also linguistic (e.g., what labels are associated with them) (Oakes & Madole, 2003). The feature values of a particular exemplar help determine whether it is a member of a category as well as any inferences that can be drawn from its category membership. An important aspect of category items is the correlational structure of their feature values, that is, whether groups of feature values tend to co-occur. Considerable research by Younger (Younger & Cohen, 1983, 1985, 1986; Younger & Fearing, 1999) has also shown that whether an infant groups all items into a single category or segregates items into two separate categories depends on the infant’s age, the distinctiveness of the feature values, and most importantly the pattern of correlation among features.

The importance of correlational structure for infant categorization was first reported by Younger and Cohen (1983, 1986). In one study, they habituated 4-, 7-, and 10-month-olds to a series of line drawings of imaginary animals. The animals differed from one another in feature values (e.g., the type of body, tail, and legs) but for any one animal a subset of the values were correlated with one another. So, for example the type of feet might have been free to vary but a bear body always co-occurred with a horse’s tail, and a giraffe body always co-occurred with a rabbit’s tail. In the test, infants were given a familiar habituation animal, a new animal that

violated the correlation, but was constructed from familiar parts (e.g., a bear body with a rabbit tail) and a totally novel animal.

Within the infant literature at least, this was the first use of the switch design (see Gentner, 1978, for an earlier use of the design with children). If infants were sensitive to the correlation among feature values, the uncorrelated test animal should be treated as novel. If infants were not sensitive to the correlation, all the feature values would be independent, and since they were equally familiar, the uncorrelated test animal should be treated like one of the familiar animals seen during habituation.

Younger and Cohen (1986) reported a developmental progression. At 4 months of age, infants responded only in terms of independent features. At 10 months, they responded to a violation of the correlation. The performance of 7-month-olds was particularly interesting. When all the features were correlated, the 7-month-olds had no trouble detecting that correlation. However, when only two of the three features were correlated, they had great difficulty with the task and did not even habituate. When they were given more habituation trials and essentially forced to habituate, the 7-month-olds dropped to the level of 4-month-olds and responded only to independent features.

Even though these correlation studies were conducted a number of years ago, they are relevant to at least three different contemporary issues. First, they provide early evidence for the constructivist information-processing principles we have presented throughout this chapter. The 4-month-old infants were processing only the lower-level independent parts of the animals, but by 10 months, they were at a more advanced level and processing the relation among the parts (the correlation among features). Seven-month-olds could process this relation when all features were correlated. When only a subset of features was correlated, however, the categorical nature of the task evidently overloaded them and they regressed to the level of the 4-month-olds.

Second, the importance of correlational information goes well beyond the integration of body parts in line drawings of animals. The developmental progression from first processing independent lower-order units to later relating those units to some higher-order whole has been observed repeatedly in infants, often using some version of the switch design. We have found it with respect to 3- to 7-month-olds' face perception (Cashon & Cohen, 2003) and 6- to 18-month-olds' understanding of

causal events (Cohen, 2004a). It has also been found in infants learning to relate an object's form to its function (Madole & Cohen, 1995; Madole et al., 1993) and their learning to associate verbal labels with objects (Werker, Cohen, Lloyd, Casasola, & Stager, 1998). The switch design has even been used to demonstrate possible precursors to early racial (Levy, 2003) and gender (Levy & Haaf, 1994) stereotyping.

Third, processing correlational information plays a prominent role in several contemporary accounts of developmental change in infant categorization. Younger (2003), for example, assumes that the age at which infants can process feature correlations depends on the nature of the features. Correlations between a subset of simple features such as color and form can be noticed as early as 3 months of age (Bhatt & Rovee-Collier, 1994; Bhatt & Rovee-Collier, 1996), but infants must be 7 to 10 months of age to notice the correlation between two features in a more complex animal categorization task (Younger & Cohen, 1986). Younger (2003) also assumes sensitivity to correlational information allows 10-month-old infants to process more than one category at a time and to move from a form of implicit categorization to a form of explicit categorization.

Oakes and Madole (2003) summarize early category development in terms of three principles related to infants' increasing access to information:

1. The pool of available features increases due to increases in motor, information processing, and linguistic ability.
2. The ability to take advantage of information in different contexts widens.
3. An increase in background knowledge constrains the pool of relevant features.

So not all correlations remain equal. Those that we learn are appropriate, such as the correlation between an object and its function, are maintained. But those that are arbitrary or inappropriate, such as the correlation between an object and some other object's function, come to be ignored (Madole & Cohen, 1995). Each of these principles incorporates a change in use of correlational information with development.

Correlations also play a central role in Rakison's (2003) account of infant category acquisition. He argues that, to understand early category and concept development, one should focus on processes related to informa-

tion integration. Representations of objects and their properties develop through associative learning and are grounded in clusters of correlated attributes. Inherent mechanisms initially predispose infants to attend to parts, motion, and size of objects. Correlations among these features lead infants to group together objects with common actions or functions.

These recent accounts of infant category acquisition by Younger (2003), Oakes and Madole (2003), and Rakison (2003) are consistent with one another and with constructivist information-processing principles. They all assume infants begin by attending to lower-level feature or part information and then form higher-level units by attending to correlations among those features.

Although all these proposals predict a developmental change in how infants process information about objects and categories, none of them gives a detailed account of the mechanism of change. This problem is not unique to the study of infant category learning. It is ubiquitous in developmental psychology. It is relatively easy to conduct research that reveals changes in behavior over age. It is much more difficult to determine the processes by which those changes occur. A promising approach to testing mechanisms of change is the use of connectionist models.

Connectionist Models of Infant Categorization

Connectionist models are becoming increasing popular tools for understanding, through simulation, the acquisition of early cognitive abilities. They are explicit computational models, based, at least by analogy, on principles of neural information processing. Numerous examples are now available of the application of connectionist models (sometimes called neural networks) to developmental phenomena (e.g., Elman et al., 1996; Mareschal, 2000, 2003; Shultz, 2003). Many types of models have been developed, some of which require external feedback to learn and some of which are self-organizing. But they all do learn or adapt as a function of experience. These models have been applied to a wide variety of phenomena within infant cognition, including object unity (Mareschal & Johnson, 2002), object permanence (Munakata, McClelland, Johnson, & Siegler, 1997), perception of causal events (Cohen et al., 2002), infant rule learning (Shultz & Bale, 2001), and categorization (Mareschal, French, & Quinn, 2000; Quinn & Johnson, 2000).

One of the more popular types of models for simulating infant habituation and categorization is an autoencoder network, shown on the right side of Figure 5.5, as taken from Mareschal and French (2000) and described by Mareschal (2003).

The left side of the figure schematically represents a simple conceptual model of habituation based on Sokolov (1963) or Cohen (1973). It assumes that individuals (in this case, infants) will direct more attention to a novel stimulus than to a familiar stimulus. When a stimulus is first presented, infants begin to encode it and then to compare it with representations stored in memory. If there is a difference (the stimulus is novel), the representation is adjusted and the infant continues to look. The system keeps cycling until a match occurs between the currently encoded stimulus and the stored representation (the stimulus is familiar). At that point, the infant looks away. This model is too simple, and it is incomplete. It does not incorporate that infants look away for multiple reasons or that, for a period of time, they may look longer at a familiar stimulus than at a novel stimulus. But it does include three processes—encoding, memory, and comparison—that seem essential to infants' eventual novelty preferences.

The autoencoder network shown on the right side of the figure incorporates these three processes. It is also much more explicit than the loose conceptual model on the left. The network includes three layers, a set of input units, hidden units, and output units, along with connections between the units. When a stimulus is presented, the input units are activated, each of which is sensitive to a particular feature or characteristic of the stimulus. Each input unit then activates, through a series of weighted connections, a set of hidden units, which in turn activate, through weighted connections, a set of output units. The pattern of activation of the input units represents the encoding portion of the model, the distributed representation of this input at the hidden unit level represents the internal representation or memory of the model, and the pattern of activation of output units represents the response of the model. An important aspect of an autoencoder network is that there are fewer hidden units than input or output units. In that way, the input information must first be summarized and compressed at the hidden unit level before being expanded back to its original size at the output level. The pattern of activation at the output is then compared with the pattern at the input. Any difference is considered to

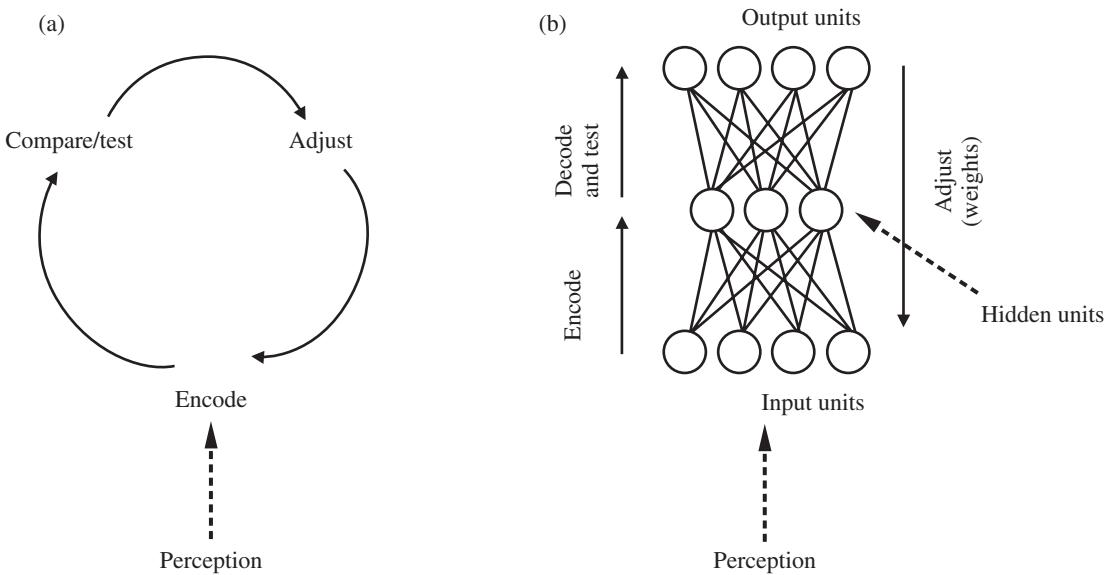

Figure 5.5 Conceptual and connectionist models of infant habituation and categorization. *Source:* From “The Acquisition and Use of Implicit Categories” (p. 363), by D. Mareschal, in *Early Category and Concept Development*, D. H. Rakison and L. M. Oakes (Eds.), 2003, New York: Oxford University Press. Reprinted with permission.

be an error and weights of connections in the network are adjusted to minimize error. The amount of error is also considered an indication of the novelty of the stimulus that was presented.

Autoencoder networks have been used to simulate infant categorization tasks. The network is first trained with exemplars from a single category (e.g., pictures of cats) and what amounts to a prototype is formed at the level of the hidden units. When a new member of the category is introduced, the output closely resembles the input. There is little error, and the response is similar to that of a familiar stimulus. But when a nonexemplar is introduced, such as a dog, the output differs from the input, error returns, and the response is to that of a novel stimulus.

Autoencoder networks have been shown to reproduce several effects reported in the infant categorization literature. One is asymmetrical generalization. Quinn, Eimas, and Rosenkrantz (1993) reported that when 3- to 4-month-old infants were trained with cat photographs, they learned a category of cats that excluded dogs, but when trained with dog photographs, their category of dogs included cats. They assumed this asymmetry occurred because most feature values of dogs were more variable and tended to overlap feature values of cats. Mareschal et al. (2000) simulated the probability distributions of cat and

dog feature values, applied them to an autoencoder network, and obtained the same asymmetrical generalization that Quinn et al. (1993) had found with infants. Based on their autoencoder model, Mareschal and French (1997) also predicted asymmetrical interference effects in infant categorization. These, too, were confirmed in an experiment with 3- to 4-month-old infants (Mareschal, Quinn, & French, 2002).

Autoencoder networks are also sensitive to correlations among feature values. As we have already mentioned, Younger (1985) reported a series of studies that showed 10-month-old infants can use correlational information either to combine all exemplars into a single category or to segregate items into two categories. She trained infants on a series of eight artificial animal drawings in a categorization task. Four features varied—length of legs, width of tail, length of neck, and separation of ears. For one group of infants, the values of the features were correlated (e.g., long legs went with a narrow tail, a short neck, and small ear separation). For the other group, the feature values were uncorrelated. Younger found that when the features were correlated, infants tended to form two separate categories of animals based on those correlations. When the features were uncorrelated, the infants formed one broad category that included all the animals. Using an autoencoder

network, Mareschal and French (2000) were able to simulate Younger's (1985) results. By plotting where each of Younger's animals fell in 3-dimensional space (using each hidden unit as a dimension), they found two separate clusters when the animals were correlated and only one cluster when they were uncorrelated.

The connectionist models of infant cognition we have mentioned so far can be considered "existence proofs." That is, if one accepts the assumptions underlying the input and the structure of the model, they show that such a model can simulate the behavior of infants on a cognitive task. Such simulations don't, of course, prove that the model portrays the way an infant actually does it. In some cases, the appropriateness of the model's assumptions can be questioned (Cohen & Chaput, 2002; Marcus, 2002; Mareschal & Johnson, 2002; Munakata & Stedron, 2002; Smith, 2002). But, some models, by demonstrating that a system can learn from experience, also serve as counterarguments to the nativist position that infants must have some core knowledge (e.g., Cohen, Chaput, and Cashon's, 2002, model of infants' causal perception; or Shultz and Bale's, 2001, model of infant rule learning).

Connectionist models of infant categorization have begun to move beyond the "existence proof" level (Cohen, 2004b). First, they have begun to take into account developmental changes in categorization; and, second, direct comparisons are beginning to be made between different models that attempt to simulate the same data. Three models (Gureckis & Love, 2004; Shultz & Cohen, 2004; Westermann & Mareschal, 2004) all attempted to reproduce the developmental changes in infant categorization reported by Younger and Cohen (1983, 1986). As noted, these studies reported a developmental progression in infants' sensitivity to correlated features in a categorization task. Four-month-olds responded in terms of independent features, 7-month-olds responded in terms of correlations when the task was simple but regressed to independent features when the task was difficult, and 10-month-olds responded to both simple and difficult tasks in terms of the correlations.

All three models were able to simulate the transition from independent features to correlated features, but each did so in a different way. Westermann and Mareschal's (2004) model assumed a developmental decrease in the size of infants' cortical receptive fields; Shultz and Cohen's (2004) model assumed a developmental increase in depth of learning; and Gureckis and

Love's (2004) model assumed an increase in perceptual or memory ability with age. However it was accomplished, each model had to propose some additional mechanism to account for the developmental change. Each model also made specific testable predictions. Finally, although all three models were able to simulate the transition from processing independent features at 4 months of age to processing the correlation among features at 10 months of age, none of the models was able to reproduce the fallback to a simpler way of processing at 7 months of age when the task became too difficult. Thus, other models are needed that include some mechanism for that fallback.

Perceptual versus Conceptual Categories

Most research on infant categorization can be classified as research on perceptual categorization in that it deals primarily with infants' identification of perceptual features (generally what something looks like and where it is located) and the pattern of intercorrelation among these perceptual features. Mandler (1992, 2000a, 2003) has drawn a sharp distinction between perceptual categorization and conceptual categorization. She lists five ways in which the two differ. First, perceptual categories compute object groups based on their appearance; conceptual categories compute class membership based on an object's role or function in events. Second, perceptual categories contain detailed information, whereas concepts are relatively crude, abstract, and devoid of specific content. Third, perceptual categories are implicit and inaccessible to conscious awareness. Concepts are used in conscious thought and recall as exemplified by deferred imitation tasks. Fourth, perceptual categories tend to begin at the basic level and then advance to a more global level, whereas the earliest conceptual categories are global, rather than basic. Finally, perceptual categories are used for purposes of recognition and identification. Concepts provide meaning and are the basis of inductive generalizations.

Mandler (2000a) has also argued that although habituation and novelty preference paradigms may provide information about perceptual categorization, they don't require the active functional involvement needed to assess an infant's conceptual understanding or meaning (see Haith and Benson, 1998, for a similar position). Instead, Mandler has argued that an examination of early conceptual development requires paradigms such as sequential touching, active manipulation, and imitation.

Mandler's view of parallel perceptual and conceptual categorization systems has not gone unchallenged. Several researchers have argued that conceptual representations are informational enrichments of earlier perceptual representations (Madole & Oakes, 1999; Oakes & Madole, 2003; Quinn & Eimas, 1997, 2000; Rakison, 2003). Although alternative theoretical accounts such as these have minor differences between them, they tend to agree that more dynamic information such as sounds, movements, functions, and possible actions on them become increasingly important features of objects. Along with any static perceptual attributes, these more dynamic features, plus the gradual addition of correlational information, contextual constraints, and causal links, can make object categories more meaningful, abstract, and conceptual.

Although Mandler (2004) provides substantial empirical support for her position, not all the evidence is consistent with it. For one thing, habituation and novelty preference paradigms are not restricted to the examination of static perceptual properties. As already noted, much of the evidence on infants' understanding of dynamic causal events comes from habituation paradigms. These paradigms have also been valuable in the examination of infants' sensitivity to functional as well as perceptual information (Madole & Cohen, 1995; Madole et al., 1993) and in infants' understanding of abstract spatial relations such as above versus below, inside versus outside (Quinn, 2003; Quinn, Adams, Kennedy, Shettler, & Wasnik, 2003), or containment and support (Casasola & Cohen, 2002; Casasola, Cohen, & Chiarello, 2003). Furthermore, with respect to causality, functional attributes, and spatial relations, the developmental transitions seem consistent with our constructivist information-processing perspective. First, infants process independent objects, then they process the object-action or object-object relations, but only with respect to the specific instances they have seen. Finally, they generalize to novel instances (they form a categorical representation).

Mandler and colleagues (Mandler & Bauer, 1988; Mandler, Bauer, & McDonough, 1991) have also reported that when active tasks are used, infants form global categories (e.g., animals versus vehicles) prior to forming basic ones (e.g., dogs versus cats). But in at least some instances, more specific category formation has been reported. Oakes et al. (1997) reported that infants in an object manipulation task formed separate categories of land versus sea animals, and in a general-

ized imitation task, they modeled at the basic level more than at the global level (Younger, Johnson, & Furrer, 2004). Even when infants do respond at a global level, such as to animals versus vehicles in a sequential touching task, some have argued that they are doing so based on attention to specific parts, such as legs versus wheels, rather than a global category (Rakison, 2003; Rakison & Butterworth, 1998a, 1998b).

After reviewing the recent evidence regarding perceptual versus conceptual categories, we reached essentially the same conclusion that Haith and Benson (1998) did several years ago, "Whether infants form categories on a perceptual or a conceptual basis is controversial and difficult to determine; the activities in which exemplars participate may provide perceptual information that muddies the perception-conception distinction" (p. 229).

Although this issue remains unresolved, the controversy has had positive consequences. It has led to more comprehensive views of infant categorization that go beyond the perception and correlation of static perceptual properties. Current theoretical notions, such as the one by Oakes and Madole (2003), are beginning to take into account the expanding types of information available as infants develop, the context in which that information occurs, and learned or preprogrammed constraints on the use of that information in category formation. Others are looking more closely at the links between object categorization and labeling (Mervis, Pani, & Pani, 2003; Waxman, 2003; Waxman & Lidz, Chapter 7, this *Handbook*, this volume), and at causal as well as correlational links between objects and labels (Gopnik & Nazzi, 2003). We expect all these avenues to be important in learning how infants move from more perceptual to more conceptual ways of organizing the world around them.

INFANT FACE PROCESSING

Research on infant face processing was not included in Haith and Benson's chapter for the *Handbook* (5th ed., 1998), although Harris (1983) mentioned it in the fourth edition. A review of this research is included in the present chapter for a variety of reasons. For one, most of those who conduct research in this area consider it to be an aspect of cognitive development; and many issues that are important in other areas of infant cognitive development, such as the existence of an innate module or domain-specific versus domain-general developmental

changes, are essential aspects of the research on infants' processing of faces. Moreover, many developmental changes that occur in infant face processing fit in nicely with the domain-general, information-processing principles to which we have frequently referred.

A better understanding of the early development of face processing also may play an important role in resolving issues, both in the adult and infant literature, that have been debated for decades. For example, by studying the development of face processing in infants, particularly newborns, researchers can shed light on whether we come into the world with a specialized innate module in the cortex for processing faces or whether areas in the cortex become specialized to process faces through experience (Kanwisher, 2000; Tarr & Gauthier, 2000). Furthermore, research with newborns might also help researchers resolve the issue of whether infants come into the world with a preference to attend to faces and facelike stimuli over other stimuli and, if so, why this is the case (de Haan, Humphreys, & Johnson, 2002; Turati, 2004).

We discuss here some of the current research that may provide answers to these questions. First, we examine recent research on newborns' apparent preference for faces (or facelike stimuli) and how that preference might enlighten our understanding of the innate module assumption. Second, we consider how infants' processing of faces changes over age, in particular becoming more specialized to process upright, human faces. Third, we discuss how these changes are related to featural versus holistic processing of upright and inverted faces as well as to infants' discrimination of same- and different-species' faces. We recognize that we are covering only a subset of the issues and research associated with early face perception (for additional information on this topic, see Kellman and Arterberry, Chapter 3, this *Handbook*, this volume).

Newborns' Preferences for Faces

Several studies have indicated that newborns orient farther with their eyes, and sometimes with their heads, to moving schematic drawings of faces than to nonface patterns (Goren, Sarty, & Wu, 1975; Johnson, Dziurawiec, Ellis, & Morton, 1991; Maurer & Young, 1983). Johnson et al. (1991) also reported, however, that this preference disappears around 1 month of age, only to reappear around 2 months of age. Based on these findings, Johnson and Morton (Johnson & Morton, 1991; Morton &

Johnson, 1991) put forth a highly cited account of newborns' apparent preference for faces, and the U-shaped developmental pattern that occurs over age, by positing two mechanisms to account for infants' face preference at birth and around 2 months of age. One mechanism, thought to be present at birth, is a *subcortical* device, referred to as CONSPEC. It provides crude information about the structure of faces and leads newborns to attend to faces. The second mechanism, believed to have its influence a month or two later, is a separate *cortical* mechanism, called CONLERN. It allows infants to learn about the individual identities of faces. According to this theory, the reason the preference for facelike stimuli disappears about 1 month of age is that at around this age CONSPEC has become inhibited and the second mechanism, CONLERN, has not yet become fully engaged. In response to one line of thinking in the adult literature suggesting that we are born with prespecified cortical circuitry intended to process faces, Johnson and de Haan (2001) have tried to make it clear that the CONLERN mechanism is not an innate module prespecified to process faces, but rather is a cortical system that develops out of experience with faces, an idea much in line with those posited by Elman et al. (1996).

More recent research in this area has focused on the nature of CONSPEC. A connectionist model by Bednar and Miikkulainen (2000), is designed to uncover possible origins of the structural information about faces used by CONSPEC. Bednar and Miikkulainen's model shows that, prenatally, the primary visual cortex can self-organize to attend to a three-dot pattern, which essentially looks like a face, by abstracting this pattern from the spontaneous firing of retinal waves thought to be produced during REM sleep. Thus, their model provides a possible mechanism by which innate structural information about faces and even visual preferences for faces might appear, without requiring any specific information in the genes other than a simple learning mechanism that builds on a three-dot pattern.

Whereas Bednar and Miikkulainen's (2000) model provides a possible explanation for how a newborn's system might develop a preference for a facelike configuration, it is unclear from much of the behavioral research whether infants actually are attracted to a three-dot pattern when they show this preference. Recent research suggests that newborns actually may not be attending to the entire region of the face that includes the two eyes and the mouth. Instead, infants may be attracted to a facial configuration because there is more information in

the upper half than in the bottom half of the stimulus. By comparing infants' looking times to nonface patterns that varied in the number and arrangement of elements in the top and bottom halves of the stimuli, Simion, Valenza, Cassia, Turati, and Umlita (2002) found that newborns preferred those items with more complexity in the top half of a rectangular contour. Turati, Simion, Milani, and Umlita (2004) found this to be true when the elements appeared inside a facelike contour. The authors referred to this as *up-down symmetry*. These findings suggest that newborns' immature sensory capabilities may lead them to prefer stimuli with up-down symmetry and thus, may play a role in their apparent preference for facelike stimuli (for a discussion, see also Simion, Cassia, Turati, & Valenza, 2001; Turati, 2004).

To be fair, it should be mentioned that Johnson and colleagues do not regard these findings as contradictory to their original, two-mechanism theory. They maintain that newborns come into the world with subcortical information about the structure of faces, but they are flexible about exactly what that structural information might be. Furthermore, the more important point from their perspective is the following:

Whatever the exact description of the basis of the newborn's orienting tendencies, none contradict our proposal that these reflect more primitive biases that could provide input to developing cortical areas rather than the existence of an innate cortical "face module." (de Haan, Humphreys, & Johnson, 2002, p. 204)

Development of Face Processing

Building on this idea that infants' processing of faces develops and takes time to become adultlike, recent research suggests that as we get older, we develop a specialization for upright, human faces. A recent study published in *Science* traces some of the developmental changes in infants' processing of same versus other species' faces. Using a visual discrimination task, Pascalis, de Haan, and Nelson (2002) found that whereas 6-month-olds showed evidence of discriminating between two human faces or two faces of Macaque monkeys, 9-month-olds and adults were found to discriminate only between the two human faces. This apparent deterioration in performance over age suggests that during the 1st year of life, infants become tuned to process faces of their own species and to disregard differences among other species. With respect to both the deterioration and

the ages involved, this apparent loss of discrimination ability is reminiscent of a similar loss in early speech perception of the ability to discriminate nonnative phonetic contrasts (Werker & Tees, 1984).

A Constructivist Information-Processing Account of Infant Face Processing

It is commonly believed that adults process faces in a holistic or configural manner when the face is in an upright orientation, but featurally when the face is in an inverted position (e.g., Farah, Tanaka, & Drain, 1995). Recent results indicate that by 7 months of age, infants show a similar pattern (Cohen & Cashon, 2001a); still other reports show that prior to this age, there is no difference in mode of processing between upright and inverted faces (Cashon & Cohen, 2003, 2004).

To assess the question of developmental changes in infants' featural versus holistic processing of faces, Cashon and Cohen used a version of the switch habituation design described earlier. Infants were habituated to two female faces and after meeting the habituation criterion, they were tested on a familiar test face (one of the two habituation faces), a novel test face (one they had only seen once during the pretest), and a switch test face (composed of the internal features—the eyes, nose, and mouth—from one of the habituation faces and the external features—the remaining features, such as the eyebrows, forehead, chin, ears, hair—from the other habituation face). Because all the facial features of the switch test face were seen during habituation, it was assumed that these elements were familiar to the infants. Thus, it was reasoned that if infants looked longer to the switch than to the familiar test face, it would be because it presented a new *relationship* between the internal and external parts of the faces. (Many researchers use different operational definitions of holistic and configural processing, and Cashon and Cohen are no exception. As can be seen from the description of their task, their definition of holistic processing is based on infants' sensitivity to the relationship between the internal and external features of a face.)

In testing infants between 3 and 10 months of age, Cashon and Cohen found many changes in processing taking place during these months (Cashon & Cohen, 2003, 2004). As illustrated in Figure 5.6, the oldest two groups, the 7- and 10-month-olds, behaved in a manner consistent with adult performance; that is, they processed upright faces holistically and inverted faces featurally. Results

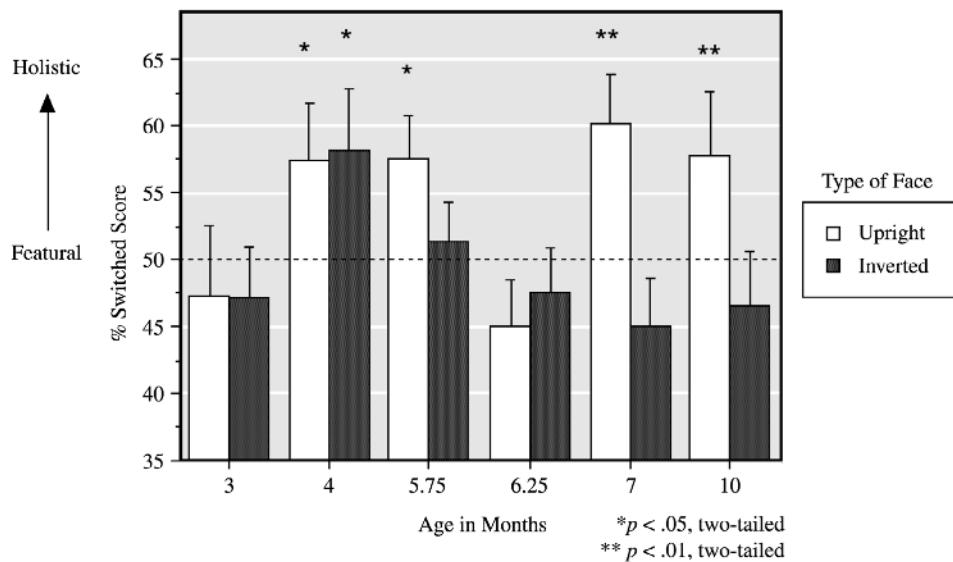

Figure 5.6 Data showing the developmental changes in infants' featural versus holistic processing of upright (white bar) and inverted (grey bar) faces between 3 and 10 months of age. The "% switched score" is equal to infants' looking time to the switched test face divided by the total looking to the switched plus familiar test faces. The authors inferred that if the % switched score was significantly higher than 50%, infants were engaging in holistic processing. Adapted from "The Construction, Deconstruction, and Reconstruction of Infant Face Perception" (p. 61), by C. H. Cashon and L. B. Cohen, in *The Development of Face Processing in Infancy and Early Childhood*. A. Slater and O. Pascalis (Eds.), 2003, New York: NOVA Science. Reprinted with permission.

with younger infants indicated that this differential processing of upright and inverted faces does not develop until 7 months of age. Three-month-olds were found to process both upright and inverted faces featurally. At 4 months, a developmental shift to holistic processing was found for both upright and inverted faces. Six-month-olds also showed no difference between upright and inverted faces, but surprisingly, they returned to processing the faces featurally. A possible reason that infants show this peculiar, curvilinear developmental pattern is discussed shortly. For now, however, the message is that although there is evidence that at some point we become specialized to upright human faces, these findings provide further support for the notion that such specialization develops and most likely results from extensive and meaningful experience with faces (see also Le Grand, Modloch, Maurer, & Henry, 2001; Nelson, 2001; Nelson & Monk, 2001).

The behavioral findings just mentioned fit nicely with ERP results (de Haan, Pascalis, & Johnson, 2002) demonstrating that the neural correlates of infants' sensitivity to the orientation of faces changes between 6 months of age and adulthood. The de Haan, Pascalis, et al. results also indicate that around 6 months of age,

infants are not as specialized in their processing of faces as adults. Together, the results of the ERP study and our behavioral research suggest that what differs during the first half of the 1st year of life compared with the second half is not that infants do not attend to the orientation of faces prior to 7 months of age, but rather that they are not completely attuned to the special status of upright faces until that time.

Returning to why infants might show the curvilinear developmental pattern found between 3 and 7 to 10 months of age, the answer can be found in the constructivist information-processing approach. The change found between 3 and 4 months, from processing a face featurally to holistically, is consistent with the constructive development proposed by the information-processing principles presented earlier. Subsequent regression to processing a face featurally again around 6 months of age also fits with these principles, if it results from an information overload. As discussed, results from de Haan, Pascalis, et al. (2002) indicate that infants are sensitive to facial orientation at this age and that upright faces have some sort of special status for adults. One possibility is that 6 months is about the age at which infants become sensitive to the meaningfulness of upright

faces. If so, the social meaning of the face may overload the system temporarily while infants reorganize their understanding of faces. The subsequent finding—that by 7 months of age, infants, for the first time, engage in different modes of processing for upright and inverted faces—supports this idea that a type of reorganization has occurred.

THE ANIMATE-INANIMATE DISTINCTION

We have proposed that, in at least a few respects, infants consider faces to be special. Infants have an early bias to attend to facelike stimuli over other stimuli; they develop a specialized response to human upright faces during the 1st year of life; and the developmental changes that occur prior to this specialization transpire much earlier with faces than with other complex stimuli. A question that arises from these findings is whether infants extend this special status just to faces or to all animate entities. Another way of asking the question is, do infants make an animate-inanimate distinction?

Research on the animate-inanimate distinction, for the most part, has focused on preschoolers (Gelman, Spelke, & Meck, 1983) and to some extent toddlers (Poulin-Dubois & Forbes, 2002). Although relatively fewer studies involve infants (e.g., Woodward, 1998), researchers have shown an interest in this area for several reasons. First, investigations of infant categorization have begun to emphasize more complex, deeper category structure, moving beyond perceptually based category research (Rakison, 2003). Second, understanding the distinction between animates and inanimates may influence infants' language acquisition. According to Slobin (1981), the prototypical agent is animate and the patient is inanimate. Thus, it could be argued that the animate-inanimate distinction might be helpful in learning semantic categories (Childers & Echols, 2004). Third, one of the differences between animate and inanimate beings is that animate entities act according to goals, desires, and intentions (Premack, 1990). Thus, infants' distinction between animates and inanimates may shed light on precursors to a later understanding of intentionality and theory of mind (Poulin-Dubois, Lepage, & Ferland, 1996; Woodward, 1998).

Rakison and Poulin-Dubois (2001) provide a summary of research on infants' animate-inanimate distinction. Here, we emphasize the most recent research in the area and discuss how these findings relate to our con-

structivist information-processing approach. A primary issue relates to the nature of the distinction between an animate entity and inanimate entity. Although several proposals have been made about what makes animates and inanimates distinct (Rakison & Poulin-Dubois, 2001), most include at least one aspect that centers on different types of motion. Mandler (1992, 2000a) has argued that during the 1st year of life infants have "image schemas" for various object movements, including self-motion versus caused motion, irregular trajectories versus straight trajectories, and movement caused at a distance versus movement caused by direct physical contact. According to Mandler, some of these schemas combine to produce a concept of animacy.

There is evidence that infants are sensitive to these different types of motion. Seminal work by Bertenthal (1993) showed that infants in the first 6 months of life are sensitive to how humans move; they discriminate upright versus inverted point-light displays of a human walking as well as dots depicting a human walking versus randomly varying dots. Furthermore, Bertenthal reported a developmental change in this respect between 3 and 5 months of age. The detection of differences in point-light displays becomes orientation specific by 5 months. Bertenthal interprets this difference as indicating that the older infants are responding at a higher level, based on meaning, rather than just perceptual structure. We agree, and would argue that meaning emerges from infants' developing sensitivity to the relation between the overall configuration of moving dots and their experience with animate objects in the world. Rakison and Poulin-Dubois (2001) note that although these findings show that infants can detect a difference between normal human movement and random movement, it remains to be seen whether this distinction extends to the entire class of animate versus inanimate entities or only to human versus nonhuman movement.

More recent evidence with point-light displays suggests that young infants make a distinction between animate and inanimate entities that goes beyond humans as the subject matter. Using a categorization-habituation task, Arterberry and Bornstein (2001) reported that 3-month-olds categorized moving point-light displays of animals separately from those of vehicles, and vice versa. This finding suggests that young infants' sensitivity to the kinds of movements objects make may extend beyond human versus nonhuman movement. They also reported that infants categorized animals and vehicles separately using static picture stimuli. Thus, it is not en-

tirely clear that infants in Arterberry and Bornstein's studies categorized animals and vehicles based on movement alone, given that the same results were found with static pictures. It is also not known whether the results of this set of studies, or Bertenthal's for that matter, extend to the broader notion of animate versus inanimate.

The studies by Bertenthal (1993) and by Arterberry and Bornstein (2001) indicate that infants can associate a type of movement with a particular object by 5 to 6 months of age. We would predict that infants' next step should be learning the relation between two moving objects in an event. As discussed with respect to causal perception, it is not until the second half of the 1st year of life that infants become sensitive to the relation between two objects in a causal event. In addition to those studies discussed, in which inanimate objects were involved in the events, Schlottmann and Surian (1999) reported that infants around 9 months of age are sensitive to causality when animate objects are involved. Their study was based on Leslie and Keeble's (1987) causal reversal paradigm but involved squares that traveled in an animate manner like a caterpillar. They were specifically interested in the notion of causality-at-a-distance whereby an object moves in response to another object approaching it, before they actually touch. Schlottmann and Surian reported that in the case of such an event, 9-month-old infants perceived the movement of the second object to be an intentional response caused by the approaching first object, even though the two objects never touched. To the authors, this finding suggested that by 9 months of age infants associate animate objects with certain nonphysical causation. What is unclear from their report is on what basis the infants perceived the objects to be animate. It is possible that the infants attended primarily to the irregular, caterpillar-like motion, or to the fact that the objects' initiation of movement was self-propelled, or perhaps to both cues. By testing infants in other conditions that involve manipulations of the type of object (animate versus inanimate), the object's position, and its starting motion, the cues to which infants attend can be determined. In any case, we predict that whereas associating animacy with a particular object might be possible at 6 months of age, detecting the relation between two animate objects may not happen until later in the 1st year, as reported by Schlottmann and Surian.

A study by Rakison and Poulin-Dubois (2002) explored in more detail how infants come to associate certain kinds of movement with particular objects. Using the switch de-

sign to test infants' associations between an object's motion and its parts versus the whole object, Rakison and Poulin-Dubois found developmental changes across three age groups, 10-, 14-, and 18-month-olds. The 10-month-olds attended to the object characteristics, that is, to the parts of each object as well as to each object as a whole, but not to the movement of the objects. The 14-month-olds attended to the association between the part of an object and the object's movement, while the 18-month-olds also attended to the association between the whole object and its movement. These developmental differences are consistent with our version of an information-processing perspective in that they involve a parts-to-whole progression as well as an integration of more and more complex information.

SUMMARY AND CONCLUSIONS

Research on infant cognition is going on at an active, even accelerating pace. In some respects, this activity represents a continuation of research on major topics such as object permanence and causality that have been examined since Piaget's (1954) early work and have been summarized in earlier *Handbook* chapters. In other respects, this activity represents a return to certain central Piagetian issues notably developmental change and constructive processes of development, which were deemphasized by researchers in the 1980s and 1990s in their search for core knowledge and innate modules. In yet other respects, recent activity indicates a breakthrough into exciting new approaches, such as connectionist modeling, that have the potential for specifying actual mechanisms of early learning and development.

Over the past decade, we also have seen changes in the significance of certain topics, such as perception of object unity and individuation, processing of human faces, and understanding of causality, animacy, and intentionality. These topics, which may initially have been thought of as aspects of traditional areas such as object permanence, have now become relatively independent areas worthy of research and theory in their own right.

We have also seen the reemergence of theorizing at a broader, more domain-general level, rather than at a local, domain-specific level. This trend certainly is apparent in attempts to explain infant categorization and its development, whether one advocates a single evolving system that progresses from processing mainly perceptual information to processing functional and linguistic

information as well (Oakes & Madole, 2003; Rakison, 2003), or a dual system that includes separate perceptual and conceptual components (Mandler, 2003).

In this chapter, we have argued that the dividing line between infant perception and infant cognition is arbitrary, and attempting to draw a sharp line is generally nonproductive when seeking to explain early cognitive development. Instead, we have proposed a set of information-processing principles that are domain general and are relevant across multiple areas of infant perception and cognition (Cohen, 1988). We have shown how our approach makes specific predictions about constructive developmental progressions as well as fallbacks to simpler ways of processing when the system becomes overloaded. In some respects, it represents a return to Piagetian principles, although it does not advocate the incorporation of motor actions to the same extent Piaget did. This approach is also concrete enough to lead to a formal connectionist model that so far has made accurate predictions regarding infants' developing understanding of simple causal events and has the potential to predict many other aspects of cognitive development (Cohen et al., 2002).

Whether one endorses our approach or some other one, the area of infant cognition is evolving on both empirical and theoretical grounds. Traditionally independent areas are merging with one another to generate new answers to difficult questions. We have emphasized the integration of cognitive and computational approaches in the development of new connectionist models. Another important merger that we only touched on is the combination of cognitive and neuroscience approaches. Bauer's chapter on infant memory (Chapter 9, this *Handbook*, this volume) provides an example of how fruitful such a merger can be.

Finally, we have been unable to include all the significant topics currently being investigated in the field of infant perception and cognition. It is not that we consider these areas to be unimportant. We simply did not have the space to include all of them. Some of these topics, such as the relation between infant perception and action or infant deferred memory and imitation, are covered in other chapters.

Nevertheless, the present chapter reflects the breadth and depth of current research on infant cognitive development. The field is changing. It no longer can be studied in isolation, but must become part of an interdisciplinary approach that includes both cognitive science and neuroscience. Developmental psychology as a whole is evolv-

ing, and recent research on infant cognition represents an important part of that evolution.

Human linguistic communication differs from the communication of other animal species in three main ways. First, and most importantly, human linguistic communication is symbolic. Linguistic symbols are social conventions by means of which one individual attempts to share attention with other individuals by directing their attentional or mental states to something in the outside world. Other animal species do not communicate with one another using linguistic symbols, most likely because they do not understand that conspecifics have attentional or mental states that they could attempt to direct or share (Tomasello, 1998c, 1999). This mental dimension of linguistic symbols gives them unparalleled communicative power, enabling their users to refer to and to predicate all kinds of diverse perspectives on objects, events, and situations in the world.

The second main difference is that human linguistic communication is grammatical. Human beings use their linguistic symbols together in patterned ways, and these patterns, known as linguistic constructions, come to take on meanings themselves—deriving partly from the meanings of the individual symbols but, over time, at least partly from the pattern itself. The process by which this occurs over historical time is called *gram-*

maticalization, and grammatical constructions add still another dimension of communicative power to human languages by enabling all kinds of unique symbol combinations. Grammatical constructions are also uniquely human, of course, because if a species does not use symbols, the question of grammar is moot.

Third, unlike all other animal species, human beings do not have a single system of communication used by all members of the species. Rather, different groups of humans have conventionalized over historical time different, mutually unintelligible systems of communication (there are more than 6,000 natural languages in the world). This means that children, unlike other animal species, must learn the communicative conventions used by those around them—indeed they take several years to acquire the many tens of thousands, perhaps even hundreds of thousands, of linguistic symbols and constructions of their natal group(s). This is much more learning in this domain—by many orders of magnitude—than is characteristic of any other species.

This chapter is about the way children master a language, the way they learn to communicate using the linguistic conventions used by those around them in both their symbolic and grammatical dimensions. We begin

with some background history and theory of the field, proceed in the next two sections to outline the major ontogenetic steps of language acquisition, and conclude the chapter with a focus on the cognitive and social processes involved in becoming a competent user of a natural language.

HISTORY AND THEORY

To investigate how children acquire a language, we must first know what a language is. This is not as straightforward as it might seem, since the specialists involved—linguists—do not agree among themselves.

The Role of Linguistics

Large-scale theories and approaches to child language acquisition are mainly characterized by the theory of linguistics that they assume as their foundation. Thus, using the linguistics of the 1950s (viz., American Structural Linguistics), the first modern researchers of child language acquisition in the 1960s attempted to identify the items and structures in children's language using exclusively the method of distributional analysis. Making basically no assumptions about possible correspondences between child and adult linguistic competence, the main finding was that many of children's earliest word combinations consisted of one constant word that could be freely combined with one of many variable words. Many of these lexically based patterns also seemed to show some consistencies among one another, however, especially with respect to ordering, and so Braine (1963) formalized these patterns into a three-rule Pivot Grammar that was supposed to be what children used to generate their language:

1. P¹ + O (*More juice, More milk, There Daddy, There Joe, etc.*).
2. O + P² (*Juice gone, Mommy gone, Flowers pretty, Janie pretty, etc.*).
3. O + O (*Ball table, Mommy sock, and so on—that is, utterances without a pivot*).

The main problem with Pivot Grammar was that, while it did capture something of the spirit of children's early language, in its formalized form it was empirically inadequate since: (a) children did not always use the same pivot in a consistent sequential position, (b) children

sometimes combined two pivots with one another, and (c) the O + O rule was essentially a wastebasket for non-canonical utterances (Bloom, 1971). It was also unclear in this account how young children could ever get from these purely childlike syntactic categories to the more adultlike syntactic categories that were being described by the linguists of the time.

The natural next attempt, therefore, was to apply the new adult linguistic models of the 1960s and 1970s to the data of child language acquisition. These attempts—which included several versions of Transformational Generative Grammar, Case Grammar, Generative Semantics, and others—were reviewed and evaluated by Brown (1973). Brown's basic conclusion was that, while children's linguistic productions could be forced into any one of the models, none of the models was totally satisfactory in accounting for all the data. But the more fundamental problem was that there was really no evidence that children employed, or even needed, the adultlike linguistic categories and rules that were being attributed to them in these models. For example, Schlesinger (1971) and Bowerman (1976) surveyed the utterances produced by several children learning several languages and found that—on internal grounds—there was no reason to assume that they were underlain by abstract syntactic categories such as "subject," "direct object," and "verb phrase." There was also a suspicion among many people who looked broadly at languages across different cultures that no single formal grammar would be adequate to account for the acquisition process in all of the world's many thousands of languages (Slobin, 1973).

Several theorists—including Brown (1973), Slobin (1970), Schlesinger (1971), Bloom (1973), and others—then suggested a semantic-cognitive basis for children's early language: the so-called Semantic Relations approach. The basic observation was that most of the semantic-syntactic relations apparent in children's early language correspond rather closely to some of the categories of sensory-motor cognition as outlined by Piaget (1952). For example, infants know nonlinguistically some things about the causal relations among agents, actions, and objects, and this might form the basis for a linguistic schema of the type: Agent-Action-Object (and similarly for Possessor-Possessed, Object-Location, Object-Attribute, etc.). While again this approach seemed to be capturing something of the spirit of early language—children mostly talk about a fairly delimited set of events, relations, and objects that correspond in

some ways to Piagetian sensory-motor categories—it was also empirically inadequate as many child utterances fit into none of the categories while others fit into several (Howe, 1976). Moreover, echoing the theoretical problems of Pivot Grammar, there were basically no serious theoretical proposals about how young children got from these semantically based syntactic categories to the more abstract syntactic categories of adults.

Swinging the pendulum back in the adult direction once again, in the 1980s a new group of theorists began to advocate a return to adult grammars, but in this case using some new formal models such as Government and Binding theory, Lexical Functional Grammar, and the like (e.g., Baker & McCarthy, 1981; Hornstein & Lightfoot, 1981; Pinker, 1984). The general consensus was that proposing a discontinuity from child to adult language—as seemed to be the case in such things as Pivot Grammar and the Semantic Relations approach—created insurmountable logical problems, that is to say, problems of learnability. These logical problems were thought by learnability theorists to be sufficient justification to make the continuity assumption, namely, that children operate with the same basic linguistic categories and rules as adults (Pinker, 1984). This general point of view was strongly associated with linguistic nativism, in which all human beings possess the same basic linguistic competence, in the form of a universal grammar, throughout their lives (Chomsky, 1968, 1980). The inadequacies of this approach soon became apparent as well, most fundamentally its inability to deal with the problems of cross-linguistic variation and developmental change—how children could “link” an abstract and unchanging universal grammar to the structures of a particular language, and why, if this was the process, children’s language looked so different from adults’. And again, there was no evidence that children actually use abstract adultlike categories—continuity was only an assumption.

Two Theories

It is easy to see in this historical sketch two distinct strands. One derives from researchers who take a formal approach to language and its acquisition—a more adult-centered approach emanating from Chomsky’s theory of generative grammar—and the other derives from researchers who take a more functional, usage-based approach to language and its acquisition—a potentially more child-centered approach with room for serious de-

velopmental change. It is these two basic orientations that still structure the current theoretical debate in the study of child language acquisition.

Chomskian generative grammar is a *formal* theory, meaning that it is based on the supposition that natural languages are like formal languages (e.g., algebra, predicate logic). Natural languages are thus characterized in terms of: (a) a unified set of abstract algebraic rules that are both meaningless themselves and also insensitive to the meanings of the elements they algorithmically combine, and (b) a lexicon containing meaningful linguistic elements that serve as variables in the rules. Principles governing the way the underlying algebra works constitute a universal grammar, the core of linguistic competence. The linguistic periphery involves such things as the lexicon, the conceptual system, irregular constructions and idioms, and pragmatics.

With regard to language acquisition, Chomskian generative grammar begins with the assumption that children innately possess a universal grammar abstract enough to structure any language of the world. Acquisition then consists of two processes:

1. Acquiring all the words, idioms, and quirky constructions of the particular language being learned (by “normal” processes of learning).
2. Linking the particular language being learned, that is, its core structures, to the abstract universal grammar.

This is the so-called *dual process* approach—also sometimes called the *words and rules* approach (Pinker, 1999)—since the “periphery” of linguistic competence is learned but the “core” is innately given in universal grammar. Because it is innate, universal grammar does not develop ontogenetically but is the same throughout the life span: This is the so-called continuity assumption (Pinker, 1984). This assumption allows generativists to use adultlike formal grammars to describe children’s language and so to assume that the first time a child utters, for example, “I wanna play” that she has an adult-like understanding of infinitival complement sentences and so can generate similar infinitival complement sentences *ad infinitum*.

In sharp contrast is the group of theories most often called *Cognitive-Functional Linguistics*, but which are sometimes also called *Usage-Based Linguistics* to emphasize their central processing tenet that language structure emerges from language use (e.g., Bybee, 1985, 1995; Croft, 1991, 2001; Givón, 1995; Goldberg, 1995;

Langacker, 1987a, 1991; see Tomasello, 1998a, 2003, for other similar approaches). Usage-based theories hold that the essence of language is its symbolic dimension, with grammar being derivative. The ability to communicate with conspecifics symbolically (conventionally, intersubjectively) is a species-specific biological adaptation. The grammatical dimension of language derives from historical processes of grammaticalization, which create various grammatical constructions (e.g., the English passive construction, noun phrase construction, or *-ed* past tense construction). As opposed to linguistic rules conceived as algebraic procedures for combining words and morphemes that do not contribute to meaning, linguistic constructions are meaningful linguistic symbols. They are nothing other than the patterns in which meaningful linguistic symbols are used in communication (e.g., the passive construction is used to communicate about an entity to which something happens). In this approach, mature linguistic competence is conceived as a structured inventory of meaningful linguistic constructions—including both the more regular and the more idiomatic structures in a given language (and all structures in between).

According to the usage-based theory, there is no such thing as universal grammar and so the theoretical problem of how a child links it to a particular language does not exist. It is a single-process theory of language acquisition, in the sense that children are thought to acquire the more regular and rule-based constructions of a language in the same way they acquire the more arbitrary and idiosyncratic constructions: They learn them. And, as in the learning of all complex cognitive activities, they then construct abstract categories and schemas out of the concrete things they have learned. Thus, in this view, children's earliest acquisitions are concrete pieces of language—words (e.g., *cat*), complex expressions (e.g., *I-wanna-do-it*), or mixed constructions (e.g., *Where's-the-_____*, which is partially concrete and partially abstract)—because early in development they do not possess the fully abstract categories and schemas of adult grammar. Children construct these abstractions only gradually and in piecemeal fashion, with some categories and constructions appearing much before others that are of a similar type from an adult perspective—due quite often to differences in the language that individual children hear (“input”). Children construct their language using general cognitive processes falling into two broad categories: (1) intention-reading (joint attention, under-

standing communicative intentions, cultural learning), by which they attempt to understand the communicative significance of an utterance; and (2) pattern-finding (categorization, schema formation, statistical learning, analogy), by which they create the more abstract dimensions of linguistic competence.

Constructions

In this chapter, we adopt a usage-based theoretical perspective on the process of language acquisition. We thus assume that what children are learning initially is concrete pieces of language, of many different shapes and sizes, across which they then generalize to construct more abstract linguistic constructions—which underlies their ability to generate creative new utterances. The central theoretical construct is therefore the construction.

A linguistic construction is prototypically a unit of language that comprises multiple linguistic elements used together for a relatively coherent communicative function, with subfunctions being performed by the elements as well. Consequently, constructions may vary in their complexity depending on the number of elements involved and their interrelations. For example, the English regular plural construction (N+s) is relatively simple, whereas the passive construction (X was VERBed by Y) is relatively complex. Independent of complexity, however, constructions may also vary in their abstractness. For example, the relatively simple English regular plural construction and the more complex English passive construction are both highly (though not totally) abstract. To repeat, even these most abstract constructions are still symbolic, as they possess a coherent, if abstract, meaning in relative independence of the lexical items involved (Goldberg, 1995). Thus, in the utterance *Mary sneezed John the football*, our construal of the action is influenced more by the transfer of possession meaning of the ditransitive construction than it is by the verb *sneeze* (since sneezing is not normally construed as transferring possession). Similarly, we know that the nonce noun *gazzers* very likely indicates a plurality without even knowing what a gazzer is.

Importantly, however, some complex linguistic structures are not based on abstract categories, but rather on particular linguistic items (Fillmore, 1988, 1989; Fillmore, Kaye, & O’Conner, 1988). The limiting case is totally fixed expressions such as the idiom *How do you do?*

which is a structure of English with an idiosyncratic meaning that dissolves if any of the particular words is changed. (One does not normally, with the same intended meaning, ask *How does she do?*) Other clear examples are such well-known idioms as *kick the bucket* and *spill the beans*, which have a little more flexibility and abstractness as different people may kick the bucket and they may do so in past, present, or future tense—but we cannot, with the same meaning, kick the pail or spill the peas. It turns out that, on inspection, a major part of human linguistic competence—much more than previously believed— involves the mastery of all kinds of routine formulas, fixed and semi-fixed expressions, idioms, and frozen collocations. Indeed one of the distinguishing characteristics of native speakers of a language is their control of these semi-fixed expressions as fluent units with somewhat unpredictable meanings (e.g., I wouldn't *put it past* him; He's *getting to me* these days; *Hang in there*; That won't *go down well* with the boss; She *put me up to* it; and so on; Pawley & Syder, 1983).

The theoretical problem for algebraic approaches such as generative grammar is what to do with these fixed and semi-fixed complex structures. They are complex and somewhat regular, and so they would seem to be a part of the core grammar to be generated by rules. But as fixed expressions, they would seem to be a part of the periphery to be memorized like words. For example, consider the “-er” construction:

The bigger they are, the nicer they are.
The more you try, the worse it gets.
The faster I run, the behinder I get.

This construction is clearly noncanonical, as both of the two clauses are difficult to classify using classical grammatical techniques. But there are obvious canonical elements as well. Also, consider such things as:

This hair dryer needs fixing.
My house needs painting.

Note in this case that although *hairdryer* and *house* are the subjects of the sentences they are the logical objects of the predicates *fixing* and *painting* (they are the objects to be acted on), which are expressed as participles. It turns out that virtually no other verbs besides *need* work in this construction of the English language (some people will accept the semantically similar verbs *re-*

quire and *want*). It would thus seem that this construction, while basically canonical, is at the same time best described in lexically specific terms.

The impossibility of making a clear distinction between the core and the periphery of linguistic structure suggests that language structure emerges from language use, and that a community of speakers may conventionalize from their language use all kinds of linguistic structures—from the more concrete to the more abstract, from the more regular to the more idiomatic, with all kinds of mixed constructions as well. If we take these points seriously, an important question for acquisition researchers becomes: if many, perhaps most, of the structures of a language (as embodied in various kinds of semifixed expressions, irregular formations, schematic idioms, and the like) may be acquired through normal processes of learning and abstraction—as they are in all theoretical accounts—then why cannot the more regular and canonical aspects of a language be acquired in this same straightforward way? Indeed, in the current approach, we will assume that all linguistic structures are acquired in the same basic way.

EARLY ONTOGENY

It is widely believed that young children begin their linguistic careers by learning words, which they then combine together by means of rules. But this is not exactly accurate. Children hear and attempt to learn whole adult utterances, instantiating various types of constructions used for various communicative purposes. Sometimes children only learn parts of these complex wholes, and so their first productions may correspond to adult words. But these are always packaged in conventional intonational patterns indicating such things as requests, comments, or questions—which correspond to the general communicative functions for which adults use more complex constructions. From the beginning, children are attempting to learn not isolated words, but rather communicatively effective speech forms corresponding to whole adult constructions. Learning words—which will not be a topic of this chapter (see Waxman & Lidz, Chapter 7, this *Handbook*, this volume)—is essentially a process of extracting elements (including their function) from these larger wholes.

In this section, our account of the early ontogeny of language focuses first, on the language children hear;

then on their early holophrases (single words or phrases that have a larger, holistic meaning); then on their early word combinations, pivot schemas, and item-based constructions; and finally on the linguistic devices they use early in development for marking basic syntactic roles such as agent and patient.

The Language Children Hear

To understand how children acquire a language, we must know something about the language they hear—both in terms of specific utterances and in terms of the constructions these instantiate. Surprisingly, very few studies have attempted to document the full range of linguistic expressions and constructions that children hear in their daily lives. The majority of studies of child-directed-speech (CDS) have focused on specific aspects (for classic studies, see the papers in Galloway & Richards, 1994; Snow & Ferguson, 1977).

Cameron-Faulkner, Lieven, and Tomasello (2003) examined all the CDS of 12 English-speaking mothers during samples of their linguistic interactions with their 2- to 3-year-old children. They first categorized each of the mothers' utterances in terms of very general constructional categories, resulting in the percentages displayed in Table 6.1 (which also includes a comparable analysis of the data of Wells, 1983, whose children were

sampled in a wider variety of activities). The overall findings were that:

- Children heard an estimated 5,000 to 7,000 utterances per day.
- Between one-quarter and one-third of these were questions.
- More than 20% of these were not full adult sentences, but instead were some kind of fragment (most often a noun phrase or prepositional phrase).
- About one-quarter of these were imperatives and utterances structured by the copula.
- Only about 15% of these had the canonical English SVO form (i.e., transitive utterances of various kinds) supposedly characteristic of the English language; and over 80% of the SVOs had a pronoun subject.

In a second analysis, these investigators looked at the specific words and phrases with which mothers initiated utterances in each of these general construction types, including such item-based frames as *Are you . . . , I'll . . . , It's . . . , Can you . . . , Here's . . . , Let's . . . , Look at . . . , What did . . . ,* and so on. It was found that more than half of all maternal utterances began with one of 52 highly frequent item-based frames (i.e., frames used more than an estimated 40 times per day for more than half the children), mostly consisting of 2 words or morphemes. Further, using the same kind of analysis, more than 65% of all of the mothers' utterances began with one of just 156 item-based frames. And perhaps most surprising, approximately 45% of all maternal utterances began with one of just 17 lexemes: *What* (8.6%), *That* (5.3%), *It* (4.2%), *You* (3.1%), *Are/Aren't* (3.0%), *Do/Does/Did/Don't* (2.9%), *I* (2.9%), *Is* (2.3%), *Shall* (2.1%), *A* (1.7%), *Can/Can't* (1.7%), *Where* (1.6%), *There* (1.5%), *Who* (1.4%), *Come* (1.0%), *Look* (1.0%), and *Let's* (1.0%). Interestingly, the children used many of these same item-based frames in their speech, in some cases at a rate that correlated highly with their own mother's frequency of use.

The language-learning child is thus faced with a prodigious task: acquiring simultaneously many dozens and dozens (perhaps hundreds) of constructions based on input in which all of the many different construction types are semi-randomly strewn. On the other hand, the task is made a bit easier by the fact that many of, indeed the majority of, the utterances children hear are grounded in highly repetitive item-based frames that

they experience dozens, in some cases hundreds, of times every day. Indeed, many of the more complex utterances children hear have as a major constituent some well-practiced item-based frame. This means that the more linguistically creative utterances that children hear every day constitute only a small minority of their linguistic experience, and even these quite often rest on the foundation of many highly frequent and relatively simple item-based utterance frames.

Earliest Language

Most Western, middle-class children begin producing conventional linguistic symbols in utterances in the months following their first birthdays. By the time they begin doing this, they typically have been communicating with other people gesturally and vocally for some months. Children's first linguistic expressions are learned and used in the context of these prior forms of nonlinguistic communication and for the same basic motives—declarative (statements) and imperative (requests)—and children soon learn to ask things interrogatively (questions) as well. There is typically a distinctive intonational pattern for each of these three speech act types. Children's first declarative utterances are sometimes about shared, topical referents and sometimes aimed at focusing the listener's attention on something new (typically assessed only from their own egocentric point of view; Greenfield & Smith, 1976).

At this early age, the communicative functions of children's early single-word utterances are an integral aspect of their reality for the child, and initially these functions (e.g., imperative or interrogative) may not be well differentiated from the more referential aspects of the utterance (Ninio, 1992, 1993). That is to say, children's early one-word utterances may be thought of as *holophrases* that convey a holistic, undifferentiated communicative intention, most often the same communicative intention as that of the adult expression from which it was learned (Barrett, 1982; Ninio, 1992). Many of children's early holophrases are relatively idiosyncratic and their uses can change and evolve over time in a somewhat unstable manner. Some holophrases, however, are a bit more conventional and stable. Children speaking all the languages of the world use their holophrases to do such things as:

- Request or indicate the existence of objects (e.g., by naming them with a requestive or neutral intonation).

- Request or describe the recurrence of objects or events (e.g., *More*, *Again*, *Another*).
- Request or describe dynamic events involving objects (e.g., as described by *Up*, *Down*, *On*, *Off*, *In*, *Out*, *Open*, *Close*).
- Request or describe the actions of people (e.g., *Eat*, *Kick*, *Ride*, *Draw*).
- Comment on the location of objects and people (e.g., *Here*, *Outside*).
- Ask some basic questions (e.g., *Whats-that?* or *Where-go?*).
- Attribute a property to an object (e.g., *Pretty* or *Wet*).
- Use performatives to mark specific social events and situations (e.g., *Hi*, *Bye*, *Thank you*, and *No*).

An important issue for later language development is what parts of adult expressions children choose for their initial holophrases. The answer lies in the specific language they are learning and the kinds of discourse in which they participate with adults, including the perceptual salience of particular words and phrases in adults' speech (Slobin, 1985). Thus, in English, most beginning language learners acquire so-called relational words such as *more*, *gone*, *up*, *down*, *on*, and *off*, presumably because adults use these words in salient ways to talk about salient events (Bloom, Tinker, & Margolis, 1993; McCune, 1992). Many of these words are verb particles in adult English, and so the child at some point must learn to talk about the same events with phrasal verbs such as *pick up*, *get down*, *put on*, *take off*, and so forth. In Korean and Mandarin Chinese, on the other hand, children learn fully adult verbs from the onset of language development because this is what is most salient in adult speech to them (Gopnik & Choi, 1995; Tardif, 1996). When they begin with an adult verb as a holophrase, children must then at some point learn, at least for some discourse purposes, to fill in linguistically the nominal participants involved in the scene (e.g., "Take-off *shirt!*"). Children in all languages also learn object labels for some events, for example, "Bike!" as a request to ride a bicycle or "Birdie" as a comment on a passing flight, which means that they still need to learn to linguistically express the activity involved (e.g., "Ride bike!" or "See birdie").

In addition, most children begin language acquisition by learning some unparsed adult expressions as holophrases—such things as "I-wanna-do-it," "Lemme-see," and "Where-the-bottle." The prevalence of this

pattern in the early combinatorial speech of English-speaking children has been documented by Pine and Lieven (1993), who found that almost all children have at least some of these so-called frozen phrases in their early speech. This is especially true of some children (especially later-born children who observe siblings; Barton & Tomasello, 1994; Bates, Bretherton, & Snyder, 1988). In these cases, there is different syntactic work to do if the child is to extract productive linguistic elements that can be used appropriately in other utterances, in other linguistic contexts, in the future. For this, the child must engage in a process of segmentation, with regard not only to the speech stream but also to the communicative intentions involved—so as to determine which components of the speech stream go with which components of the underlying communicative intention. Functionally speaking, then, children's early one-unit utterances are entire semantic-pragmatic packages—holophrastic expressions—that express a single relatively coherent, yet undifferentiated, communicative intention. Why children begin with only one-unit expressions—either individual words or holistic expressions—is not known at this time. But it is presumably the case that in many instances they initially only attend to limited parts of adult utterances, or can only process one linguistic unit at a time.

Item-Based Constructions

Children produce their earliest multiword utterances to talk about many of the same kinds of things they talked about previously with their holophrases—since indeed many, though not all, early multiword constructions may be traced back to earlier holophrases. From the point of view of linguistic form, the utterance-level constructions underlying these multiword utterances come in three types: word combinations, pivot schemas, and item-based constructions.

Word Combinations

Beginning at around 18 months of age, many children combine two words or holophrases in situations in which they both are relevant—with both words having roughly equivalent status. For example, a child has learned to name a ball and a table and then spies a ball on a table and says, “Ball table.” Utterances of this type include both “successive single-word utterances” (with a pause between them; Bloom, 1973) and “word combinations”

or “expressions” (under a single intonational contour). The defining feature of word combinations or expressions is that they partition the experiential scene into multiple symbolizable units—in a way that holophrases obviously (by definition) do not—and they are totally concrete in the sense that they are comprised only of concrete pieces of language, not categories.

Pivot Schemas

Beginning at around this same age, however, many of children's multiword productions show a more systematic pattern. Often there is one word or phrase that seems to structure the utterance in the sense that it determines the speech act function of the utterance as a whole (often with help from an intonational contour), with the other linguistic item(s) simply filling in variable slot(s)—the first type of linguistic abstraction. Thus, in many of these early utterances, one event-word is used with a wide variety of object labels (e.g., “More milk,” “More grapes,” “More juice”) or, more rarely, something like a pronoun or other general expression is the constant element (e.g., *I* _____ or _____ *it* or even *It's* _____ or *Where's* _____). Following Braine (1963), we may call these pivot schemas.

Braine (1976) established that this is a widespread and productive strategy for children acquiring many of the world's languages. And Tomasello, Akhtar, Dodson, and Rekau (1997) found that 22-month-old children who were taught a novel name for an object knew immediately how to combine this novel name with other pivot-type words already in their vocabulary. That is, when taught a novel object label as a single word utterance (e.g., “Look! A wug!”), children were able to use that new object label in combination with their existing pivot-type words in utterances such as “Wug gone” or “More wug.” This productivity suggests that young children can create linguistic categories at this young age, specifically categories corresponding to the types of linguistic items that can play particular roles in specific pivot schemas (e.g., “things that are gone,” “things I want more of”). However, these same children do not make generalizations across the various pivot schemas. Thus, Tomasello et al. (1997) also found that when taught a novel verb as a single-word utterance for a novel scene (e.g., “Look! Meeking!” or “Look what she's doing to it. That's called meeking.”), these same 22-month-old children were not then able to say creative things like “Ernie meeking!”—because they had never heard how *meeking* structured a pivot schema with an actor. Each pivot schema is thus at

this point a constructional island, and so at this stage of development, children do not have an overarching grammar of their language.

Item-Based Constructions

Not only are pivot schemas organized locally, but even within themselves they do not have syntax; that is, “Gone juice” does not mean something different from “Juice gone” (and there is no other marking to indicate syntactic role for elements in pivot schemas). The consistent ordering patterns in many pivot schemas are very likely direct reproductions of the ordering patterns children have heard most often in adult speech, with no communicative significance. This means that although young children are using their early pivot schemas to partition scenes conceptually with different words, they are not using syntactic symbols—such as word order or case marking—to indicate the different roles being played by different participants in that scene.

On the other hand, item-based constructions go beyond pivot schemas in having syntactic marking as an integral part of the construction. The evidence that children have, from fairly early in development, such syntactically marked item-based constructions is solid. Most important are a number of comprehension experiments in which children barely 2 years of age respond appropriately to requests that they “Make the bunny push the horse” (reversible transitives) that depend crucially and exclusively on a knowledge of canonical English word order (e.g., Bates et al., 1984; DeVilliers & DeVilliers, 1973; Roberts, 1983). Successful comprehension of word order with familiar verbs is found at even younger ages if preferential looking techniques are used (Hirsh-Pasek & Golinkoff, 1991, 1996). In production as well, many children around their second birthdays are able to produce transitive utterances with familiar verbs that respect canonical English word order marking (Tomasello, 2000).

However, there is abundant evidence from many studies of both comprehension and production that the syntactic marking in these item-based constructions is still verb specific, depending on how a child has heard a particular verb being used. For example, Tomasello (1992) found that almost all of his daughter’s early multiword utterances during her second year of life revolved around the specific verbs or predicative terms involved. The lexically specific pattern of this phase of combinatorial speech was evident in the patterns of participant roles with which individual verbs were used. Thus, during exactly the same

developmental period, some verbs were used in only one type of construction and that construction was quite simple (e.g., *Cut _____*), whereas other verbs were used in more complex frames of several different types (e.g., *Draw _____*, *Draw _____ on _____*, *Draw _____ for _____*, *_____ draw on _____*). Interestingly and importantly, within any given verb’s development, there was great continuity such that new uses of a given verb almost always replicated previous uses and then made one small addition or modification (e.g., the marking of tense or the adding of a new argument). In general, by far the best predictor of this child’s use of a given verb on a given day was not her use of other verbs on that same day, but rather her use of that same verb on immediately preceding days. (See Lieven, Pine, & Baldwin, 1997; Pine & Lieven, 1993; Pine, Lieven, & Rowland, 1998, for some very similar results in a sample of 12 English-speaking children from 1 to 3 years of age. For additional findings of this same type in other languages, see Allen, 1996, for Inuktitut; Behrens, 1998, for Dutch; Berman, 1982, for Hebrew; Gathercole, Sebastián, & Soto, 1999, for Spanish; Pizutto & Caselli, 1992, for Italian; Rubino & Pine, 1998, for Portuguese; Serrat, 1997, for Catalan; and Stoll, 1998, for Russian.)

Similarly, in experimental studies, when children who are themselves producing many transitive utterances are taught a new verb in any one of many different constructions, they mostly cannot transfer their knowledge of word order from their existing item-based constructions to this new item until after their third birthdays—and this finding holds for comprehension as well (Tomasello, 2000). These findings would seem to indicate that young children’s early syntactic marking—at least with English word order—is only local, learned for different verbs on a one-by-one basis (see next section for a review of these studies). What little experimental evidence we have from nonce verb studies of case-marking languages (e.g., Berman, 1993; Wittek & Tomasello, 2005) is in general accord with this developmental pattern.

The main point is that unlike in pivot schemas, in item-based constructions children use syntactic symbols such as morphology, adpositions, and word order to syntactically mark the roles participants are playing in these events, including generalized slots that include whole categories of entities as participants. But all of this is done on an item-specific basis; that is, the child does not generalize across scenes to syntactically mark similar participant roles in similar ways without having

heard those participants used and marked in adult discourse for each verb specifically. This limited generality is presumably due to the difficulty of categorizing or schematizing entire utterances, including reference to both the event and the participant roles involved, into more abstract constructions—especially given the many different kinds of utterances children hear and must sort through. Early syntactic competence is therefore best characterized as a semi-structured inventory of relatively independent verb island constructions that pair a scene of experience and an item-based construction, with very few structural relationships among these constructional islands.

Processes of Schematization

From a usage-based perspective, word combinations, pivot schemas, and item-based constructions are things that children construct out of the language they hear around them using general cognitive and social-cognitive skills. It is thus important to establish that, at the necessary points in development, children have the skills they need to comprehend, learn, and produce each of these three types of early constructions.

First, to produce a word combination under a single intonation contour, children must be able to create a multiple-step procedure toward a single goal, assembled conceptually ahead of time (what Piaget, 1952, called “mental combinations”). They are able to do this in non-linguistic behavior quite readily, from about 14 to 18 months of age in their own problem solving, and, moreover, they are also able to copy such sequences from the behavior of other persons at around this same age. Thus, Bauer (1996) found that 14-month-old infants were quite skillful at imitatively learning both 2- and 3-step action sequences from adults—mostly involving the constructing of complex toy objects (e.g., a toy bell) that they saw adults assembling. Children were sensitive to the order of the steps involved as well. These would seem to be the right skills at the right time for constructing word combinations.

Second, the process by which pivot schemas are formed—as abstractions across individual word combinations—is presumably very similar to the way 1-year-olds form other kinds of sensory-motor schemas, including those learned through observation of others’ behavior: what may be called schematization. Thus, Piaget (1952) reports that when infants repeatedly enact the same action on different objects, they form a sensory-motor schema consisting of (a) what is general in all of the various actions and (b) a kind of slot for the

variable component. As one example, Brown and Kane (1988) taught 2-year-old children to use a certain kind of action with a particular object (e.g., pull a stick) and then gave them transfer problems in which it was possible for them to use the same action but with a different object creatively (e.g., they learned to pull stick, pull rope, pull towel). Their skill at doing this demonstrates exactly the kind of cognitive ability needed to create a pivot schema across different utterances so as to yield something like *Pull X*. Ultimately, if the child forms a generalized action or event schema with a variable slot for some class of items (e.g., *Throw X*), that slot and class of items are defined by their role in the schema, which is why Nelson (1985) calls them slot-filler categories. This means that in the case of pivot schemas such as *Throw X*, *X gone*, and *Want X*, the slot could be thought of as something like “throwable things,” “things that are gone,” “things I want more of,” and so forth. This primacy of the schema in defining the slot leads to the kinds of coercion evidenced in creative uses of language in which an item is used in a schema that requires us to interpret it in an unusual way. For example, under communicative pressure, a child might say “I’m juicing it” as she pours juice onto something, or “Where’s-the swimming?” as she looks for a picture of a swimming activity in a book. This process of “functional coercion” is perhaps the major source of syntactic creativity in the language of 1- and 2-year-old children.

Third and finally, it is not clear how young children learn about syntactically marking their utterance-level constructions, so creating item-based constructions. Essentially what they need to learn is that whereas some linguistic symbols are used for referring and predicated things about the world, others (including word order) are used for more grammatical functions. These functions are many and various but they all share the property that they are parasitic on the symbols that actually carry the load of referring and predicated. Thus, with special reference to utterance-level constructions, an accusative case marker (or an immediate postverbal position) can only function symbolically if there is some referential expression to indicate the entity that is the object of some action; we may thus call syntactic markers second-order symbols (Tomasello, 1992). Although children do engage in nonlinguistic activities that have clear and generalized roles, there is really nothing in nonlinguistic activities that corresponds to such second-order symbols. (The closest might be the designation of participant roles in some forms of pretend play—but that is typically a much later developmental achievement.)

Children presumably learn to deal with such symbols when they hear such things as, in English, *X is pushing Y* and then on another occasion *Y is pushing X*, each paired with its own real world counterpart. From this, they begin to see that the verb island construction involving *push* is structured so that the “pusher” is in the preverbal position and “pushee” is in the postverbal position regardless of the specific identity of that participant.

Marking Syntactic Roles

From a psycholinguistic point of view, linguistic constructions are comprised of four and only four types of symbolic elements: words, morphological markers on words, word order, and intonation/prosody (Bates & MacWhinney, 1982). Of special importance for utterance-level constructions are the syntactic devices used for marking the participant roles (typically expressed as noun phrases, NPs) to indicate the basic “who-did-what-to-whom” of the utterance, what are sometimes called agent-patient relations. The two major devices that languages use for this purpose are (1) word order (mainly of NPs) and (2) morphological marking (casemarking on NPs and agreement marking between NPs and verb).

Word Order

In their spontaneous speech, young English-speaking children use canonical word order for most of their verbs, including transitive verbs, from very early in development (Bloom, 1992; Braine, 1971; Brown, 1973). And as reported, in comprehension tasks, children as young as 2 years of age respond appropriately to requests that they “Make the doggie bite the cat” (reversible transitives) that depend crucially and exclusively on a knowledge of canonical English word order (e.g., DeVilliers & DeVilliers, 1973). But to really discover the nature of children’s underlying linguistic representations, we need to examine utterances we know children are producing creatively; this means overgeneralization errors (which they could not have heard from adults) and the use of novel words introduced in experiments.

First, children’s overgeneralization errors—indicating a more abstract understanding of word order and constructional patterns—include such things as *She falled me down* or *Don’t giggle me* in which the child uses intransitive verbs in the SVO transitive frame productively. Pinker (1989) compiled examples from many sources and found that children produce a number of such overgeneralizations, but few before about 3 years of age.

Second, production experiments focused on the marking of agent-patient relations by word order in English typically introduce young children to a novel verb in a syntactic construction such as an intransitive or passive and then see if they can later use that verb in the canonical SVO transitive construction. Cues to syntactic roles other than word order (e.g., animacy of the S and O participants, use of case-marked pronouns) are carefully controlled and/or monitored. Experiments of this type have clearly demonstrated that by 3½ or 4 years of age most English-speaking children can readily assimilate novel verbs to an abstract SVO schema that they bring to the experiment. For example, Maratsos, Gudeman, Gerard-Ngo, and DeHart (1987) taught children from 4½ to 5½ years of age the novel verb *fud* for a novel transitive action (human operating a machine that transformed the shape of Play-Doh). Children were introduced to the novel verb in a series of intransitive sentence frames such as “The dough finally fuddled,” “It won’t fud,” and “The dough’s fudding in the machine.” Children were then prompted with questions such as “What are you doing?” (which encourages a transitive response such as “I’m fudding the dough”). The general finding was that the vast majority of children from 4½ to 5½ years of age could produce a canonical transitive SVO utterance with the novel verb, even though they had never heard it used in that construction.

But the same is not true for younger children. Over a dozen studies similar to that of Maratsos et al. (1987) have been done with 2- and 3-year-olds, and they are generally not productive (see Tomasello 2000, for a review). When findings across all ages are compiled and quantitatively compared, we see a continuous developmental progression in which children gradually become more productive with novel verbs in the transitive SVO construction during their third and fourth years of life and beyond, evidencing a growing understanding of the working of canonical English word order (see Figure 6.1).

Akhtar (1999) used a different novel verb methodology to investigate young children’s knowledge of English word-order conventions. An adult modeled novel verbs for novel transitive events for young children at 2;8, 3;6, and 4;4 years of age. One verb was modeled in canonical English SVO order, as in *Ernie meeking the car*, whereas two others were in noncanonical orders, either SOV (*Ernie the cow tamming*) or VSO (*Gopping Ernie the cow*). Children were then encouraged to use the novel verbs with neutral questions such as *What’s happening?* Almost all of the children at all three ages produced exclusively SVO utterances with the novel

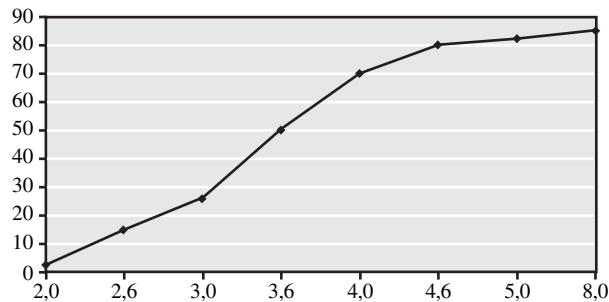

Figure 6.1 Percentage of children who produce transitive utterances using novel verbs in different studies. Adapted from “Do Young Children Have Adult Syntactic Competence?” by M. Tomasello, 2000, *Cognition*, 74, pp. 209–253. Reprinted with permission.

verb when that is what they heard. However, when they heard one of the noncanonical SOV or VSO forms, children behaved differently at different ages. In general, the older children used their verb-general knowledge of English transitivity to correct the noncanonical uses of the novel verbs to canonical SVO form. The younger children, in contrast, much more often matched the ordering patterns they had heard with the novel verb, no matter how bizarre that pattern sounded to adult ears. Abbot-Smith, Lieven, and Tomasello (2001) have recently extended this methodology to younger ages (children at 2;4, using intransitives) and found that even fewer children (less than half as many as Akhtar’s youngest children) corrected the adult’s strange word order utterances. The results of these two studies combined are depicted in Figure 6.2.

Perhaps surprisingly, young children also fail to show a verb-general understanding of canonical English word order in comprehension studies using novel verbs in which they must act out (with toys) a scene indicated by an SVO utterance. Thus, Akhtar and Tomasello (1997) exposed young children to many models of *This is called dacking* used to describe a canonical transitive action. They then, using novel characters, asked the children to *Make Cookie Monster dack Big Bird*. All 10 of the children 3;8 were excellent in this task, whereas only 3 of the 10 children at 2;9 were above chance in this task—even though most did well on a control task using familiar verbs. In a second type of comprehension test, children just under 3 years of age first learned to act out a novel action on a novel apparatus with two toy characters, and only then (their first introduction to the novel verb) did the adult hand them two new characters and request *Can you make X meek Y* (while pushing the ap-

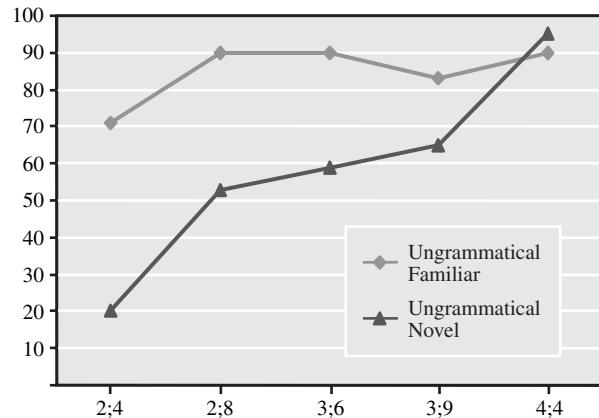

Figure 6.2 Percentage of utterances in which children “corrected” weird word order to canonical English SVO with familiar and unfamiliar verbs in two studies. *Source:* From “Acquiring Basic Word Order: Evidence for Data-Driven Learning of Syntactic Structure,” by N. Akhtar, 1999, *Journal of Child Language*, 26, pp. 339–356. Reprinted with permission; “What Children Do and Do Not Do with Ungrammatical Word Orders,” by K. Abbot-Smith, E. Lieven, and M. Tomasello, 2001, *Cognitive Development*, 16, pp. 1–14. Reprinted with permission.

paratus in front of them)? In this case, children’s only exposure to the novel verb was in a very natural transitive sentence frame used for an action they already knew how to perform. Since every child knew the names of the novel characters and on every trial attempted to make one of them act on the other in the appropriate way, the only question was which character should play which role. These under-3-year-old children were, as a group, at chance in this task, with only 3 of the 12 children performing above chance as individuals. Similar results, using a different comprehension methodology (a token placement task), were found by Bridges (1984). Using a comprehension methodology in which children had to point to the agent of an utterance—the main clue to which was word order, Fisher (1996) found positive results for children averaging 3;6 years of age (and Fisher, 2002, found somewhat weaker evidence for the same effect in children at 2;6).

Another technique used to assess children’s comprehension of various linguistic items and structures is so-called preferential looking. In this technique, a child is shown two displays (often on two television screens) and hears a single utterance (through a centrally located loudspeaker) that describes only one of the pictures felicitously. The question is which picture she will look at longer. The relevant studies are those using novel or very

low frequency verbs, so we know that children have had no previous experience with them. In almost all of these studies, the comparison is between transitives and intransitives. Thus, Naigles (1990) found that when they hear canonical SVO utterances English-speaking children from 2;1 prefer to look at one participant doing something to another (causative meaning) rather than two participants carrying out synchronous independent activities. This study shows that in the preferential looking paradigm young 2-year-old children know enough about the simple transitive construction to know that it goes with asymmetrical activities (one participant acting on another) rather than symmetrical activities (two participants engaging in the same activity simultaneously). What it does *not* show, as is sometimes claimed, is an understanding of word order. That is, it does not show that young children can connect the preverbal position with the agent (or subject) and the postverbal position with the patient (or object) in a transitive utterance—which would be required for a full-blown representation of the transitive construction, and which is indeed required of children in both act-out comprehension tasks and novel verb production tasks.¹

The overall conclusion is thus that in both production and comprehension the majority of English-speaking children do not fully understand word order as a verb-general, productive syntactic device for marking agents and patients (subjects and objects) until after 3 years of age (although some minority of children may understand it before). In some cases, even the presence of animacy cues (agents were animate, patients inanimate) does not help. But, of course, most English-speaking children are hearing SVO utterances with one or more case-marked pronouns (*I-me, he-him, they-them, we-us*, etc.), and so we now turn to an investigation of their understanding of case marking—which is much more important in some other languages than it is in English.

Case and Agreement

In the 1960s and 1970s, a number of investigators speculated that word order should be easier than case and

¹The only preferential looking study that attempted to examine this knowledge is by Fisher (2000). However, the sentences she gave children (ages 1;9 and 2;2) had prepositional phrases that provided additional information (e.g., *The duck is gorping the bunny up and down*). Thus, the child merely had to interpret *bunny up and down* to prefer the picture in which the bunny was indeed moving up and down.

agreement for children to learn as a syntactic device because canonical ordering is so fundamental to so many sensory-motor and cognitive activities (Braine, 1976; Bruner, 1975; McNeill, 1966; Pinker, 1981). However, cross-linguistic research has since exploded this word order myth (Weist, 1983). That is, cross-linguistic research has demonstrated that in their spontaneous speech, children learning many different languages—regardless of whether their language relies mainly on word order, case marking, or some combination of both—generally conform to adult usage and appear to mark agent-patient relations equally early and appropriately. Indeed, on the basis of his review, Slobin (1982) concluded that children learning languages that mark agent-patient relations clearly and simply with morphological (case) markers, such as Turkish, comprehend agent-patient syntax earlier than children learning word order languages such as English. In support of his argument, Slobin cited the fact that some children learning case marking languages overgeneralize case markers in ways indicating productive control while they are still only 2 years old (Slobin, 1982, 1985).

In comprehension experiments, children learning morphologically rich languages, in which word order plays only a minor role in indicating agent-patient relations, comprehend the syntactic marking of agent-patient relations as early or earlier than children learning word order languages such as English. Representative studies are reported by Slobin and Bever (1982) for Turkish, Hakuta (1982) for Japanese, and Weist (1983) for Polish (see Slobin, 1982, and Bates & MacWhinney, 1989, for reviews). But it should be noted that in neither comprehension nor production do we have the kind of nonce word studies that could provide the most definitive evidence of children's productive knowledge of case marking. The few nonce verb studies we have of case-marking languages (e.g., Berman, 1993; Wittek & Tomasello, 2005) show a very slow and gradual developmental pattern of increasing productivity, just as with word order marking in English and similar languages.

For English, most of the discussion of case marking has centered around pronoun case errors, such as *me do it* and *him going*. About 50% of English-speaking children make such errors, most typically in the 2- to 4-year age range, with much variability across children. The most robust phenomenon is that children often substitute accusative forms for nominative forms ("Me going") but very seldom do the reverse ("Billy hit I"). Rispoli (1994, 1998) notes that the particular pronouns that

English-speaking children overgeneralize proportionally most often are the objective forms *me* and *her* (and not the subjective forms *I* and *she*). Rispoli attributes these facts to the morphophonetic structure of the English personal pronoun paradigm:

I	she	he	they
me	her	him	them
my	her	his	their

It is easily seen that *he-him-his* and *they-them-their* each has a common phonetic core (*h-* and *th-*, respectively) whereas *I-me-my* and *she-her-her* do not. And indeed, the errors that are made most often are ones in which children in these latter two cases use the forms that have a common initial phoneme (*me-my* and *her-her*) to substitute for the odd-man-out (*I* and *she*), with the *her-for-she* error having the overall highest rate (because of the fact, according to Rispoli, that *her* occurs as both the objective and genitive form; the so-called double-cell effect). The overall idea is thus that children are making retrieval errors based on both semantic and phonological factors.

Currently, there is no widely accepted explanation of children's pronoun case errors in English, and it is likely that several different factors play a role. Of most importance to resolve the issue in a theoretically interesting way is cross-linguistic research enabling the examination of pronoun paradigms with different morphophonemic and syntactic properties.

Cue Coalition and Competition

In all languages, there are multiple potential cues indicating agent-patient relations. For example, in many languages, both word order and case marking are at least potentially available, even though one of them might most typically be used for other functions (e.g., in many morphologically rich languages, word order is used primarily for pragmatic functions such as topicalization). In addition, in attempting to comprehend adult utterances, children might also attend to information that is not directly encoded in the language; for example, they may use animacy to infer that in an utterance containing the lexical items *man*, *ball*, and *kick*, the most likely interpretation is that the man kicked the ball, regardless of how those items are syntactically combined.

In an extensive investigation of language acquisition in a number of different languages, Slobin (reviewed in 1982) identified some of the different comprehension strategies that children use to establish agent-patient relations, depending on the types of problems their par-

ticular language presents to them. A central discovery of this research, as noted, was that children can more easily master grammatical forms expressed in "local cues" such as bound morphology as opposed to more distributed cues such as word order and some forms of agreement. This accounts for the fact that Turkish-speaking children master the expression of agent-patient relations at a significantly earlier age than do English-speaking children. In addition, Turkish is especially "child friendly," even among languages that rely heavily on local morphological cues. Slobin (1982) outlines 12 reasons why Turkish agent-patient relations are relatively easy to learn. An adaptation of that list (focusing on nominal morphology) follows. Turkish nominal grammatical morphemes are:

- Postposed, syllabic, and stressed, which makes them perceptually more *salient*.
- Obligatory and employ almost perfect one-to-one mapping of form to function (no fusional morphemes or homophones), which makes them more *predictable*.
- Bound to the noun, rather than freestanding, which makes them more *local*.
- Invariably regular across different nominals and pronominals, which makes them readily *generalizable*.

All of these factors coalesce to make Turkish agent-patient relations especially easy to learn, and their identification is a major step in discovering the basic processes of language acquisition that are employed by children in general.

A central methodological problem, however, is that in natural languages many of these cues go together naturally, and so it is difficult to evaluate their contributions separately. Therefore, Bates and MacWhinney (summarized in 1989) conducted an extensive set of experimental investigations of the cues children use to comprehend agent-patient relations in a number of different languages. The basic paradigm is to ask children to act out utterances using toy animals, with agent-patient relations indicated in different ways—sometimes in semi-grammatical utterances with conflicting cues. For example, an English-speaking child might be presented with the utterance "The spoon kicked the horse." In this case, the cue of word order is put in competition with the most likely real-world scenario in which animate beings more often kick inanimate things than the reverse. From an early age, young English-speaking children make the spoon "kick" the horse, which simply shows the power

of word order in English. Interestingly, when presented with an equivalent utterance, Italian-speaking children ignore word order and make the horse kick the spoon. This is because word order is quite variable in Italian, and so, since there is no case marking (and in this example agreement is no help because both the horse and the spoon are third-person singular), semantic plausibility is the most reliable cue available. German-speaking children gradually learn to ignore both word order and semantic plausibility (animacy) and simply look for nominative and accusative marking on the horse and the spoon (Lindner, 2003).

Constructing Lexical Categories

Syntactic roles such as agent and patient, or subject and object, represent syntagmatic categories defined by the role of the element in the larger constructional whole. As utterance-level constructions gradually become more abstract, therefore, these categories become more abstract with them. Another important part of the process of grammatical development is the construction of paradigmatic categories such as noun and verb. Unlike syntactic roles, paradigmatic categories are not explicitly marked in language. That is, whereas such things as agent/subject are symbolically indicated by word order or grammatical morphology in the construction, nouns and verbs have no explicit marking (despite the fact that they often have some morphology serving other functions, e.g., plural markers on nouns, that can be used to identify them). Consequently, the category cannot be organized around any specific linguistic symbol, but can only be based on commonalities in the way the members of the category function (i.e., on distribution). Thus, *pencil* and *pen* occur in many of the same linguistic contexts in utterances—that is, do many of the same kinds of things in combining with articles to make reference to an object, in indicating subjects and objects as syntactic roles, and so on—and so a language user will come to form a category containing these and similarly behaving words in it.

The prototypical paradigmatic linguistic categories, and the only ones that are even candidates for universal status, are nouns and verbs. The classic notional definitions—nouns indicate person, place, or thing, and verbs indicate actions—clearly do not hold, as many nouns indicate actions or events (e.g., *party*, *discussion*) and many verbs indicate nonactional state's affairs that are sometime very difficult to distinguish from things indi-

cated by adjectives (e.g., *be noisy*, *feel good*, which in different languages may be indicated by either a verb or an adjective). On the other hand, Maratsos (1982) points out that both nouns and verbs have characteristic small-scale combinatorial properties; for example, nouns occur with determiners and plural markers and verbs occur with tense and aspect markers. Although these can be used to recognize instances of the categories once they are formed, obviously the core notions underlying nouns and verbs are cognitively and communicatively much deeper. Evidence for this is the simple fact that some of the most prototypical nominals do not have the same small-scale combinatorial properties as others; that is, pronouns and proper names do not occur with determiners or plural markers.

Langacker (1987b) provides a functionally based account of nouns and verbs that goes much deeper than both simplistic notional definitions and purely formal properties. Langacker stresses that nouns and verbs are used not to refer to specific kinds of things but rather to invite the listener to construe something in a particular way in a particular communicative context. Thus, we may refer to the very same experience as either “exploding” or “an explosion,” depending on our communicative purposes. In general, nouns are used to construe experiences as bounded entities (like an explosion), whereas verbs are used to construe experiences as processes (like exploding). Hopper and Thompson (1984) contend further that the discourse functions of reference and predication provide the communicative reason for construing something as either a bounded entity, to which one may refer with a noun, or a process that one may predicate with a verb. Importantly, it is these communicative functions that explain why nouns are associated with such things as determiners, whose primary function is to help the listener locate a referent in actual or conceptual space; and verbs are associated with such things as tense markers, whose primary function is to help the listener locate a process in actual or conceptual time (Langacker, 1991). After an individual understands the functional basis of nouns and verbs, formal features such as determiners and tense markers may be used to identify further instances.

From a functional point of view, Bates and MacWhinney (1979, 1982) propose that early nouns are anchored in the concept of a concrete object and early verbs are anchored in the concept of concrete action—and these are generalized to other referents only later. The problem is that young children use adult nouns from

quite early in development to refer to all kinds of nonobject entities such as *breakfast, kitchen, kiss, lunch, light, park, doctor, night, and party*, and they use many of their verbs to predicate nonactional states of affairs (e.g., *like, feel, want, stay, be*; Nelson, Hampson, & Shaw, 1993). Also problematic for accounts such as these, grounded in the reference of terms, is that early in development young children also learn many words that are used as both nouns and verbs (e.g., *bite, kiss, drink, brush, walk, hug, help, and call*; Nelson, 1995). It is unclear how any theory that does not consider communicative function primary, in the sense of the communicative role a word plays in whole utterances, can account for the acquisition of these dual category words.

Instead, the developmental data support the view that children initially understand paradigmatic categories very locally and mosaically, in terms of the particular kinds of things particular words can and cannot do communicatively. Thus, with respect to nouns, Tomasello et al. (1997) found that when 22-month-old children were taught a novel name for a novel object in a syntactically neutral context ("Look! A wuggie.") they immediately combined this new word with many predicative terms ("Hug wuggie," "Wuggie gone," etc.), indicating that they saw something in common between wuggies and the kinds of things one can hug or that can be gone (perhaps aided by the article *a*). Children of this same tender age also were able to indicate when they saw two "Wuggies," even though they had never heard this word used as a plural. However, a very interesting fact helping to specify the processes involved is that these two productive achievements, in syntax and morphology, were very poorly correlated. The children who could productively combine *wuggie* with other words syntactically were not the same ones who could create a productive plural with this same word. This suggests that children are forming their paradigmatic categories for very local communicative purposes, in mosaic and piecemeal fashion, not for all of the many more abstract and interrelated functions that underlie these categories in adults. Exactly how these processes might apply to words that fit the adult category of noun less well (nonobject common nouns, proper nouns, mass nouns) is not known at this time.

With respect to verbs, Akhtar and Tomasello (1997) did a similar study with slightly older 2- and 3-year-old children and found that, as in the analogous case with nouns, children became productive with novel verbs syntactically and morphologically in an uncorrelated fashion—again suggesting local, functionally specific, mosaically acquired, paradigmatic categories. Evidence from other languages also suggests that young children's paradigmatic categories develop in a gradual and piecemeal way as they attempt to assimilate to their more locally based categories the wider array of more abstract functions that underlie the adult version of the category (see Rispoli, 1991, for various types of evidence).

Overall, children's early paradigmatic categories are best explained in the same theoretical terms as their other cognitive categories. As noted in the discussion of slot-filler categories in early pivot schemas, Nelson (1985, 1996) and Mandler (2000) have both argued that the essence of concepts lies in function; human beings group together things that behave in similar ways in events and activities. In the case of linguistic categories such as noun and verb, however, it is important to be clear that these are categories not of entities in the world (i.e., not referents) but of pieces of language (words and phrases). When words and phrases are grouped together according to similarities in what they do communicatively—grounded in such functions as reference and predication—cognitively and linguistically coherent categories are the result.

The main cognitive skill necessary to form such categories is statistical or distribution learning. Importantly, it has recently been discovered that even prelinguistic infants are able to find patterns in sequentially presented auditory stimuli. Thus, Saffran, Aslin, and Newport (1996) exposed 8-month-old infants to 2 minutes of synthesized speech consisting of four tri-syllabic nonsense words such as *bidakupadotigolabu*-*bidakutupiropadoti*. . . . They were then exposed to two new streams of synthesized speech simultaneously (one presented to the left and one presented to the right) to see which they preferred to listen to (as indicated by the direction they turned their head). One of these streams contained "words" from the original (e.g., *tupiro* and *golabu*), whereas the other contained the same syllables but in a different order (i.e., there were no words from the original). Infants preferred to look toward the speech stream containing the words to which they had originally been exposed.

Subsequent studies have shown that infants can also find patterns even when the syllables from the original speech stream and the test speech stream are not the same. Thus, Marcus, Vijayan, Bandi Rao, & Vishton (1999) found that 7-month-old infants exposed repeatedly over a three-minute period to tri-syllabic nonsense words

with the pattern ABB (e.g., wididi, delili) preferred in subsequent testing to look toward the speech stream containing other words having this same ABB pattern even though the specific syllables involved were totally new (e.g., bapopo). Gómez and Gerken (1999) found a very similar results with 12-month-old infants. Interestingly, infants can also find patterns of this same type in both nonlinguistic tone sequences and even in visually presented sequences (Kirkham, Slemmer, & Johnson, *in press*; Saffran, Johnson, Aslin, & Newport, 1999). These pattern-finding skills are thus not specific to language learning. Also, when tamarin monkeys are tested in these same procedures, they show these same abilities (Hauser, Weiss, & Marcus, 2002; Newport, Aslin, & Hauser, 2001; Ramus, Hauser, Miller, Morris, & Mehler, 2000). These pattern-finding skills are thus not uniquely human.

LATER ONTOGENY

During the preschool years, English-speaking children begin to be productive with a variety of abstract utterance-level constructions, including such things as: transitives, intransitives, dit transitives, attributives, passives, imperatives, reflexives, locatives, resultatives, causatives, and various kinds of question constructions. Many of these are so-called argument-structure constructions, and they are used to refer to experiential scenes of the most abstract kind, including such things as: people acting on objects, objects changing state or location, people giving people things, people experiencing psychological states, objects or people being in a state, things being acted on, and so forth (Goldberg, 1995). It is presumably the case that these abstract constructions represent children's generalizations across many dozen (or more) item-based constructions, especially verb island constructions.

Children also construct smaller constructions that serve as the major internal constituents of utterance-level constructions. Most especially, they construct nominal constructions (NPs) in order to make reference to things in various ways (*Bill, my father, the man who fell down*) and verbal constructions (VPs) in order predicate for something about those things (*is nice, sleeps, hit the ball*). Children also create, a bit later in development, larger and more complex constructions containing multiple predicates such as infinitival complements (*I want him to go*), sentential complements (*I think it will fall over*), and relative clauses (*That's the doggy I bought*). These smaller and larger constructions

also are important components in children's later linguistic competence.

Theoretically, we are concerned here again with the nature of the cognitive processes that enable young children to generalize from their linguistic experience and so build up these highly abstract constructions. In addition, in this section, we also address the difficult question of why children make just the generalizations they do, and not some others that might be reasonable from an adult point of view.

Abstract Constructions

The most abstract constructions that English-speaking children use early in development have mostly been studied from an adult perspective—using constructions defined from an adult model. We follow suit here, but the truth is that many of the constructions listed here probably should be differentiated in a more fine-grained way (as families of subconstructions) once the necessary empirical work is done.

Identificationals, Attributives, and Possessives

Among the earliest utterance-level constructions used by many English-speaking children are those that serve to identify an object or to attribute to it some property, including a possessor or simple location (Lieven, Pine, & Dresner-Barnes, 1992). In adult language, these would almost invariably require some form of the copula, *to be*, although children do not always supply it. Quite often, these constructions revolve around one or a few specific words. Most common for the identification function are such things as *It's a/the X; That's a/the X; or This's a/the X*. Most common for the attributive function are such things as: *Here's a/the X; There's a/the X*. Most common for the possessive function are such things as: *(It's) X's _____; That's X's/my _____; This is X's/your _____*. Clancy (2000) reports some very similar constructions for Korean-speaking children, and a perusal of the studies in Slobin's cross-linguistic volumes reveals many other languages in which these are frequently used child constructions for focusing attention on, or attributing a property to, an external entity.

Simple Transitives, Simple Intransitives, and Imperatives

The simple transitive construction in English is used for depicting a variety of scenes that differ greatly from one another. The prototype is a scene in which

there are two participants and one somehow acts on the other. English-speaking children typically produce utterances of this type in their spontaneous speech early in language development for various physical and psychological activities that people perform on objects—everything from pushing to having to dropping to knowing. The main verbs young children use in the transitive construction are such things as *get, have, want, take, find, put, bring, drop, make, open, break, cut, do, eat, play, read, draw, ride, throw, push, help, see, say, and hurt*.

The simple intransitive construction in English is also used for a wide variety of scenes. In this case, the only commonality is that they involve a single participant and activity. The two main types of intransitives are the so-called unergatives, in which an actor does something (e.g., *John smiled*) and the so-called unaccusatives, in which something happens to something (e.g., *The vase broke*). English-speaking children typically produce utterances of both of these types early in language development, with unergatives such as *sleep* and *swim* predominating (unaccusatives occurring most often with the specific verbs *break* and *hurt*). The main verbs young children use in the intransitive construction—including imperative uses—are such things as *go, come, stop, break, fall, open, play, jump, sit, sing, sleep, cry, swim, run, laugh, hurt, and see*.

Ditransitives, Datives, and Benefactives

All languages of the world have utterance-level constructions for talking about the transfer of objects (and other things) between people (Newman, 1996). In English, there is a constellation of three related constructions for doing this: the *to*-dative, the *for*-dative (or benefactive), and the double-object dative (or ditransitive). Many verbs occur in both the *to*-dative and the double-object dative constructions (e.g., *give, bring, offer*), with the choice of which construction to use jointly affected by the semantic and discourse status of the participants (Erteschik-Shir, 1979). Most clearly, the prepositional form is most appropriate when the recipient is new information and what is being transferred is known (compare the natural “*Jody sent it to Julie*” with the unnatural “*Jody sent Julie it*”). However, the selection of a construction is only partially determined by discourse because a great many English verbs occur only in the prepositional form (e.g., *donate*) and a few occur only in the ditransitive (e.g., *cost, deny, fine*). The main verbs young children use in the ditransitive construction are such things as *get, give, show, make, read,*

being, buy, take, tell, find, and send (see Campbell & Tomasello, 2001).

Locatives, Resultatives, and Causatives

Beginning with their first words and pivot schemas, English-speaking children use a variety of locative words to express spatial relationships in utterance-level constructions. These include prepositions such as *X up, X down, X in, X out, on X, off X, over X, and under X*, and verb + particle constructions such as *pick X up, wipe X off, and get X down*. Once children start producing more complex structures designating events with two or more participants, two-argument locative constructions are common. For Tomasello’s (1992) daughter, these included such utterances as “*Draw star on me*” and “*Peoples on there boat*” which were produced at 20 months of age. By 3 years of age, most children have sufficient flexibility with item-based constructions to talk explicitly about locative events with three participants, most often an agent causing a theme to move to some object-as-location (e.g., “*He put the pen on the desk*”).

The resultative construction (as in “*He wiped the table clean*”) is used, most typically, to indicate both an action and the result of that action. Although no experimental studies of the resultative construction have yet been conducted with novel verbs, the occurrence of novel resultatives in spontaneous speech attests to the productivity of the construction from sometime after the third birthday. In Bowerman’s (1982) study of her two daughters, the following developmental progression was observed. At around 2 years of age, the two children learned various combinations of “causing verb + resulting effect” such as *pull+up* and *eat+all gone*. For the next year or so, each child accumulated an assortment of these forms that were used in an apparently adultlike manner. Subsequently, each child, at some point after her third birthday, seemed to reorganize her knowledge of the independently learned patterns and extract a more abstract schema. Evidence for this reorganization came from each child’s production of a number of novel resultative utterances such as “*And the monster would eat you in pieces*” and “*I’ll capture his whole head off*.”

Causative notions may be expressed in English utterance-level constructions either lexically or phrasally. Lexical causatives are simply verbs with a causative meaning used in the transitive construction (e.g., “*He killed the deer*”). Phrasal causatives are important because they supply an alternative for causativizing an intransitive verb that cannot be used transitively. Thus, if Bowerman’s daughter had been

skillful with phrasal causatives, she could have said, instead of “Don’t giggle me,” “Don’t make me giggle”; and instead of “Stay this open” she could have said “Make this stay open.” *Make* is thus the direct causation matrix verb in English, but an important related verb—that is in fact the most frequent such verb for young English learners—is *let*, as in “Let her do it,” or “Let me help you.” Another common matrix verb that follows this same pattern is *help*, as in “Help her get in there” or “Help him put on his shoes.” It is unknown whether young children see any common pattern among the utterances in which these three different matrix verbs are used.

Passives, Middles, and Reflexives

The English passive construction consists of a family of related constructions that change the perspective from the agent of a transitive action (relative to active voice constructions) to the patient and what happened to it. Thus, “Bill was shot by John” takes the perspective of Bill and what happened to him, rather than focusing on John’s act of shooting (with the truncated passive “Bill was shot” serving to strengthen this perspective further). In addition to this general function of the passive, Budwig (1990) has shown that the “get” and “be” forms of the passive are themselves associated with distinct discourse perspectives. Thus, the prototypical “get” passive in “Spot got hit by a car” or “Jim got sick from the water” tends to be used when there is a negative consequence which occurs when an animate patient is adversely affected by an inanimate entity or a nonagent source. In contrast, the “be” passive construction in “The soup was heated on the stove” is used when there is a neutral outcome of an inanimate entity undergoing a change of state where the agent causing the change of state is unknown or irrelevant. In general, actional transitive verbs can be used in passive constructions quite readily, whereas many stative verbs seem to fit less well (e.g., *She was loved by him*). This was demonstrated experimentally by Sudhalter and Braine (1985), who found that preschoolers were much better at comprehending passive utterances containing actional verbs (e.g., *kick, cut, dress*) than they were at comprehending passive utterances containing experiential verbs (e.g., *love, see, forget*).

English-speaking children typically do not produce full passives in their spontaneous speech until 4 or 5 years of age, although they produce truncated passives (often with *get*) and adjectival passives much earlier (e.g., “He got dunked” or “He got hurt”). Israel, Johnson, and Brooks (2000) analyzed the development of chil-

dren’s use of the passive participle. They found that children tended to begin with stative participles (e.g., *Pumpkin stuck*), then use some participles ambiguously between stative and active readings (e.g., *Do you want yours cut?*—do you want it to undergo a cutting action or, alternatively, do you want to receive it already in a cut state), then finally use the active participles characteristic of the full passive (e.g., *The spinach was cooked by Mommy*). Although passive utterances are infrequent in English-speaking children’s spontaneous speech, a number of researchers have observed that older preschoolers occasionally create truncated passives with verbs that in adult English do not passivize, for example, “It was bandaged,” “He will be died and I won’t have a brother anymore,” indicating some productivity with the construction (Bowerman, 1982, 1988; Clark, 1982).

It is important to note that children acquiring certain non-Indo-European languages typically produce passive sentences quite early in development. This result has been obtained for children learning Inuktitut (Allen & Crago, 1996), K’iche’ Mayan (Pye & Quixtan Poz, 1988), Sesotho (Demuth, 1989, 1990), and Zulu (Suzman, 1985). Allen and Crago (1996) report that a child at age 2.0–2.9 (as well as two slightly older children) produced both truncated and full passives quite regularly. Although a majority of these were with familiar actional verbs, they also observed passives with experiential predicates and several clearly innovative forms with verbs that do not passivize in adult Inuktitut. The reasons for this precocity relative to English-speaking children are hypothesized to include the facts that: (a) Inuktitut passives are very common in child-directed speech; and (b) passive utterances are actually simpler than active voice constructions in Inuktitut because the passivized verb has to agree only with the subject, whereas the transitive verb has to agree with both subject and object.

There is very little research on English-speaking children’s use of so-called middle voice constructions (medio-passives) such as “This bread cuts easily” or “This piano plays like a dream” (see Kemmer, 1993). The prototype of this construction involves an inanimate entity as subject, which is held responsible for the predicate (i.e., why the adverb is typically needed; “This bread cuts” or “This piano plays” by themselves are scarcely grammatical). Budwig, Stein, and O’Brien (2001) looked at a number of utterances of young children involving inanimate subjects and found that the most frequent constructions of this type in young English-speaking children’s speech were such things as “This doesn’t pour

good.” Reflexives are also not common in English-speaking children’s early language (or in adult English), although they do produce a few things such as “I hurt myself.” However, reflexives are quite common in the speech of young children learning languages in which these constructions are frequent in child-directed speech. For example, most Spanish-speaking youngsters hear and use quite early such things as *Se cayó* (It fell down), *Me siento* (I sit down), *Levántate* (Stand up!), and *Me lavo las manos* (I wash my hands).

Questions

Questions are used primarily to seek information from an interlocutor. In many languages, this is done quite simply through a characteristic intonation (“He bought a *house*?”) or by the replacement of a content word with a question word (“He bought a *what*?”). Although both of these are possible in English, two other forms are more common: wh- questions and yes/no questions. In the classic structural linguistic analysis, English questions are formed by subject-auxiliary inversion (sometimes with do-support) and wh- movement. These rules assume that the speaker has available a simple declarative linguistic representation, which she then transforms into a question by moving, rearranging, or inserting grammatical items. Thus, “John kicked the ball” becomes either “Did John kick the ball?” or “What did John kick?”

But this rule-based analysis is highly unlikely initially in development for two main reasons. First, some English-speaking children learn some wh- question constructions before they learn any other word combinations. For instance, Tomasello’s (1992) daughter learned to ask where-questions (e.g., “Where’s-the bottle?”) and what-questions (e.g., “What’s that?”) as her first multi-word constructions. Second, everyone who has studied children’s early questions has found that their earliest constructions are tied quite tightly to a small number of formulae. For example, in their classic analysis, Klima and Bellugi (1966) suggested that almost all the wh-questions of Adam, Eve, and Sarah emanated from two formulae: *What NP (doing)?* and *Where NP (going)?* Fletcher’s (1985) subject produced almost all of her early questions with one of three formulae: *How do . . .*, *What are . . .*, and *Where is . . .* More recently, Dabrowska (2001) looked in detail at one child’s earliest uses of wh-questions in English and found that 83% of her questions during her third year of life came from one of just 20 formulas such as *Where’s THING? Where THING go? Can I ACT? Is it PROPERTY?*

One phenomenon that bears on this issue is so-called inversion errors. English-speaking children sometimes invert the subject and auxiliary in wh- questions and sometimes not—leading to errors such as *Why they’re not going?* A number of fairly complex and abstract rule-based accounts have been proposed to account for these errors, and, as usual, some researchers have claimed that children know the rules but apply them only optionally or inconsistently (e.g., Ingram & Tyack, 1979). However, in a more detailed analysis, Rowland and Pine (2000) discovered the surprising fact that the child they studied from age 2 to age 4 consistently inverted or failed to invert particular wh-word–auxiliary combinations on an item-specific basis. He thus consistently said such incorrect things as *Why I can . . . ? What she will . . . ? What you can . . . ?* but at the same time, he also said such correct things as *How did . . . ? How do . . . ? What do . . . ?* In all, of the 46 particular wh-word auxiliary pairs this child produced, 43 of them were produced either 100% correctly or 100% incorrectly (see also Erreich, 1984, who finds equal number of inversion errors in wh- and yes/no questions). Again, the picture is that children learn questions as a collection of item-based constructions, moving only gradually to more abstract representations.

Analogy

Children begin to form abstract utterance-level constructions by creating analogies among utterances emanating from different item-based constructions. The process of analogy is very like the process of the schematization for item-based schemas/constructions; it is just that analogies are more abstract. Thus, whereas all instances of a particular item-based schema have at least one linguistic item in common (e.g., the verb in a verb island schema), in totally abstract constructions (such as the English ditransitive construction) the instances need have no items in common. So the question is: On what basis does the learner make the alignments among constituents necessary for an analogy among complex structures?

The answer is that the learner must have some understanding of the functional interrelationship that makes up the two structures being aligned. In the most systematic research program on the topic, Gentner and colleagues (Gentner & Markman, 1995; Gentner & Medina, 1998) stress that the essence of analogy is the focus on relations. When an analogy is made, the objects involved are effaced; the only identity they retain is their role in the relational structure. Gentner and colleagues have

much evidence that young children focus on relations quite naturally and so are able to make analogies quite readily. An example is as follows. Children are shown two pictures: one of a car towing a boat (hitched to its rear) and one of a truck towing a car (hitched to its rear), and this car is identical in appearance to the car in the other picture. After some training in making analogies, the experimenter then points to the car in the first picture and asks the child to find the one doing the same thing in the second picture. Children have no trouble ignoring the literal match of cars across the two pictures and choosing the truck. In essence, they identify in both pictures the “tow-er,” or the agent, based on the role it is playing in the entire action depicted.

Gentner and colleagues also stress what they call the systematicity principle: In making analogies structures are aligned as wholes, as “interconnected systems of relations.” In the current context, this simply means that learners align whole utterances or constructions, or significant parts thereof, and attempt to align all the elements and relations in one comparison. In doing this, learners search for “one-to-one correspondence” among the elements involved and “parallel connectivity” in the relations involved. In the current context, this means that the learner makes an analogy between utterances (or constructions) by aligning the arguments one to one, and in making this alignment, she is guided by the functional roles these elements play in the larger structure. For example, in aligning *the car is towing the boat* and *the truck is towing the car*, the learner does not begin to match elements on the basis of the literal similarity between the two *cars*, but aligns *the car* and *the truck* because they are doing the same job from the perspective of the functional interrelations involved. This analysis implies that an important part of making analogies across linguistic constructions is the meaning of the relational words, especially the verbs, involved—particularly in terms of such things as the spatial, temporal, and causal relations they encode. But there is basically no systematic research relevant to the question of how children might align verb meanings in making linguistic analogies across constructions.

Gentner and colleagues also have some specific proposals relevant to learning. For example, they propose that even though in some sense neutralized, the object elements that children experience in the slots of a structure can facilitate analogical processes. In particular, they propose that in addition to type variability in the slots, also important is consistency of the items in the slots (i.e., a given item occurs only in one slot and not in

others). When all kinds of items occur promiscuously in all of the slots in two potentially analogous relational structures, structure mapping is made more difficult (Gentner & Medina, 1998). For example, children find it even easier to make the analogy cited earlier if in the two pictures a car is towing a boat and a car is towing a trailer, so that the tow-er is identical in the two cases. This principle explains why children begin with item-based constructions. They find it easier to do structural alignments when more of the elements and relations are not just similar functionally but also similar, or even identical, perceptually—the process of schematization as it works in, for example, verb island constructions. Children then work their way up to the totally abstract analogies gradually. There are also some proposals from the morphological domain, that a certain number of exemplars is needed—a “critical mass”—before totally abstract analogies can be made (Marchman & Bates, 1994). But if this is true, the nature of this critical mass (e.g., verb types versus verb tokens) is not known at this time; there is no research.

It is thus possible that abstract linguistic constructions are created by a structural alignment across different item-based constructions, or the utterances emanating from them. For example, some verb island constructions that children have with the verbs *give*, *tell*, *show*, *send*, and so forth, share a “transfer” meaning, and appear in the form: NP1 + V + NP2 + NP3. In the indicated transfer, NP1 is the giver, NP2 is the receiver, and NP3 is the gift. So the aligning must be done on the basis of *both* form and function: Two utterances or constructions are analogous if a “good” structure mapping is found both on the level of linguistic form (even if these are only categorically indicated) and on the level of communicative function. This consideration is not really applicable in nonlinguistic domains. It may also be that in many cases particular patterns of grammatical morphology in constructions (e.g., *X was VERBed*)—which typically designate abstract relations of one sort or another—facilitate, or even enable, recognition of an utterance as instantiating a particular abstract construction.

The only experimental study of children’s construction of an abstract linguistic construction (as tested by their ability to assimilate a nonce verb to it) was conducted by Childers and Tomasello (2001). In this training study, 2½-year-old English-speaking children heard several hundred transitive utterances, such as *He’s kicking it*, involving 16 different verbs across three separate sessions. Half the children learned new English verbs

(and so increased their transitive verb vocabularies during training—toward a critical mass) whereas the other half heard only verbs they already knew. Within these groups, some children heard all the utterances with full nouns as agent and patient, whereas others heard utterances with both pronouns (i.e., *He's VERB-ing it*) and also full nouns as agent and patient. They were then tested to see if they could creatively produce a transitive utterance with a nonce verb. The main finding was that children were best at generalizing the transitive construction to the nonce verb if they had been trained with pronouns and nouns, regardless of the familiarity of the trained verbs (and few children in a control condition generalized to the novel verb at all). That is, the consistent pronoun frame *He's VERB-ing it* (in combination with type variation in the form of nouns as well) seemed to facilitate children's formation of a verb-general transitive construction to a greater degree than the learning of additional transitive verbs with nouns alone, in the absence of such a stabilizing pronominal frame.

The results of this study are consistent with Gentner's more general analysis of the process of analogy in several ways. First, they show that children can make generalizations, perhaps based on analogy, across different item-based constructions. Second and more specifically, they also show that the material that goes in the slots, in this case NP slots, plays an important role (see also Dodson & Tomasello, 1998). In English, the pronoun *he* only goes in the preverbal position, and, although the pronoun *it* may occur in either position in spontaneous speech, it occurs most frequently in postverbal position in child-directed speech, and that is the only position in which the children heard it during training. These correspondences between processes in the creation of nonlinguistic analogies and in the creation of abstract linguistic constructions constitute impressive evidence that the process is basically the same in the two cases.

Constraining Generalizations

Importantly, there must be some constraints on children's linguistic abstractions, and this is a problem for both of the major theories of child language acquisition. Classically, a major problem for generative theories is that as the rules and principles are made more elegant and powerful through theoretical analyses, they become so abstract that they generate too large a set of grammatical utterances; and so constraints (e.g., the subjacency

constraint) must be posited to restore empirical accuracy. In usage-based theories, children are abstracting as they learn, but they cannot do this indiscriminately; they must make just those generalizations that are conventional in the language they are learning and not others. It is thus clear that any serious theory of syntactic development, whatever its basic assumptions, must address the question of why children make just the generalizations they do and not others.

We may illustrate the basic problem with so-called dative alternation constructions. The situation is this: Some verbs can felicitously appear in both ditransitive and prepositional dative constructions, but others cannot; for example:

He gave/sent/bequeathed/donated his books to the library.

He gave/sent/bequeathed/*donated the library his books.

Why should the other three verbs be felicitous in both constructions, but *donate* be felicitous only in the prepositional dative? The four verbs have very similar meanings, and so it would seem likely that they should all behave the same. Another example is:

She said/told something to her mother.

She *said/told her mother something.

Again, the meanings of the verbs are very close, and so the difference of behavior seems unprincipled and unpredictable (Bowerman, 1988, 1996). Other similar alternations are the causative alternation (*I rolled the ball; The ball rolled*) and the locative alternation (*I sprayed paint on the wall; I sprayed the wall with paint*)—both of which also apply only to limited sets of verbs.

One solution is quite simple. Perhaps children only learn verbs for the constructions in which they have heard them. Based on all of the evidence reviewed here, this is very likely the case at the earliest stages of development. But it is not true later in development, especially in the 3- to 5-year age period. Children at this age overgeneralize with some regularity, as documented most systematically by Bowerman (1982, 1988; see Pinker, 1989, for a summary of evidence). As reported earlier, her two children produced things like: “Don't giggle me” (at age 3.0) and “I said her no” (at age 3.1). It is thus not the case that children are totally conservative throughout development, and so this cannot be the whole answer.

A second solution is also simple. When children make overgeneralization errors, adults may correct them, and so children's overgeneralization tendencies are constrained by the linguistic environment. But this is not true in the sense that adults do not explicitly correct child utterances for their grammatical correctness (Brown & Hanlon, 1970). Adults, at least Western middle-class adults, do respond differently to well-formed and ill-formed child utterances, however. For example, they continue conversing to well-formed utterances, but they revise or recast ill-formed utterances (e.g., Bohannon & Stanowicz, 1988; Farrar, 1992). But this kind of indirect feedback is generally not considered by most theorists sufficient to constrain children's overgeneralization tendencies because it is far from consistent. It is also not clear that this type of feedback is available to all children learning all languages. Nevertheless, it is still possible that linguistic feedback from adults may play some role—although neither a necessary nor a sufficient role—in constraining children's overgeneralization tendencies.

Given the inadequacy of these simple solutions, three factors have been most widely discussed. First, Pinker (1989) proposed that there are certain very specific and (mostly) semantic constraints that apply to particular English constructions and to the verbs that may or may not be conventionally used in them. For example, a verb can be used felicitously with the English transitive construction if it denotes "manner of locomotion" (e.g., *walk* and *drive* as in *I walked the dog at midnight* or *I drove my car to New York*), but not if it denotes a "motion in a lexically specified direction" (e.g., *come* and *fall* as in **He came her to school* or **She falled him down*). How children learn these verb classes—and they must learn them since they differ across languages—is unknown at this time. Second, it has also been proposed that the more frequently children hear a verb used in a particular construction (the more firmly its usage is entrenched), the less likely they will be to extend that verb to any novel construction with which they have not heard it used (Bates & MacWhinney, 1989; Braine & Brooks, 1995; Clark, 1987; Goldberg, 1995). And third, if children hear a verb used in a linguistic construction that serves the same communicative function as some possible generalization, they may infer that the generalization is not conventional—the heard construction preempts the generalization. For example, if a child hears *He made the rabbit disappear*, when she might have expected *He disappeared the rabbit*, she may infer that *dis-*

appear does not occur in a simple transitive construction—since the adult seems to be going to some lengths to avoid using it in this way (the periphrastic causative being a more marked construction).

Two experimental studies provide evidence that indeed all three of these constraining processes—entrenchment, preemption, and knowledge of semantic subclasses of verbs—are at work. First, Brooks, Tomasello, Lewis, and Dodson (1999) modeled the use of a number of fixed-transitivity English verbs for children from 3;5 to 8;0 years—verbs such as *disappear* that are exclusively intransitive and verbs such as *hit* that are exclusively transitive. There were four pairs of verbs, one member of each pair typically learned early by children and typically used often by adults (and so presumably more entrenched) and one member of each pair typically learned later by children and typically used less frequently by adults (less entrenched). The four pairs were: *come-arrive*, *take-remove*, *hit-strike*, *disappear-vanish* (the first member of each pair being more entrenched). The finding was that, in the face of adult questions attempting to induce them to overgeneralize, children of all ages were less likely to overgeneralize the strongly entrenched verbs than the weakly entrenched verbs; that is, they were more likely to produce *I arrived it* than *I comed it*.

Second, Brooks and Tomasello (1999b) taught novel verbs to children 2.5, 4.5, and 7.0 years of age. They then attempted to induce children to generalize these novel verbs to new constructions. Some of these verbs conformed to Pinker's (1989) semantic criteria, and some did not. Additionally, in some cases, experimenters attempted to preempt generalizations by providing children with alternative ways of using the new verb (thus providing them with the possibility of answering *What's the boy doing?* with *He's making the ball tam*—which allows the verb to stay intransitive). In brief, the study found that both of these constraining factors worked, but only from age 4.5. Children from 4.5 years showed a tendency to generalize or not generalize a verb in line with its membership in one of the key semantic subclasses, and they were less likely to generalize a verb to a novel construction if the adult provided them with a preempting alternative construction. But the younger children showed no such tendency.

Overall, entrenchment seems to work early, from 3;0 or before, as particular verb island constructions become either more or less entrenched depending on usage. Preemption and semantic subclasses begin to

work sometime later, perhaps not until 4 years of age or later, as children learn more about the conventional uses of verbs and about all of the alternative linguistic constructions at their disposal in different communicative circumstances. Thus, just as verb-argument constructions become more abstract only gradually, so also are they constrained only gradually.

Nominal and Verbal Constructions: Learning Morphology

Across the languages of the world, utterance-level constructions are constituted by two major types of subconstructions: nominal and verbal constructions. Actually, in real discourse, nominal and verbal constructions are often used alone as full utterances, which is one strong piece of evidence for their reality as functionally coherent and independent constructions. Thus, when someone is asked “Who is that over there?” a reasonable utterance in response is the nominal “Bill” or “My father,” and when someone is asked further “What is he doing?” a reasonable utterance in response is the verb or verb phrase “Sleeping” or “Playing tennis.” Of course many utterances are constituted by some combination of nominals and verbals: “My father is playing tennis.”

Nominal Constructions

Nominals are used by people to make reference to “things.” In many theories, the prototype is concrete objects (people, places, and things). But it is well known that nominals may be used to refer to basically any kind of entity at all, real or imagined. Thus, when the need arises, there are ways of construing actions, properties, and relationships as if they were things, on analogy with concrete objects. For example, we may say such things as “Skiing promotes good health,” “That blue looks awful in my painting,” and “Bigger is better.” Indeed, there are some languages that do not really have a clear-cut class of concrete nouns specialized for the single function of reference, such as *dog* and *tree*; but rather they have a single class composed of words that can be used as either nouns or verbs depending on whether they are used as nouns or verbs—similar to English words such as *cut* (*I cut the bread, There's a cut on my finger*) or *hammer* (*I'm hammering in this nail with my hammer*). Langacker (1987b) notes that the discourse function of identifying the participants in events and states of affairs requires language users to construe whatever

they wish to talk about as a thing, so that it can be referred to, no matter its true ontological status.

In making reference to a thing, speakers must choose among various nominal constructions—for example, proper name, noun + article, pronoun—based on the exigencies of the communicative situation at hand. Of most importance for this choice is the speaker’s assessment of the knowledge and expectations of the listener at any given moment based on their currently shared perceptual situation and on their previously shared experience, especially in the immediately preceding discourse context. In the terminology of Langacker (1991), speakers must “ground” their conventional act of reference in the current speech situation involving particular persons in a particular usage event. In the terminology of pragmatic theorists, speakers must assess the cognitive availability (accessibility, topicality, givenness) of the referent for the listener (Ariel, 1988; Givón, 1993; Gundel, Hedberg, & Zacharski, 1993).

Typically, speakers choose to use a pronoun (*he*) or a proper name (*Jennie*) to refer to an entity that is either in the current attentional focus of speaker and listener or else can easily be recovered from memory (e.g., because it is shared knowledge who *Jennie* is). The most studied referential strategy of young children is one used when recoverability is harder, specifically, the use of a full noun phrase containing some kind of common noun and some kind of determiner(s). Such full noun phrases do not assume, at least not to the same degree as pronouns and proper names, shared knowledge between speaker and listener. In addition, they also employ a more analytic technique of reference than proper names and pronouns, typically using multiple words or morphemes to indicate the intended referent. Thus, full noun phrases typically comprise two separately indicated subfunctions: A common noun (*boy, yard, party*) is used to indicate a category of things, and a determiner (*a, the, my*) is used to help the listener to specify an individual member of that category.

Children produce full noun phrases in their very earliest multiword speech, sometimes as whole utterances (e.g., saying “A clown” when asked “What is that?” or “My blanket” when asked “What do you want?”). The determiners used in these early utterances fall mainly into three categories. The first is demonstratives, as in *this ball* or *that cookie*. These are often used deictically with pointing, but their perspectival aspect (physical or psychological distance from speaker) is not mastered for several years. The second category is possessives, as in

my shoes or *Maria's bike*. These are also used quite early in language development and they are of special importance because they seem to be used quite accurately from the beginning (see, e.g., Tomasello, 1998b). This early mastery of possessive noun phrases means that all of the trouble that children have with other kinds of noun phrases involving such things as definite and indefinite articles, are not due to general difficulties with forming a phrase consisting of a common noun plus a determiner. Their difficulties must come from somewhere else, presumably the additional perspectival and/or pragmatic dimensions that must be mastered for appropriate use of these other types of determiners in noun phrases.

The determiners that have been studied most extensively in English acquisition are the definite and indefinite articles, *the* and *a*. Appropriate usage of these is notoriously difficult for second-language learners of English, especially for those coming from languages that do not have articles at all (e.g., Japanese or Russian). Although textbook accounts quite often present these words as contrasting alternatives, the fact is that each of them has a wide range of uses, some of which are quite unrelated to one another. Indeed, the historical situation is that across many languages the definite determiner derives from a demonstrative—a mainly deictic function—whereas the indefinite determiner derives from the number word for *one*—a very different function. In English, the definite determiner was grammaticalized from a demonstrative many generations before the indefinite determiner was grammaticalized from the number word for *one* (Trask, 1996).

There are two main difficulties that children have to overcome to use English articles appropriately. The first difficulty is that these words encode two different, but highly correlated, dimensions of the referential situation: specificity and givenness. On the one hand, the definite article *the* serves to pick out a specific entity, as in “I want the cookie” (that’s in your hand), whereas the indefinite article *a* serves to pick out a nonspecific entity, as in “I want a cookie” (any cookie). On the other hand, the definite article *the* is used when the speaker can assume that the referent is to some degree given (or available) for the listener (e.g., “I have the kite”—the one we just talked about), whereas the indefinite article *a* is used to introduce a new referent into the discourse situation even if that entity is definite (e.g., “I have a kite”—you’ll find it upstairs). These two aspects, specificity and givenness, most often occur in a totally confounded manner, and indeed it is only in somewhat

special uses that they are unconfounded. The second difficulty is that this second dimension of article use—taking into account listener perspective (givenness)—may be especially difficult cognitively for 2- and 3-year-old children. Much research in developmental psychology has demonstrated that the requisite perspective-taking skills are much better developed in 4-year-olds (see Flavell, 1997, for a review).

Brown’s (1973) naturalistic observations have documented that by 3 years of age English-speaking children use the definite and indefinite articles quite flexibly and appropriately with respect to the specificity of the referent intended. However, Brown also notes that this spontaneous usage provides little evidence one way or the other for children’s skills with the perspectival component, especially in the most demanding case in which the intended referent is known by the speaker but unknown to the listener (i.e., where givenness is different for speaker and listener). This especially difficult case has been the target of a number of experimental investigations, and not surprisingly, the general finding is that when young children have a referent they wish to introduce to someone for whom it is totally new in the discourse context, they tend to overuse the definite article (the egocentric error). For example, with no introductory comments whatsoever, they might tell a friend, “Tomorrow we’ll buy the toy” (Maratsos, 1976).

Emslie and Stevenson (1981) had children tell a story from a set of pictures to another child sitting on the other side of a partition. They found that 3-year-olds used the articles consistently and appropriately with regard to specificity. With regard to perspective, the key task was one in which children were asked to narrate a story from a series of pictures to another child, and in the middle of the series a picture of a completely new and irrelevant object or person appeared—definitely requiring an indefinite article for its introduction (e.g., “And then a snake appeared in the grass . . .”). They found that only the 4-year-olds (not the 3-year-olds) consistently used the indefinite article to introduce the novel referent for their unsuspecting listener. In a similar experimental task, Garton (1983) found that children before their fourth birthdays did not use the definite and indefinite articles differentially for adults either wearing or not wearing a blindfold.

Verbal Constructions

Just as nominals are grounded in space, in the sense that they help the listener to locate the intended referent,

clauses are grounded in time to help the listener identify which particular event is being indicated (Langacker, 1991). This is typically done in two ways that work together. The internal temporal contour of a clause is designated by some marking of its grammatical aspect (e.g., progressive aspect marks ongoingness, as in *X is/was smiling*), while the external placement of the event along a time line, grounded in the speech moment, is designated by some marker of its tense (e.g., past tense; Comrie, 1976). These work together in narrative discourse to enable such temporal juggling as *While I was Xing, she Yed*. In addition, and importantly, many clauses also contain some indication of the speaker's attitude toward the event or state of affairs. For example, in English, people frequently mark their attitude through the use of modal auxiliaries such as *may, can, can't, won't, should, might, must, could, would*, and so on—and with a number of different kinds of things in other languages (e.g., marking how the speaker came to know what she is saying, so-called evidentiality). All of this works together—with some grammatical morphemes in some languages being plurifunctional in the extreme—in what is called tense-aspect-modality (TAM) marking. TAM marking may be done either with freestanding words or with grammatical morphology, depending on exactly which of these things in a given language has been grammaticalized, and to what degree.

To ground their clauses in the current speech event, speakers must locate the symbolized state or event in time. Weist (1986), building on Smith (1980), proposes four stages in children's ability to linguistically indicate the temporal ordering of events using tense marking in an adultlike manner:

1. *Age 1;6*: talk about events in the here and now only.
2. *Age 1;6 to 3;0*: talk about the past and future.
3. *Age 3;0 to 4;6*: begin to talk about past and future relative to a reference time other than now (typically indexed with adverbs such as *when*).
4. *Age 4;6 and older*: talk about past and future relative to a reference time other than now using adultlike tensing system (typically verb morphology).

The problem with this neat account is that the linguistic indication of tense interacts in complex ways with the linguistic indication of aspect, and it does this differently in different languages. As one example, the best-known hypothesis about children's early ability to indicate temporal relations in their early language is the Aspect Before

Tense hypothesis. Beginning with Antinucci and Miller (1976), it has been noted that children tend to use past tense most often with change of state (telic) verbs and present tense (or present progressive) most often with activity (atelic) verbs. In the strongest version of the Aspect Before Tense hypothesis, Antinucci and Miller hypothesized that until about 2;6 children use past tense only for changes of state in which at the end state is still perceptually present, and indeed children at this age think that the past tense marker actually indicates that an event is bounded (telic) and completed (perfective), rather than one that occurred in the past (independent of its telicity and perfectiveness). Thus, the first past tense verbs are prototypically things like *dropped, spilled, and broke* in which all of these things are confounded.

Antinucci and Miller (1976) attributed this pattern of use to children's immature conception of time. However, this strictly cognitive explanation is no longer held by anyone. This is because, first of all, even before their second birthdays many children do on some occasions clearly refer to past situations with activity verbs that have no current perceptual manifestations (Gerhardt, 1988). Second, in a number of comprehension experiments in which children must choose the picture that best depicts a present tense, past tense, or future tense utterance regardless of aspect, they perform well from a relatively early age (e.g., see Weist, Wysocka, Witkowska-Stadnik, Buczowska, & Konieczna, 1984; Weist, Lyytinen, Wysocka, & Atanassova, 1997, for Polish-speaking children; and McShane & Whittaker, 1988, and Wagner, 2001, for English-speaking children). And third, a number of studies on second language acquisition have shown that second language learning children and adults also use tense-aspect marking in the same biased way as young children, and they presumably are not cognitively immature (Li & Shirai, 2000).

Nevertheless, it is a fact that in basically all languages that have been studied, children much prefer to use the past tense for events construed as telic and perfective, such as *broke* and *made*, and they much prefer to use present tense (or progressive) for events construed as atelic and imperfective, such as *playing* and *riding*. Thus, it is relatively rare to hear a 1-year-old or young 2-year-old saying things like *breaking* or *making, played* or *rode*. The languages for which this has been documented include English, Italian, French, Polish, Portuguese, German, Japanese, Mandarin Chinese, Hebrew, and Turkish (see Li & Shirai, 2000, for a review). Quantitatively, in a diary study Clark (1996) found that, between the ages of 1;7 and 3;0, her son used the pro-

gressive *-ing* with activity verbs about 90% of the time, and he used the past tense *-ed* with the accomplishment subclass of change-of-state verbs about 60% of the time. Tomasello (1992) found that an even higher percentage of *-ed* use occurred with change-of-state verbs.

It turns out that one major reason children show this pattern is quite straightforward: This is the pattern they hear in the language around them. Shirai and Andersen (1995) call this the *distributional bias* hypothesis, namely, that the distribution of tense and aspect markers with particular classes of verbs in children's speech follows the distribution the children hear in the language around them. And so, once again, what we see is an adult pattern in the use of grammatical words and morphemes that most often conflates and/or confounds distinctions that the child will need to segregate if she is to attain adultlike competence with these grammatical words and morphemes. Presumably, to make all the appropriate distinctions in the current case, the child needs to hear and comprehend enough instances of activity verbs construed imperfectively in the past tense, change-of-state verbs construed in the progressive aspect, and all other possible combinations. Only wide and varied experience with many different such patterns provides the raw material necessary for the child to segment and sort out which components of a given clausal construction are being used to indicate which components of the temporal profile the speaker intends to indicate. As in the case of a nominal constructions with determiners—in which the child must sort out such things as referent specificity and listener perspective, which are often confounded—it is no surprise that it takes children many years to do this, and that it is easier to do in languages in which historical grammaticalization patterns have led to fewer conflations and confoundings of these types (Slobin, 1985, 1997).

Learning Morphology

The need to ground nominal and verbal constructions in the ongoing speech event is present constantly. Although there are major differences among languages, these constant communicative pressures have led in many cases to the grammaticalization of forms for effecting these functions, and recurrent functions other than grounding may also lead to the creation of grammatical morphology (e.g., plurals and case marking). From the point of view of learning and generalization, grammatical morphology displays a number of interesting properties. Among these is the fact that children sometimes overregularize grammatical morphemes, which has put them in the center of some major theoretical debates about the

nature of cognitive representation in general. In addition, because they are often not very salient in the speech stream—and perhaps for other reasons such as their plurifunctionality in many cases—second language learners and children with the specific language impairment often have special problems with grammatical morphemes.

One of the most intriguing phenomena of child language acquisition is U-shaped developmental growth. That is, in some cases children seem to learn the conventional adult way of saying things early in development, but then become worse as they get older, for instance, saying such things as *mans, feets, comed, sticked, putted* and so forth—returning only later to the conventional adult forms. The traditional interpretation of this developmental pattern is that early on children learn, for example, the past tense form *came* by rote as an individual lexical item; later they learn to use the regular past tense morpheme *-ed* and apply it whenever they want to refer to the past (sometimes inappropriately, as in *comed*). Finally, before school-age, they learn that there are exceptions to the general rule and display adultlike competence (Bowerman, 1982; Kuczaj, 1977). U-shaped developmental growth is thus intriguing because it seems to signal changes in underlying linguistic representations and processes.

Perhaps ironically, given that English is a morphologically impoverished language, the grammatical morpheme that has been studied most intensively in this regard is the English past tense *-ed*. The largest and most systematic study of children's acquisition of the English past tense was conducted by Marcus et al. (1992). They examined written transcripts of 83 English-speaking preschool-age children and found that overgeneralization errors were relatively rare proportionally (2.5% of irregular tokens produced *had*, inappropriately, the *-ed*), and they occurred at this same low rate throughout the preschool period. Typically, for a given verb children produced the correct past tense form before they produced the overgeneralized form, and they made the overgeneralization error least often with the irregular verbs they heard most often in parental speech. For a particular child's use of a specific verb, there was sometimes a relatively extended period (weeks to months) in which both the correct form and the overgeneralized form coexisted.

Marcus et al. (1992) explain these results with one form of a dual process model. Children acquire the irregular forms by rote learning, but they acquire the regular forms by establishing a rule. Rote learning is

subject to all the parameters of “normal” learning, such as the effects of frequency and similarity among exemplars; rule learning is impervious to these effects. (The existence of these different processes is supposed to be of great theoretical significance because they confirm the existence of rule-based cognitive representations that are not subject to the normal laws of learning; Pinker, 1991, 1999). But the specifics of English past tense acquisition clearly do not fit this neat picture; children sometimes misapply the rule (overgeneralize), even in some cases using both correct and incorrect forms during the same developmental period. Marcus et al. explain these anomalies by invoking in addition the principle of preemption (what they call the uniqueness principle or blocking) and some factors that affect its application. The basic idea is that the regular rule applies whenever it is not blocked (i.e., it is a default rule). This means that when children have an irregular form (e.g., *sang*) it blocks application of the regular *-ed* rule, but when they do not have such a form, they might reasonably produce *singed*. The problem with this account, of course, is the finding that children often use both the correct and overgeneralized forms at the same time. Marcus et al. deal with this empirical problem by hypothesizing that blocking sometimes does not work as it is supposed to, basically due to “performance errors.” Lexical retrieval is probabilistic and frequency dependent; children sometimes have trouble retrieving infrequent irregular forms and so the rule gets applied simply because it is not properly blocked.

However, some aspects of this account have been called into question. Maratsos (2000) points out that the error rate reported by Marcus et al. (1992) was computed by pooling all verbs together, and thus very high frequency verbs statistically swamped out low frequency verbs. Indeed, verbs that appeared infrequently for a given child (less than 10 times) were excluded from some analyses altogether. Thus, for example, one child produced 285 past tenses for the verb *say*, with a very low error rate of 1%. This same child, however, produced 40 different verbs less than 10 times each (155 tokens altogether). The overgeneralization error rate for these individual verbs was 58%. But because of their low token frequency, all of these verbs together contributed less to the computation of the overall error rate than the verbs *say* by itself. In addition, Maratsos also points out that many individual verbs used by individual children are used in both correct and overgeneralized forms for a period of many months (in a few cases, years), which

could only happen in the rule + blocking account if the child experienced persistent and long-lived retrieval problems of a type Marcus et al. do not discuss.

Maratsos’ alternative account is based on the notion of competition—a weaker, frequency-based kind of preemption. In this account, children can produce past tense forms either by rote or by rule, and there may be a period in which they produce both for a given verb. The winner of the competition will be determined eventually by the form the child hears most often in the speech around her (and perhaps by other factors); that is, the most frequent form comes gradually to block the less frequent form, regardless of which is regular or irregular. In contrast, in the Marcus et al. (1992) account, there is an asymmetry between regulars and irregulars; the regular does not even need to be heard a single time to win, since it is a default. The only role for frequency is as a performance factor that interferes with the normal mechanism.

In general, the acquisition of productive systems of grammatical morphology in natural languages is extremely difficult. According to Klein and Perdue (1997), most adult second-language learners, especially those learning in more natural settings outside the classroom, develop what they call the *basic variety* of a language. This consists of lexical items combined in syntactic constructions, but typically with only one morphological form of each word. Similarly, McWhorter (1998) argues and presents evidence that one of the distinguishing characteristics of pidgin and Creole languages (typically relatively new languages created under unusual situations of language contact) is their relatively impoverished systems of grammatical morphology. It is also well known that one of the major diagnostic features of children with specific language impairment is their relatively poor mastery of the grammatical morphemes in their language (Bishop, 1997; Leonard, 1998). Finally, when perfectly competent adult speakers of a language are put under various kinds of processing pressure as they listen to a story (e.g., the spoken language describing the story is distorted by white noise or subjects must perform a distracting task while listening), what falls apart most readily in subsequent tests of retention is the grammatical morphology (Dick et al., 2001).

There are three basic reasons that grammatical morphology is an especially weak link in language learning. First, it is typically expressed in phonologically reduced, unstressed, monosyllabic bits in the interstices of utterances and constructions. Second, in some though by

no means all cases, it also carries very little concrete semantic weight; for example, the English third person *-s* agreement marker is in most cases almost totally semantically redundant. Research with children with specific language impairment has shown that greater semantic weight facilitates children's acquisition of a grammatical morpheme (Bishop, 1997; Leonard, 1998). Third, many grammatical morphemes are plurifunctional (e.g., English articles encoding specificity and definiteness) in ways that make acquisition of the full range of uses in appropriate contexts extremely difficult. Perhaps for all these reasons, Farrar (1990, 1992) found that children's acquisition of some particular grammatical morphemes in English (e.g., past tense *-ed*, plural *-s*, progressive *-ing*) was facilitated when mothers used these morphemes as immediate recasts of the child's utterances that were missing them. Recasts are well-known to help children identify elements with low salience since they provide the child with an immediate comparison of her own immature utterance and the corresponding full adult morphology (Nelson, 1986).

Complex Constructions

All natural languages have ways for talking about multiple events and states of affairs related to one another in complex ways. In the most straightforward cases, a speaker simply strings together different clauses across time, linking them with various kinds of appropriate connectors (or not). In other cases, however, the different clauses are more tightly interrelated and thus appear as constituents in a single complex construction under a single intonation contour, which in most cases is a historical grammaticalization of discourse sequences in which specific types of clauses have recurred together repeatedly in the speech community. The linking of clauses, whether more loosely or more tightly, serves various discourse functions. These include expressing speaker attitudes about things (as in infinitival and sentential complements), specifying referents in more detail (as in relative clauses), and indicating the spatial-temporal-causal interrelations among events (as in adverbial clauses—not dealt with here).

Infinitival Complement Constructions

Between 2 and 3 years of age, English-speaking children begin to acquire complex constructions indicating speaker attitudes about such things as intention, volition, or compulsion. The most common are *wanna* *V*, *hafta* *V*, *gotta* *V*, *needta* *V* (and perhaps *gonna* *V*), and

they typically structure the earliest complex sentences that English-speaking children learn and use—typically emerging at around the second birthday. Gerhardt (1991) analyzes children's use of *wanna* as indicating "internal volition" or desire, their use of *hafta* (and *gotta*) as indicating "external compulsion" (often due to a social norm such as a rule), and *needta* as indicating "internal compulsion" (almost no choice due to an internal state).

Following the classic studies of Limber (1973) and Bloom, Tackeff, and Lahey (1984), Diessel (2004) reported the largest study to date of nonfinite complement clauses. He studied a wider range of constructions, including participial and *wh* infinitive constructions; and he investigated four children up to 5 years of age in quantitative detail. The first finding is that over 95% of children's utterances with nonfinite complement clauses contained to-infinitives, and these were the first to emerge as well. (The other 5% were such things as the participials *Start V-ing* and *Stop V-ing* and a very few *wh* infinitives such as "I know what to do.") Like Bloom et al. (1989), Diessel found that the first matrix verbs to appear were *wanna*, *hafta*, and *gotta*, which emerged at about 2;3 and accounted for over 90% of all the to-infinitives over the course of the entire study. Initially children used these in very formulaic ways. That is, almost all of the first to-infinitives produced by these children had as subjects the first-person pronoun *I*, they were in present tense (assuming *gotta* as present tense), and they were not negated; thus the prototype was things like *I wanna play ball*, *I hafta do that*, and *I gotta go*.

From age 2 to age 5, these children's growing linguistic sophistication with this class of constructions was manifest in three main ways. First, their use of the semi-modals became less formulaic and more diverse, so that they now included third-person subjects (e.g., "Dolly wanna drink that") and negatives (e.g., "I don't like to do all this work"). Second, they learned a wider range of matrix verbs, including such things as *forget* (e.g., "I forgot to buy some soup") and *say* (e.g., "The doctor said to stay in bed all day"). Third, the children learned more complex constructions with an NP between the two verbs. As in Bloom et al.'s study, these first emerged at around 2;6 to 3;0, and were dominated by four matrix verbs that accounted for 88% of all the utterances of this type:

<i>See X VERB-ing</i>	<i>Want X to VERB</i>
<i>Watch X VERB-ing</i>	<i>Make X VERB</i>

After 3 years of age, other matrix verbs representing a more diverse set of constructions emerged. In general, Diessel found a developmental progression from constructions in which the matrix verb and main verb were more tightly integrated—utterances with the semi-modals *wanna*, *hafta*, and *gotta*—to those in which the two verbs were more distinct, as in the constructions with an intervening NP, and two full propositions were expressed.

Sentential Complement Constructions

Whereas many of the most common matrix verbs with infinitival complements are generally similar to deontic modals (*should*, *must*) in their concern with purpose/intention/compulsion, many of the most common matrix verbs with sentential complements are similar to epistemic modals (*may*, *might*) in their concern with certainty/perception/knowledge. But again, the matrix verbs in sentential complements—such things as *think*, *know*, *believe*, *see*, *say*—are not modal auxiliaries but tensed verbs. In addition, and in contrast to infinitival complements, the second clause in sentential complement constructions is also a fully tensed clause with an overt subject (i.e., it is a fully independent clause). The prototype, then, is utterances like “I know she hit him” and “I think I can do it.” Once again, the classic studies are by Limber (1973) and Bloom and colleagues (Bloom, Rispoli, Gartner, & Hafitz, 1989), who found that sentential complement constructions emerged later than infinitival complement constructions, typically between 2;6 and 3;0. They also found that the earliest verbs used in these constructions were a very delimited set, mainly *think*, *know*, *look*, and *see*.

Diessel and Tomasello (2001) looked at young English-speaking children’s earliest utterances with sentential complements from 2 to 5 years of age. They found that virtually all of them were composed of a simple sentence schema that the child had already mastered combined with one of a delimited set of complement-taking matrix verbs (see also Bloom, 1992). These matrix verbs were of two types. First were epistemic verbs such as *think* and *know*. As one example, in almost all cases, children used *I think* to indicate their own uncertainty about something, and they basically never used the verb *think* in anything but this first-person, present tense form; that is, there were virtually no examples of *He thinks . . .*, *She thinks . . .*, and so on, virtually no examples of *I don’t think . . .*, *I can’t think . . .*, and so on, and virtually no examples of *I*

thought . . ., *I didn’t think . . .*, and so on. And there were almost no uses with a complementizer (virtually no examples of *I think that . . .*). It thus appears that for many young children, *I think* is a relatively fixed phrase meaning something like *Maybe*. The child then pieces together this fixed phrase (or one of the other similar phrases like *I hope . . .*, *I bet . . .*, etc.) with a full proposition, with its function being as a sort of evidential marker (not as a matrix clause that embeds another as in traditional analyses). The second kind of matrix verbs were attention-getting verbs like *look* and *see*, used in conjunction with full finite clauses. In this case, children used these matrix verbs almost exclusively in imperative form (again almost no negations, no nonpresent tenses, no complementizers), suggesting again an item-based approach not involving syntactic embedding. Thus, when examined closely, children’s earliest complex sentences look much less like adult sentential complements (which are used most often in written discourse) and much more like various kinds of pastiches of established item-based constructions.

Relative Clause Constructions

Relative clauses are not like complement clauses because they do not involve coordination with a main clause at all. Rather, relative clauses serve the very different function of specifying noun phrases in detail. Textbook descriptions focus on so-called restrictive relative clauses; for example, “The dog that barked all night dies this morning,” in which the relative clause serves to identify a noun by using presupposed information (both speaker and listener already know that there was barking all night; that’s why it can be used as identifying information). Because relative clauses are a part of a noun phrase argument, they are classically characterized as embedded clauses, and so they have attracted much research attention in both linguistics and developmental psycholinguistics.

The largest study of children’s acquisition of relative clauses is by Diessel and Tomasello (2000), who studied four English-speaking children between ages 1;9 and 5;2 in quantitative detail. In this study, they made a surprising discovery: virtually all of these children’s earliest relative clauses were of the same general form, and this form was not the form typically described in textbooks. Examples would be:

Here’s the toy that spins around.

That’s the sugar that goes in there.

What is noteworthy here is (a) the main clause is a presentational construction (predicate nominal or closely related), basically introducing a new topic using a pro-form (*here, that*) and the copula (-'s); and (b) the information in the relative clause is not presupposed, as in textbook (restrictive) relative clauses, but rather is new information about the just-introduced referent. The main point is that even this very complex construction is firmly based in a set of simpler constructions (copular presentationals) that children have mastered as item-based constructions some time before relative clauses are first acquired and produced.

PROCESSES OF LANGUAGE ACQUISITION

From a cognitive science point of view, the central issue in the study of language development is the nature of children's underlying linguistic representations and how these change during ontogeny. Summarizing all that has gone before in this chapter, we now address directly these two issues.

The Growing Abstractness of Constructions

Based on all the available evidence, it would appear that children's early linguistic representation are highly concrete, based in concrete and specific pieces of language not in abstract categories (although they have some open slot-filler categories as well). We have cited: (a) analyses of children's spontaneous productions showing very restricted ranges of application of many early linguistic items and structures, asynchronous development of item-based constructions that from an adult point of view should have similar structures, and gradual and continuous development within specific item-based structures; (b) production experiments in which young children use nonce verbs in the way adults have used them, failing to generalize them to other of their existing constructions—suggesting that these existing constructions are item-based and not verb-general; and (c) comprehension experiments in which young children, who know the activity they are supposed to act out in response to a nonce verb, fail to assign the correct agent-patient roles to the characters involved based on canonical word order cues (in English)—again suggesting that their constructions at this point are item-based and not totally general.

There is one other recent finding that supports this same conclusion further. Savage, Lieven, Theakston, and Tomasello (2003) primed English-speaking children with either active or passive sentences, in some cases with high lexical overlap between the priming sentence and the sentence the child was likely to produce (i.e., the prime used some pronouns and grammatical morphemes that the child could use in her target utterance even though different objects and actions were involved) and in some cases with very low lexical overlap (i.e., the prime used only nouns, which the child could not use in her target utterance since different objects were involved). In some ways, this method could be considered the most direct test yet of children's early syntactic representations because successful priming in the high lexical overlap condition would suggest that their linguistic knowledge is represented more in terms of specific lexical items, whereas priming in the low lexical overlap condition would suggest that their linguistic knowledge is represented more abstractly. The answer is that the older children, around 6 years of age, could be structurally primed to produce a particular construction such as the passive. The younger children, who had just turned 3 years old, could not be primed structurally; but they were primed by the more lexically specific primes. Four-year-old children fell somewhere in between these two extremes. So once more—in this case using a very different method, widely accepted in the adult psycholinguistic community—we find that children's early linguistic representations are very likely based in specific item-based constructions (with some abstract slots), and it is only in the late preschool period that their utterance-level constructions take on adultlike abstractness.

But rather than thinking of children's utterance-level constructions as either concrete or abstract, it is probably better to think of them as growing gradually in abstractness over time as more and more relevant exemplars are encountered and assimilated to the construction. One reasonable interpretation of all of the studies directly aimed at children's underlying linguistic representation—as reviewed here—is thus as follows. From about 2 or 2½ years of age children have only very weak verb-general representations of their utterance-level constructions, and so these show up only in preferential looking tasks that require weak representations. But over the next months and years, their linguistic representations grow in strength and abstractness, based on both the type and token frequency with which they hear certain linguistic structures. These now begin to show

themselves in tasks requiring more active behavioral decision making or even language production requiring require stronger representations. This hypothesis is in the general spirit of a number of proposals suggesting that, if cognitive representations retain information about the variety of individual instances, they may be felicitously described as being either weaker or stronger based mainly on their type and token frequency (e.g., Munakata et al., 1997). It is also consonant with the view that linguistic knowledge and linguistic processing are really just different aspects of the same thing. Thus, things like frequency and the probabilistic distribution of lexical items in the input not only play a crucial role in how children build up their linguistic representations, but also form an integral part of those representations in the end state (see the papers in Barlow & Kemmer, 2000; Elman et al., 1996).

Psycholinguistic Processes of Development

In accounting for how children learn linguistic constructions and make generalizations across them, we have argued and presented evidence for the operation of certain general cognitive processes. Tomasello (2003) argues that we may segregate these into the two overall headings: intention-reading, comprising the species-unique social cognitive skills responsible for symbol acquisition and the functional dimensions of language; and pattern-finding, the primate-wide cognitive skills involved in the abstraction process. More specifically, these two kinds of general cognitive abilities interact in specific acquisition tasks to yield the processes we have outlined in various places previously. Thus, we have previously made reference to four specific sets of processes:

1. Intention-Reading and Cultural Learning, which account for how children learn linguistic symbols in the first place (discussed here very little).
2. Schematization and Analogy, which account for how children create abstract syntactic constructions (and syntactic roles such as subject and direct object) out of the concrete pieces of language they have heard.
3. Entrenchment and Competition, which account for how children constrain their abstractions to those that are conventional in their linguistic community.
4. Functionally Based Distributional Analysis, which accounts for how children form paradigmatic categories of various kinds of linguistic constituents (e.g., nouns and verbs).

These are the processes by which children construct a language, that is, a structured inventory of linguistic constructions. For a full account, we also need to look briefly at the processes by which children actually produce utterances. By way of summary, we look at each of these processes in turn.

Intention-Reading and Cultural Learning

Because natural languages are conventional, the most fundamental process of language acquisition is the ability to do things the way that other people do them, that is, social learning broadly defined. The acquisition of most cultural skills, including skills of linguistic communication, depend on a special type of social learning involving intention-reading that is most often called cultural learning, one form of which is imitative learning (Tomasello, Kruger, & Ratner, 1993). This can be seen most clearly in experiments in which young children reproduce an adult's intended action even when she does not actually perform it (Meltzoff, 1995) and in which they selectively reproduce only an adult's intentional, but not accidental, actions (Carpenter, Akhtar, & Tomasello, 1998a). To make matters more complicated, the acquisition of language involves the imitative learning of adult behaviors expressing not just simple intentions but communicative intentions (roughly, intentions toward my intentions). Children's ability to read and learn the expression of communicative intentions can be seen most clearly in word-learning studies in which young children have to identify the adult's intended referent in a wide variety of situations in which word and referent are not both present simultaneously (Tomasello, 2001).

In human linguistic communication, the most fundamental unit of intentional action is the utterance as a relatively complete and coherent expression of a communicative intention, and so the most fundamental unit of language learning is stored exemplars of utterances. This is what children do in learning holophrases and other concrete and relatively fixed linguistic expressions (e.g., *Thank you*, *Don't mention it*). But as they are attempting to comprehend the communicative intention underlying an utterance, children are also attempting to comprehend the functional roles being played by its various components. This is a kind of "blame assignment" procedure in which the attempt is to determine the functional role of a constituent in the communicative intention as a whole—what we have called segmenting communicative intentions. Identifying the functional roles of the components of utterances is only possible if

the child has some (perhaps imperfect) understanding of the adult's overall communicative intention—because understanding the functional role of X means understanding how X contributes to some larger communicative structure. This is the basic process by means of which children learn the communicative functions of particular words, phrases, and other utterance constituents and, with help from pattern-finding skills, categories of these terms.

Schematization and Analogy

Young children hear and use, on a numbingly regular basis, the same utterances repeated over and over but with systematic variation, for example, as instantiated in item-based schemas such as *Where's-the X?*, *I wanna X*, *Let's X*, *Can you X?*, *Gimme X*, *I'm Xing it*. Forming schemas of this type means imitatively learning the recurrent concrete pieces of language for concrete functions, as well as forming a relatively abstract slot designating a relatively abstract function. This process is called schematization, and its roots may be observed in various primates who schematize everything from food-processing skills (Whiten, 1998) to arbitrary sequences in the laboratory (Conway & Christiansen, 2001).

The variable elements or slots in linguistic schemas correspond to the variable item of experience in the referential event for which that schema is used. Thus, in *Where's-the X*, the speaker's seeking is constant across instances but the thing being sought changes across situations; in *I'm Xing it*, the acting on an object is constant but the particular action varies. The communicative function of the item in a slot is thus constrained by the overall communicative function of the schema, but it is still somewhat open; it is a slot-filler category in the sense of Nelson (1985). This primacy of the schema leads to the kinds of functional coercion evidenced in creative uses of language in which an item is used in a schema that requires the listener to interpret that item in an unusual way; for example, under communicative pressure a child might say something like "Allgone sticky," as she watches Mom wiping candy off her hands.

One special form of schematization is analogy, or alternatively, we might say that one special form of analogy is schematization. Both exemplify the process by which children try to categorize, in the general sense of this term, whole utterances and/or significant other linguistic constructions (e.g., nominals). In general, we may say that an analogy can be made only if there is some understanding of the functional interrelations of

the component parts of the two entities to be analogized across. In the case of syntactic constructions, analogies are made not on the basis of surface form but on the basis of the functional interrelations among components in the two constructions being analogized. Thus, the *X is Y-ing the Z* and the *A is B-ing the C* are analogous because the same basic relational situation is being referred to in each case; and X and A play the role of actor, Y and B the activity, and Z and C the undergoer. In this way, different constructions develop their own syntactic roles, first locally in item-based constructions (e.g., "thrower" and "thing thrown"), and then more globally in abstract constructions (e.g., transitive-subject, ditransitive-recipient). There may even emerge late in development, in some languages, a super-abstract subject-predicate construction containing an abstract syntactic role such as "subject" more generally, based on abstractions across various abstract constructions. Perceptual similarity (or even identity) of the objects involved in analogies, while not strictly necessary, does in many cases facilitate human beings in their attempts to make analogies (the study of Childers & Tomasello, 2001, provides support for this hypothesis). If so, this explains why children begin by schematizing across utterances with common linguistic material. Thus they create item-based constructions before they attempt to make totally abstract analogies based on a structure-mapping that involves little or no common linguistic material across utterances.

An important part of item-based and abstract constructions is various kinds of syntactic marking, specifically indicating the syntactic roles that participants are playing in the scene or event as a whole. Special symbols such as case markers and word order are the most common devices that languages use in general to mark the basic "who's doing what to whom" of an utterance. This kind of marking of roles may be thought of as the use of second-order symbols, since the function of the markers is to indicate how the linguistic items they mark should be construed in the meaning of the utterance as a whole.

Entrenchment and Preemption

There must be constraints to schematization and analogy, and these are provided by entrenchment and pre-emption. Entrenchment simply refers to the fact that when an organism does something in the same way successfully enough times, that way of doing it becomes habitual and it is very difficult for another way of doing that same thing to enter into the picture. Preemption, or

contrast, is a communicative principle of roughly the form: If someone communicates to me using Form X, rather than Form Y, there was a reason for that choice related to the speaker's specific communicative intention. This motivates the listener to search for that reason and so to distinguish the two forms and their appropriate communicative contexts. Together, entrenchment and preemption may be thought of as a single process of competition in which the different possible forms for effecting different classes of communicative functions compete with one another based on a number of principles, including frequency/entrenchment.

It is nevertheless true that we know very little about the specifics of how all this works. Thus, we know very little about the nature and frequency of the syntactic overgeneralization errors that children make at different developmental periods. Further, there is only one empirical study evaluating the effectiveness of entrenchment in preventing syntactic overgeneralizations (Brooks et al., 1999), and that study has no direct measures of the exact frequency of the verbs involved. Similarly, there is only one study of preemption and of semantic classes of verbs as constraining factors (Brooks & Tomasello, 1999a), and this study worked with only a narrow range of structures and verbs. And so, until we actually do some of the empirical work necessary to see how these general principles are applied to specific linguistic items and structures in specific languages, we will still be doing a fair amount of hand waving about how children make exactly the generalizations they do and not others. But of course it must be added that generative approaches engage in a fair amount hand waving themselves in appealing to abstract principles of universal grammar to constrain children's generalizations as well.

Functionally Based Distributional Analysis

Paradigmatic categories such as noun and verb provide language learners with many creative possibilities because they enable learners to use newly learned items in the way that other similar items have been used in the past—with no direct experience. These categories are formed through a process of functionally based distributional analysis in which concrete linguistic items (e.g., words or phrases) that serve the same communicative function in utterances and constructions over time are grouped together into a category. Thus, noun is a paradigmatic category based on the functions that different words of this type serve within nominal constructions—with related categories being such things as pronouns and common nouns, based on the related but different

functions these perform. Paradigmatic categories are thus defined in functional terms by their distributional-combinatorial properties: Nouns are what nouns do in larger linguistic structures. This provides the functional basis by means of which these paradigmatic linguistic categories cohere.

It is important to emphasize that this same process of functionally based distributional analysis also operates on units of language larger than words. For example, what is typically called a noun phrase may be constituted by anything from a proper name to a pronoun to a common noun with a determiner and a relative clause hanging off it. But for many syntactic purposes, these may all be treated as the same kind of unit. How can this be, given their very different surface forms? The only reasonable answer is that they are treated as units of the same type because they all do the same job in utterances: They identify a referent playing some role in the scene being depicted. Because of the varying form of the nominals involved, it is difficult to even think of an alternative to this functionally based account.

Categorization is one of the most heavily researched areas in the cognitive sciences, including developmental psychology. But how children form categories in natural languages—a process of grouping together, not items of perceptual or conceptual experience, but rather items used in linguistic communication—has been very little investigated. The arguments made here suggest that future research on children's skills of linguistic categorization should focus on communicative function as an essential element analogous to the focus on function in the work of Nelson and Mandler on event categories and slot-filler categories in nonlinguistic domains. It is only by investigating how children identify and equate the functional roles linguistic items play in the different constructions of which they are a part that we will discover how children build the abstract categories responsible for so much of linguistic creativity.

Production

If children are not putting together creative utterances with meaningful words and meaningless rules, then how exactly do they do it? In the current view, what they are doing is constructing utterances out of various already mastered pieces of language of various shapes, sizes, and degrees of internal structure and abstraction—in ways appropriate to the exigencies of the current usage event. To engage in this process of symbolic integration, in which the child fits together into a coherent whole such things as an item-based construction and a novel item to

go in the slot, the child must be focused on both form and function. The growth of working memory is an integral part of this process (Adams & Gathercole, 2000).

Lieven, Behrens, Speares, and Tomasello (2003) recorded a 2-year-old child learning English using extremely dense taping intervals: 5 hours per week for 6 weeks. To investigate this child's constructional creativity, all her utterances produced during the last one-hour taping session at the end of the 6-week period were designated as target utterances. Then, for each target utterance, there was a search for similar utterances produced by the child (not the mother) in the previous 6 weeks of taping. The main goal was thus to determine for each utterance recorded on the final day of the study what kinds of syntactic operations were necessary for its production, that is to say, in what ways did the child have to modify things she had previously said (her stored linguistic experience) to produce the thing she was now saying. We may call these operations *usage-based syntactic operations* since they explicitly indicate that the child does not put together each of her utterances from scratch, morpheme by morpheme, but rather, she puts together her utterances from a motley assortment of different kinds of preexisting psycholinguistic units.

What was found by this procedure was that (a) about two-thirds of the multiword utterances produced on the target day were exact verbatim repetitions of utterances the child had said before (only about one-third were novel utterances); (b) of the novel multiword utterances, about three-quarters consisted of repetition of some part of a previously used utterance with only one small change, for example, some new word was filled into a slot or added on to the beginning or end. For example, the child had said many hundreds of times previously *Where's the _____?* and on the target tape she produced the novel utterance *Where's the butter?* The majority of the item-based, utterance-level constructions that the child used on the last day of the study had been used by the child many times during the previous 6 weeks; (3) only about one-quarter of the novel multiword utterances on the last tape (a total of 5% of all utterances during the hour) differed from things this child had said before in more than one way. These mostly involved the combination of filling in and adding onto an established utterance-level construction, but there were several utterances that seemed to be novel in more complex ways.

It is important to note that there was also very high functional consistency across different uses of this child's utterance-level constructions, that is, the child filled a given slot with basically the same kind or kinds

of linguistic items or phrases across the entire 6-week period of the study. Based on these findings, we might say that children have three basic options for producing an utterance on a particular occasion of use (1) they might retrieve a functionally appropriate concrete expression and just say it as they have heard it said; (2) they might retrieve an utterance-level construction and simultaneously "tweak" it to fit the current communicative situation by filling a new constituent into a slot in the item-based construction, adding a new constituent onto the beginning or end of an utterance-level construction or expression, or inserting a new constituent into the middle of an utterance-level construction or expression; or (3) they might produce an utterance by combining constituent schemas without using an utterance-level construction on the basis of various kinds of pragmatic principles governing the ordering of old and new information.

These processes of utterance production may be called usage-based syntactic operations because the child does not begin with words and morphemes and glue them together with contentless rules; rather, she starts with already constructed pieces of language of various shapes, sizes, and degrees of abstraction (and whose internal complexities she may control to varying degrees), and then "cuts and pastes" these together in a way appropriate to the current communicative situation. It is important to note in this metaphor that to cut and paste effectively, a speaker is always making sure that the functions of the various pieces fit together functionally in the intended manner—one does not cut and paste indiscriminately in a word-processing document but in ways that fit. These processes may also work at the level of utterance constituents and their internal structure.

Individual Differences

Most of the work on individual differences in language development has focused on vocabulary. Individual differences in grammar, the learning of constructions, is much less well-documented. But there is at least some interesting work on individual differences in both the rate and the style of early grammatical development (see Bates et al., 1988, and Lieven, 1997, for overviews).

Rate

There are several widely used standardized instruments for measuring the rate of children's grammatical development (often in clinical settings), but they are fairly

labor intensive and require linguistically sophisticated researchers. Consequently, there is only one that has been used to conduct large-scale norming studies and that is the MacArthur Communicative Development Inventory (MCDI; Fenson et al., 1994), which is basically a standardized parent interview. The section of the instrument that deals with grammar asks parents to mark on a computerized form which of two alternatives “sounds most like the way your child talks right now.” For example, parents are asked to choose between *Baby crying* and *Baby is crying* or between *I like read stories* and *I like to read stories* or between *I want that* and *I want the one you got* or between *I no do it* and *I can't do it*.

Fenson et al. (1994) conducted a large-scale norming study with the MCDI with over 1,000 English-speaking children from 16 to 30 months of age. Giving a score of 1 for the more sophisticated alternative of each pair (and 0 for the less sophisticated), they found that at 24 months of age 25% of English-speaking children obtain a score of 2 or less, whereas another 25% obtain a score of 25 or more (out of a total possible 37). At 30 months of age, the lowest 25% of the children scored 15 or below, whereas the highest 25% were basically at ceiling with a score of 36 or greater. To the extent that this “quick and dirty” assessment is accurate (and the score children obtain correlates well with their grammatical sophistication as scored by more complex methods in the laboratory), we can see that children’s grammatical skills are extremely highly variable for the first 2½ years of life at the very least.

Explanations for this variability basically fall into two categories. On the one hand, it may be that some children are more efficient learners than others. For example, girls consistently score slightly higher than boys on the MCDI as a whole, and this may be because they are better language learners. There also some very interesting data showing that children with larger working memories seem to learn and process language more efficiently (Adams & Gathercole, 2000). But in general, we have very little information on specific child variables that may be responsible for individual differences in typically developing children in the domain of grammar.

On the other hand, we have very large amounts of data demonstrating that the language learning environment in which children grow up is responsible for at least some of the individual differences in rate of development. Nelson (1977) found that providing young children with extra exemplars of some complex syntactic constructions facilitated their acquisition of those con-

structions. Similarly, the training study of Childer’s and Tomasello (2001), described earlier, also demonstrated that a large number of exemplars of a syntactic construction given to children over a short period can facilitate their acquisition of that construction quite dramatically. And Huttenlocher, Vasilyeva, Cymerman, and Levine (2003) have found that children’s mastery of complex constructions (multiclause sentences) are strongly related not only to the frequency with which their parents use these constructions, but also to the frequency with which their teachers at school use these constructions (thus diminishing the plausibility of shared genetics between parent and child as an explanation for the parent-child correlations).

But it is not only the quantity of language that children hear that affects their language development, in some cases, it is also the quality of that language. For example, Farrar (1990, 1992) found that children’s acquisition of some particular grammatical morphemes in English (e.g., past tense *-ed*, plural *-s*, and progressive *-ing*) was facilitated when mothers used these morphemes as immediate recasts of the child’s utterances that were missing them; for example, the child might say “I kick it” and the mother might reply “Yes, you kicked it.” Adult conversational replies that maintain the child’s topic and to some extent her meaning, while at the same time recasting it into a more adultlike form, are thought to be especially important in helping children to identify grammatical elements with low salience since they provide them with an immediate comparison of their own immature utterance and the corresponding full adult form with full morphology and grammar (Nelson, 1986).

Style

Nelson (1973) proposed that some children acquire linguistic competence by focusing mostly on words, whereas others acquire their language by focusing more on larger phrases and fixed expressions such as *Gimme dat*. She called the first type of learner “referential” and the second type “expressive” (Bates et al., 1988, called the first type of learner “analytic” and the second type “holistic”). As a dichotomous classification, this typology has not fared well empirically, as most children acquire both words and larger phrases/expressions simultaneously. However, there does seem to be a continuum such that some children seemed to acquire large vocabularies before they produce longer sentences, whereas other children produce seemingly longer ex-

pressions (whose internal structure they may or may not understand) from early in development (Lieven, 1997).

The factors responsible for such individual differences in language acquisition style are not known. Noting that there are also individual differences that may be characterized as analytic-holistic in human visual information processing, Bates et al. (1988) speculated that perhaps some children may be more inclined toward analytic or holistic processing strategies naturally. Also interesting is the possibility that some children are naturally greater risk takers than others, and so attempt longer utterances with less well-developed skills than others (Dale & Crain-Thoreson, 1993, report that it is more advanced children that tend to make *I-you* reversal errors, perhaps because they are greater risk takers). On the other hand, there is some evidence that later-born children tend to adopt more holistic strategies; it is therefore possible that being exposed to more third-party, child-directed speech (i.e., as parents talk to the sibling) plays some role (Barton & Tomasello, 1994). It is also possible that experiencing language mostly in imperative utterances also tends to make children more holistic learners (Barton & Tomasello, 1994).

Atypical Development

Because language is such a complicated phenomenon, it can go wrong in many different ways. The scientific study of atypical language development has for the most part focused on four developmental disorders that have serious consequences for language acquisition: Down syndrome, Williams syndrome, autism, and specific language impairment. Although there is much clinical literature focused on issues of language diagnosis and assessment for all of these groups, there is actually surprisingly little basic research on the process of grammatical development in any of them.

Down Syndrome

Children with Down syndrome are significantly delayed in their grammatical development. And it is not just an overall delay; they produce simpler and shorter sentences than typically developing children and Williams syndrome children who have the same vocabulary size (Singer et al., 1994, as cited in Tager-Flusberg, 1999). Most Down syndrome children never master truly complex syntactic constructions involving sentence embedding and the like (Fowler, 1990), even though significant

gains in language development continue to occur in many of these children well into adolescence (Chapman, Schwartz, & Kay-Raining Bird, 1991).

Although not enough research has been done to be sure, it would seem that the main problem of children with Down syndrome is a cognitive one. They have a number of cognitive weaknesses—many but not all of which show up on standard IQ tests—that might plausibly be linked to their delayed language development. In particular, although no experiments have been done, there is some suggestive correlational evidence that the specific problem, or at least one specific problem, may be with working memory in the auditory domain (Jarrold, Baddeley, & Phillips, 2002; Laws & Gunn, 2004).

Williams Syndrome

Children with Williams syndrome also have a number of cognitive deficits—some but not all of which show up on standard IQ tests—especially in the domain of spatial perception and cognition (Mervis, Morris, Bertrand, & Robinson, 1999). Although initial reports suggested that these children might nevertheless have relatively normal language development (e.g., Bellugi, Marks, Bahrle, & Sabo, 1988), more recent research demonstrates that they do indeed have significantly delayed syntactic development in general, with the majority of Williams children never able to correctly understand complex syntax such as sentence embedding (Karmiloff-Smith et al., 1998; Mervis et al., 1999).

One reason why Williams syndrome children were originally thought to have such amazing syntactic skills is because in the original studies they were compared to children with Down syndrome, and as noted, these children have syntactic development that is poorer than would be expected from their vocabulary sizes. Williams syndrome children, on the other hand, have syntactic development that is accurately predicted both by their vocabulary size and by their mental age as assessed by IQ tests (see Tager-Flusberg, 1999, for a review). In addition, just as for children with Down syndrome, there is correlational evidence for children with Williams syndrome that a specific cognitive problem contributing to their language delay is auditory working memory (Mervis et al., 1999).

Children with Autism

Autism is a disorder less of general cognition than of social cognition and social relations. It is thus not surprising that about half of all children with autism do not

have the social-cognitive and communication skills necessary to acquire any serviceable language, and those who do almost invariably have abnormal pragmatic skills. In a study looking at standardized language scores for young adults with autism who used some language, Howlin, Goode, Hutton, and Rutter (2004) found that 44% had a language age below 6 years; 35% scored within the 6- to 15-year range; and only 16% scored above the 15-year level.

The grammatical development of those children with autism who do speak has been very little studied, but it is clear that it is significantly delayed (Tager-Flusberg et al., 1990). When sentences of equal length are compared between children with autism and typically developing children, the sentences of children with autism are significantly less complex syntactically (Scarborough et al., 1991). The most plausible explanation for this finding is that children with autism are highly echolalic/imitative/repetitive. They have quite a bit of formulaic speech, which makes them appear more syntactically competent than they really are (Tager-Flusberg & Calkins, 1990), although these researchers did not find that sentences which were immediate repetitions of adult utterances were syntactically more complex than spontaneously produced sentences). In general, there are very few studies of grammatical development in children with autism, and no studies of older children involving complex syntax.

Specific Language Impairment

The diagnosis specific language impairment (SLI) is intended to identify children who have language problems but no other obvious cognitive or social-cognitive deficits (including no problems with hearing). This means that children with this diagnosis actually form a fairly heterogeneous group, whose only commonality is that their language development gets off to a fairly slow start and continues to be an area of weakness. There are no widely accepted subgroupings of children with SLI, but some researchers refer to a minority of these children as having pragmatic language impairment (PLI), which resembles autism in some ways (Bishop, 1997). More commonly, researchers refer to expressive SLI and expressive-receptive SLI, with the most severe problems associated with the latter diagnosis which involves problems of language comprehension.

Although not typically detectable on IQ tests, it turns out that SLI children, or at least some of these children, quite often have relatively subtle perceptual or cognitive

deficits of one kind or another (Leonard, 1998, chaps. 5 and 6). Thus, a possible problem for some SLI children is in processing speech, that is, in dealing with the rapid vocal-auditory sequences that make up complex sentences (Tallal, 2000). This can often result in problems specifically with grammatical morphology, which is often of low perceptual salience in the speech stream (Leonard et al., 2003). Also, there is very good recent evidence that, like many children with atypical language development, some of SLI children's problems with language may derive from problems with auditory working memory (Bishop, North, & Donlan, 1996; Conti-Ramsden, 2003; Gathercole & Baddeley, 1990).

CONCLUSIONS

Acquiring a language is one of the most complicated tasks facing developing children. To become competent users of natural language, children must, at the very least, be able to comprehend communicative intentions as expressed in utterances; segment communicative intentions and ongoing speech and so extract individual words from these utterances; create linguistic schemas with slots; mark syntactic roles in item-based constructions; form abstract constructions across these schemas via analogy; perform distributional analyses to form paradigmatic categories; learn to take their current listener's perspective into account in both forming and choosing appropriately among conventional nominal and clausal constructions; learn to comprehend and express different modalities and negation (speaker attitude); acquire competence with complex constructions containing two or more predicates; learn to manage conversations and narratives, keeping track of referents over long stretches of discourse; cut and paste together stored linguistic units to produce particular utterances appropriate to the current communicative context; and on and on.

There are no fully adequate theoretical accounts of how young children do all of this. One problem has been that quite often the study of language acquisition has been cut off from the study of children's other cognitive and social skills with linguistic theories that barely make reference to these other skills. But in the current view, our best hope for unraveling some of the mysteries of language acquisition rests with approaches that incorporate multiple factors, that is, with approaches that incorporate not only some explicit lin-

guistic model, but also the full range of biological, cultural, and psycholinguistic processes involved. Specifically, it has been argued here that children need to be able (a) to read the intentions of others to acquire the productive use of meaningful linguistic symbols and constructions and (b) to find patterns in the way people use symbols and thereby to construct the grammatical dimensions of language. The outstanding theoretical question in the field is whether, in addition, children's language learning also incorporates an innate universal grammar and, if so, what functions this additional element might serve.

In the meantime, there is much to be done empirically. We know very little about how children segment the communicative intentions behind utterances into their subcomponents. We know very little about how children form analogies across complex linguistic constructions. Perhaps the weakest part of all theories of language acquisition is how children come to constrain the generalizations that they make to just those generalizations that are conventional in their linguistic community. And how children use their mind-reading skills to take into account listener perspective is only now being seriously studied. The utterance production process is also one that requires much more intensive investigation. In general, the way forward in the study of language acquisition involves both more intensive empirical investigations of particular phenomena and more breadth in the range of theoretical and methodological tools utilized.

EARLY WORD LEARNING: THE GATEWAY BETWEEN LINGUISTIC AND CONCEPTUAL ORGANIZATION

Word learning, perhaps more than any other developmental achievement, stands at the very crossroad of human conceptual and linguistic organization (P. Bloom, 2000; S. A. Gelman, Coley, Rosengren, Hartman, & Pappas, 1998; Hollich, Hirsh-Pasek, & Golinkoff, 2000; Waxman, 2002; Woodward & Markman, 1998). Like Janus, the two-headed Roman god of beginnings, word learners must set their sights in two distinct directions. Facing the conceptual domain, infants form core *concepts*¹ to capture the relations among the objects and

The National Institutes of Health (HD-28730 and DC-006829 to the first and second authors, respectively), the National Science Foundation (BCS-0418309 to the second author), and the CNRS (Paris) provided support for this chapter. We are grateful to A. Booth, D. G. Hall, T. Lavin, E. Leddon, and the editors of this volume for comments on earlier versions.

¹We use the term *concept* to refer to a symbolic mental representation. For the concepts considered in this chapter (e.g., DOG or FURRY), the extension of that representation include

events that they encounter. Facing the linguistic domain, infants cull *words* and *phrases* from the melody of the human language in which they are immersed. Even before they take their first steps, infants make important advances in each of these domains. And perhaps even more remarkably, recent evidence reveals that from the onset of word learning, infants' advances in the conceptual and linguistic domains are powerfully linked.

Janus was known to the Romans not only as the god of beginnings, but also as the guardian of gateways and transitions. Like Janus, young word learners stand at an important gateway. Across the world's communities, infants' first words are greeted with a special joy because they mark infants' entrance into a truly symbolic system

individual instances that the infant has encountered (e.g., her own pet dog; its furry tail). The representation must also be sufficiently abstract to include in its extension (at least some) instances that she has not encountered (e.g., my dog; her furry ears). Used in this way, the term *concept* refers to an abstract mental representation that may be built up from infants' direct experiences and whose semantics may be organized around various kinds of relations, including category-based, property-based, or action-based commonalities.

of social commerce. In acquiring their first words, infants acquire much more than a symbolic means of reference. Word learning serves as a gateway into the fundamental social, conceptual, and linguistic abilities that are the hallmark of the human mind. From a social perspective, word learning permits infants to apprehend and to influence the contents of other minds. From a conceptual perspective, word learning supports the evolution of the increasingly abstract and flexible mental representations that are the signature of the human conceptual system. There is no doubt that other species of animals also have sophisticated social and conceptual abilities (see Cole, Chapter 15, this *Handbook*, this volume). But in the human, these systems stand out for their flexibility, force, and inductive strength; and each of these is supported strongly by language. As will become apparent as the chapter unfolds, word learning both contributes to and is supported by infants' discovery of the fundamental syntactic and semantic properties of human language, and the interactions among these.

Just as young word learners are faced with the task of pulling together their knowledge with the linguistic and conceptual domains, our goal in this chapter is to bring together two distinct intellectual traditions—generative linguistics and cognitive psychology—within a distinctly developmental framework. In wedding these two disciplines, our primary aim is to highlight synergies between them and to forge a path for new investigations that take advantage of the contributions of each. We therefore focus on those facets of word learning where the two intellectual traditions come together most richly, which leads us to focus primarily on how the links between the conceptual and linguistic systems evolve. More specifically, we consider the developmental trajectory of several kinds of words (e.g., nouns, adjectives, verbs) and how they become linked to meaning. We acknowledge that one grammatical form—*noun*—has held a privileged position, dominating both the infants' early lexicon and the developmental research agenda. But we also point out that nouns are not, in fact, the paradigm case for word learning. After underscoring the central role played by nouns in acquisition, we move on to highlight the very different conceptual entailments and linguistic requirements underlying the acquisition of other grammatical forms, including adjectives and verbs.

The Puzzle of Word Learning

In the course of their daily lives, human infants naturally find themselves in situations in which an individual

(perhaps a parent or an older sibling) gazes at an ongoing stream of activity (perhaps a puppy playing in a park) and utters a string of words (perhaps “Look at that adorable puppy! He's running away! Let's go find its mommy”). To successfully learn a word (e.g., *puppy*) from this (indeed from any) context, infants must (a) identify the relevant entity from the ongoing stream of activity (focusing in this case on the puppy and not the act of running, etc.), (b) parse the relevant piece of sound (*pup'ē*) from the ongoing stream of continuous speech, and (c) establish a mapping between that entity and that sound.

At first glance, this appears to be straightforward. After all, don't we essentially solve the puzzle for infants when we focus their attention on the object of interest while introducing its name? Certainly, adults may strive to teach words in this way, and they apparently do so more in some cultural communities than in others (cf. Hoff, 2002; Ochs & Schieffelin, 1984). However, a closer look reveals that word-learning tutorials like these are the exception instead of the rule. To begin, many words, even in infant-directed speech, do not refer to an object or to anything else that we can point to (e.g., “He's *running* away!” or “*No!*”). And even for words that do refer, the referent is often absent at the time of the naming episode (e.g., “Time to go get your *sister*,” “Where'd your *mom* put your *shoes*?” or “You really need a *nap*”).

Even in the most straightforward tutorials, when the word has a referent and the referent is present throughout the naming episode, matters are not so simple. Successful word learning requires that the learner map a word (e.g., *puppy*) to a concept (PUPPY),² and this means extending that word systematically beyond the individual(s) with which the word was initially introduced.³ In our example, this means extending the word *puppy* to certain other objects (other puppies), but excluding all the rest (kitties, adult dogs, bunnies, and televisions).

²Throughout this chapter, we use the following typographical conventions: italics = refer to a word, small capitals = refer to a concept.

³There is one special class of word—the proper noun (e.g., *Lassie*)—whose function is to pick out a distinct individual (e.g., the dog *Lassie*). However, two points bear mentioning. First, these words do refer to concepts (that happen to include only one unique member; see Hall, 1999; Hall & Lavin, 2004; Macnamara, 1994; Markman & Jaswal, 2004; Xu, Carey, & Welch, 1999). Second, the vast majority of words, and indeed most of the words first acquired by infants, do not refer to a distinct individual but to a range of individuals.

Notice, then, that the names for concrete objects depend on a pairing between a word and an abstract concept. To establish such mappings, infants must hold some principled expectations about the range of possible extensions for a given word, and these may come from the conceptual, perceptual, or linguistic system (Bates & Goodman, 1997; Chomsky, 1975; Murphy, 2002; Quine, 1960; Quinn & Eimas, 2000).

Finding the linguistic units also requires the learner to engage in a certain degree of abstraction. Just as knowledge of a concept like PUPPY requires that one be able to inspect anything in the world and decide whether it is a puppy (whether it is in the extension of the concept), knowledge of the phonological form of a word requires that one be able to pull out varying instances of that word in the flow of the speech stream. Just as the concept PUPPY requires us to abstract over instances of short puppies, black puppies, and furry puppies, knowledge of the phonological word /pup'ē/ requires us to abstract over different utterances of the word that show wide variation in acoustic features due either to differences between speakers, to effects of coarticulation with surrounding words, or to phonological rules that alter the form of the word (e.g., *electric/electricity*; see Saffran, Werker, & Werner, Chapter 2, this *Handbook*, this volume for an excellent review; also Aslin, Saffran, & Newport, 1998; Fisher, Church, & Chambers, 2004; Fisher & Tokura, 1996; Jusczyk, 1997; Mehler et al., 1988; Morgan & Demuth, 1996).

The third piece of the word-learning puzzle—establishing a mapping between the conceptual and linguistic units—is also much richer than it appears at first glance. It is a universal feature of human language that many kinds of words (e.g., nouns, adjectives, verbs) can be applied correctly in the very same naming episode, and that each kind of word highlights a unique aspect of that episode and supports a unique pattern of extension. Consider again the vision of puppies playing in the park. Count nouns (e.g., “Look, it’s a *puppy*”) not only refer to an individual puppy, but extend broadly to other members of the same object category (to other puppies, but not to bunnies). In contrast, proper nouns (e.g., “Look, it’s *Lassie*”), which refer specifically to the named individual, cannot be extended further. And if we provide an adjective (“Look, it’s *fluffy*”), the meaning is again quite different. Here, we refer to a property of the named individual, but not the individual itself, and we can extend that word to other instances of that property, independent of the particular entity embodying it (e.g., to any other fluffy thing, including [some, but not all] puppies,

bunnies, and bedroom slippers). Finally, verbs (“Look, it’s *running*”) refer to a relation or an activity involving that individual at that moment in time, and are extended to similar activities, involving very different actors (e.g., horses, children) at different times and places.⁴

To summarize, to be successful word learners, infants must (a) identify the relevant conceptual units (e.g., an individual, a category of individuals, an event), (b) identify the relevant linguistic units (e.g., words), and (c) establish a mapping between them. We have argued that at its core, word learning requires a certain degree of abstraction in each of these domains. Any given utterance of a word must be related to an abstract phonological representation, and any given individual must be related to an abstract concept.

Early Solutions to the Puzzle of Word Learning

Despite these apparent logical difficulties, infants learn words with impressive ease and alacrity. By roughly 12 months, infants reliably recognize words in fluent speech and are beginning to produce words on their own; by roughly 24 months, they produce hundreds of words and begin to combine them systematically to form phrases. Perhaps more remarkable still is the fact that by 2 to 3 years of age, they discover that there are distinct kinds of words (distinct grammatical forms) and that these are linked to distinct kinds of meaning (Brown, 1957, 1958; Gentner, 1982; Macnamara, 1979; Waxman, 1990; Waxman & Gelman, 1986). In fact, the evidence reveals that they mine these links, taking the grammatical form of a novel word as a cue to establishing its meaning (for thorough reviews of recent literature, see Hall & Lavin, 2004; Markman & Jaswal, 2004; Woodward & Markman, 1998).

Toddlers acquiring English systematically restrict the extension of a proper noun to the named individual (Hall, 1991, 1999; Hall & Lavin, 2004; Jaswal & Markman, 2001), but extend count nouns more broadly, to the named individual and to other members of the same object category (Waxman, 1999; Waxman & Markow, 1995). They systematically extend adjectives to properties of objects (Klibanoff & Waxman, 2000; Mintz & Gleitman, 2002; Prasada, 1997; Waxman & Klibanoff, 2000; Waxman &

⁴ And, don’t forget that the speaker is under no obligation to talk about what is happening in the world at that moment. A speaker is about as likely to say, “remember our camping trip last summer” as “what a cute puppy” in the context of a puppy (Chomsky, 1959).

Markow, 1998) and verbs to categories of events (Fisher & Tokura, 1996; Hollich, Hirsh-Pasek, et al., 2000; Naigles, 1990; Tomasello, 2003; Tomasello & Merriman, 1995).

But how do infants discover the mappings between grammatical form and meaning? The full repertoire of such mappings cannot be innately specified because languages differ in the grammatical forms that they represent, in the way they mark these grammatical forms on the surface, and in the ways they recruit these forms to convey fundamental bits of meaning (Baker, 2001; Croft, 1991; Frawley, 1992; Hopper & Thompson, 1980). In the face of these differences, there appear to be some universals. In particular, in all human languages, object concepts are lexicalized as nouns and event concepts as verbs (Brown, 1957, 1958; Dixon, 1982). But at the same time, there is considerable cross-linguistic variation. Within the class of nouns, some languages (like English) make a grammatical distinction between mass and count nouns, whereas others (like Japanese) may not (Imai & Haryu, 2004). Even more dramatic evidence for this kind of flexibility comes from cross-linguistic comparisons of the grammatical form *adjective*. Some languages (including English, Spanish, and the African language Dyirbal) have richly developed, open-class systems of adjectives, but others (e.g., the Bantu languages) have sparse adjective systems, including as few as 10 terms (Dixon, 1982; Lakoff, 1987). Moreover, in many languages (e.g., Mohawk, Mandarin) it is extremely difficult to determine whether there is a grammatical category *adjective* that is distinct from the category *verb*. In Mohawk, for example, most morphological and syntactic tests put the class of concepts that are labeled by adjectives in English into the class of verbs (Baker, 2001).⁵

⁵In some languages, it is even difficult to determine whether any words can be assigned to specific grammatical categories at all, leading some to argue that in these languages, the grammatical categories are perhaps better characterized as phrase-size units rather than as words (Davis & Matthewson, 1999; Demirdache & Matthewson, 1996; Wojdak, 2001). The putative category-neutrality in these languages makes it clear that we should separate the lexical category of a word from its syntactic usage. That is, a word may be lexically specified as, say, being a noun, but in certain uses, it will be performing the function of a verb (or vice versa). This point can be seen clearly even in English when we examine gerunds (e.g., The *sinking* of the boat was ordered by the admiral), where a verbal concept (*SINK*) is used as the head of a noun phrase. In cases like this, a word that is lexically a verb behaves syntactically like a noun. (see Abney, 1987; Frank & Kroch, 1995; Harley & Noyer, 1998 for discussion and analysis).

Even within a given language, the boundaries around the grammatical forms are permeable. Although a core semantic function of nouns is to refer to object concepts (e.g., PUPPY, TABLE), nouns can also be used to refer to properties (e.g., HEIGHT, BELIEF), events (e.g., EARTHQUAKE, DESTRUCTION), and abstract notions (e.g., FREEDOM, IDEA). And although a core semantic function of verbs is to refer to events (DECIDE, JUMP), verbs can also refer to properties (APPEAR, KNOW) or states (LIKE, STAND). Indeed, the very same underlying concept can sometimes be expressed by both a noun and a verb:

- (1) The results of the election were a *surprise* to me (N).

The results of the election *surprised* me (V).

It therefore follows that the links between grammatical categories (noun, verb) and semantic categories (thing, event) are not rigidly fixed, even within a given language, but are correlational (P. Bloom, 1994; Macnamara, 1986; Pinker, 1989).

How do infants discover these links? It would be unreasonable to assume that from the start, infants' expectations mirror those of the mature speakers of their language, because as we have seen, infants must discover which grammatical forms are represented in their language and how they are recruited to convey meaning. It is reasonable, however, to ask whether infants might approach the task of acquisition with some language-general expectations in place to guide acquisition from the start and which could then be fine-tuned as the infant gained experience with the details of their native language (see Saffran et al., Chapter 2, this *Handbook*, this volume, for a similar developmental view).

PLAN OF THE CHAPTER

To address these issues, we open with a section on initial acquisitions, focusing briefly on the linguistic, conceptual, and social underpinnings that precede the advent of infants' first words. We then consider infants' initial forays into mapping their first words to meaning. To foreshadow, recent evidence reveals that infants cross the threshold into word learning equipped with a powerful and initially general expectation linking the linguistic and conceptual units. This general initial link gets bona fide word learning off the ground and sets the stage for subsequent lexical, grammatical, and conceptual developments. In the next section, we ask how young word learn-

ers move beyond this initially broad link. The evidence suggests that infants first tease out the grammatical category *noun* from among the other grammatical forms, and map them specifically to individual objects and categories of objects. This early establishment of a noun-to-category link serves as the foundation that enables infants to discover the other essential grammatical forms (e.g., adjectives, verbs) and map them to their respective meanings. After considering several consequences of the early acquisition of nouns, we focus on the acquisition of adjectives and verbs. In both cases, the patterns of acquisition differ importantly from the acquisition of nouns, and appear to depend on the prior acquisition of (at least some) nouns. We suggest that this follows directly from the distinct informational requirements and conceptual entailments of each of these distinct predicate forms.

Several overarching themes appear throughout the chapter. Each has figured largely in the history of research on word learning and each continues to exert considerable force in contemporary theoretical and empirical work.

Cross-Linguistic Evidence

One theme is related to the place of cross-linguistic evidence in theories of acquisition. As noted, the mappings between grammatical and conceptual categories vary across languages. This variability illustrates two related points. First, the precise mappings between particular grammatical and conceptual categories must involve learning. Second, cross-linguistic comparisons can be a powerful tool for discovering which aspects of word learning (if any) might derive from principles of grammatical architecture and which might be more malleable across development and across languages (Bornstein et al., 2004; Bowerman & Levinson, 2001; Gentner, 1982; Imai & Gentner, 1997; Maratsos, 1998; Sera, Bales, & del Castillo Pintado, 1997; Sera et al., 2002; Snyder, Senghas, & Inman, 2001; Uchida & Imai, 1999).

The Privileged Position of Nouns

This chapter also calls attention to the developmental priority of one grammatical form—*noun*—in early acquisition. We consider the evidence for and the sources underlying the dominance of nouns over other grammatical forms in the early lexicon. But we also point out that the very fact that nouns are acquired so early serves as a strong signal that this grammatical category may differ importantly from the others. From this observation, it

follows that noun learning may not be the paradigmatic case for word learning more generally. As a result, the vast majority of research and theory on word learning, which has focused predominantly on the acquisition of nouns (primarily those nouns referring to individual objects and categories of objects), can only take us so far. Language is filled with words referring to properties (*blue*), events (*jump*), and relations (*meet*) and with words that quantify over objects (*the, every, some*) and events (*always, never, sometimes*). The language learner must ultimately come to understand the mapping between a wide range of linguistic devices and the meanings they convey. A fully representative theory of word learning requires that we adopt a broad perspective, encompassing the acquisition of the full range of word-types learned by children. In essence, then, we are suggesting that the very real developmental priority for nouns in early acquisition should not be equated with a research priority to focus on nouns to the exclusion of other kinds of words.

Structure: In the Input or in the Mind

The cognitive sciences have been shaped by the fundamental tension between nature and nurture, and the field of word learning is no exception. Although this tension has traditionally been viewed as oppositional, it is now clear that these are best seen as complementary, working hand-in-glove to support acquisition. Researchers must study the input to detect what structure, if any, is available to help infants discover words and assign them to meanings (L. Bloom, 2000; Bornstein et al., 2004; Hoff, 2002; Hoff & Naigles, 2002; Huttenlocher, Haight, Bryk, Seltzer, & Lyons, 1991; Huttenlocher & Smiley, 1987; Huttenlocher, Vasilyeva, Cymerman, & Levine, 2002; MacWhinney, 2002; Naigles & Hoff-Ginsberg, 1995, 1998; Samuelson, 2002; Tomasello, 2003). It is also important to bear in mind that what *counts* as the input may be a function of development. At different developmental points, the learner may be able to apprehend different aspects of the very same piece of input, due either to maturation of their perceptual and conceptual systems or to their knowledge about the particular language they are learning.

In addition to examining the input, researchers must examine the representational capacities of the learner to detect what structure, if any, is inherent in the mind to make acquisition possible (R. Gelman & Williams, 1998). In these ventures, one must be mindful that structure may derive from the perceptual system (Jusczyk, 1997; Quinn & Eimas, 2000; Smith, 1999), the

conceptual system (Baillargeon, 2000; Spelke, 2003), the linguistic system (Crain, 1991; Lidz, Waxman, & Freedman, 2003), or might be the product of interactions among these systems (Hirsh-Pasek, Golinkoff, Hennon, & Maguire, 2004). Moreover, because word learning is a cascading developmental phenomenon, different representational structures or constraints on acquisition may become available at different points in development.

Recent research has made great strides in integrating these formerly oppositional sources of acquisition, documenting that learners are exquisitely sensitive to the input and at the same time, that there is structure within the learner that guides acquisition. The current mandate is to be as precise as possible about the balance between these sources and the interplay between them as development unfolds.

In word learning, this interplay between expectations inherent in the learner and the shaping role of the environment is essential (P. Bloom, 2000; Chomsky, 1980; Gleitman, 1990; Gleitman, Cassidy, Nappa, Papafragou, & Trueswell, *in press*; N. Goodman, 1955; Jusczyk, 1997; Quine, 1960). Certainly, infants cull information from the environment, for they learn precisely the words and the grammatical forms of the language that surrounds them, and precisely the concepts to which they are exposed (e.g., CD PLAYERS and SQUIRRELS in the United States; SCYTHES and PECCARIES in rural Mexico). But just as certainly, infants are guided by powerful internal expectations that guide the process and are themselves shaped in the course of acquisition.

This observation is especially important because, as pointed out, human languages differ not only in their cadences and their individual words, but also in the ways in which kinds of words (e.g., nouns, adjectives, verbs) are recruited to express fundamental aspects of meaning. Any theory of word learning must be sufficiently constrained to account for what appear to be universal patterns of acquisition in the face of this cross-linguistic variation. At the same time, it must be sufficiently flexible to accommodate the systematic variations that occur across languages and across developmental time.

In view of these overarching themes, our goal is to consider word learning from an integrative, dynamic, and distinctly developmental perspective, treating seriously the relative contributions of expectations held by the learner and the shaping role of the environment, as they unfold over time. In our view, infants' initial expectations, and their initial perceptual, conceptual, social, and linguistic sensitivities are not rigidly fixed. At each

step along the way, their abilities and sensitivities unfold, calibrated on the basis of the knowledge and structure that they have culled from the ambient language. Word learning, then, is a cascading process, in which information becomes available incrementally, as learners work their way toward solving pieces of the acquisition puzzle. Each accomplishment makes apparent a new problem and a new set of potential solutions.

SETTING THE STAGE FOR WORD LEARNING: FOUNDATIONAL CAPACITIES

In this section, we consider the linguistic, conceptual, and social underpinnings to word learning and their evolution over the 1st year of life.

Identifying the Words

Before word-learning can begin in earnest, infants must be able to parse a word from the continuous speech stream, and recognize that word across a range of utterances and from a range of different speakers. This task is difficult because there are few overt breaks in the speech stream and because the acoustic signature of a word varies dramatically as a function of the surrounding words and the speaker. Infants' solution to this piece of the word-learning puzzle emerges gradually over the 1st year of life. During this very active period, their sensitivities become increasingly tailored by the structural features of the native language in which they are immersed. Because this very active area of research is covered ably and in elegant detail in Saffran et al. (Chapter 2, this *Handbook*, this volume), we touch only briefly on two issues that are intimately tied to word learning (for other excellent reviews, see Aslin et al., 1998; Echols & Marti, 2004; Fisher et al., 2004; Guasti, 2002; Jusczyk, 1997; Werker & Fennell, 2004).

Discovering the Words and Word-Sized Units

Decades of research have revealed that there is considerable structure in the linguistic input, to which infants gradually and systematically become sensitive. But it is also clear that infants approach the task equipped with some perceptual preferences or biases that enable them to take advantage of the structure in the input and, in this way, to discover the potential words of their language (Christophe, Mehler, & Sebastián-Gallés, 2001;

Fernald & McRoberts, 1996; Johnson, Jusczyk, Cutler, & Norris, 2003; Jusczyk, 1997; Liu, Kuhl, & Tsao, 2003; Morgan & Demuth, 1996).

Even at birth, infants prefer human speech (and particularly infant-directed speech, with its exaggerated rhythmic and pitch contours) over other sources of auditory stimulation (Jusczyk & Luce, 2002; Mehler et al., 1988; Singh, Morgan, & White, 2004; Vouloumanos & Werker, 2004). However, infants' attentional preferences for particular features undergo dramatic developmental change. During roughly the first 5 to 6 months, the melodies of infant-directed speech serve a primarily affective and attentional function, engaging and modulating infants' attention. By approximately 6 months of age, "words begin to emerge from the melody" (Fernald, 1992, p. 403) as infants become increasingly sensitive to cues in the speech stream that permit them to segment the continuous speech signal into word-sized units (Echols & Marti, 2004; Guasti, 2002; Jusczyk & Aslin, 1995; Saffran, Aslin, & Newport, 1996). Some cues (e.g., distributional, prosodic, and coarticulatory cues) appear to be universal and to be available early enough to get the process of word segmentation and identification off the ground. Other cues (e.g., phonetic, phonotactic, and morphologic cues) appear to be language-specific and to become available later, as infants discover which features carry the most weight in the language they are acquiring (Bosch & Sebastián-Gallés, 1997; Friederici & Wessels, 1993; Kuhl, Williams, Lacerda, Stevens, & Lindblom, 1992; Nazzi, Jusczyk, & Johnson, 2000; Werker & Tees, 1984).

But whatever their origin, infants' evolving attention to these cues supports their discovery of the word and phrase boundaries of their native language. By 5 to 6 months of age, infants recognize their own names (Mandel, Jusczyk, & Pisoni, 1995), and by 6 to 7 months, they have begun to establish the meaning of other highly salient words (Tincoff & Jusczyk, 1999). These segmentation skills, in turn, make it possible for infants to track the relations (statistical and algebraic) among linguistically relevant units (Brent & Cartwright, 1996; Chambers, Onishi, & Fisher, 2003; Gomez & Gerken, 1999; Marcus, Vijayan, Rao, & Vishton, 1999; Mintz & Gleitman, 2002; Pena et al., 2003; Saffran et al., 1996; Shi & Werker, 2001; Shi, Werker, & Morgan, 1999). This is key, because successful word learning depends not only on the individual elements (sounds, syllables, words) but also on the relations among them.

Discovering the Distinction between Open- and Closed-Class Words

Infants' sensitivity to the relations among words permits them to distinguish between two very broad classes of words: open class (content words, including nouns, adjectives, verbs) and closed class words (function words, including determiners, quantifiers, and prepositions; Gómez, 2002; Morgan, Shi, & Allopenna, 1996; Shady, 1996; Shady & Gerken, 1999; Shi et al., 1999; Shi & Werker, 2003). By 9 to 10 months of age, infants prefer to listen to open class words, possibly because they receive greater stress and enjoy more interesting melodic contours than do closed class words.

This preference for open class words represents an important step on the way to word learning, for it ensures that by the close of their 1st year, infants not only parse words successfully, but also devote special attention to just those words (the open class, content words) that have rich conceptual content and that will appear first in their productive lexicon. Moreover, infants' rather exquisite sensitivity to the relative position of open and closed class words provides an entry point into the discovery of other distinct grammatical form categories (Brent & Cartwright, 1996; Gómez, 2002; Redington, Chater, & Finch, 1998; Shi & Werker, 2003).

Identifying the Relevant Concepts

The solution to this second piece of the puzzle rests on the infants' ability to identify objects and events in the environment, and to notice relations among them. Once again, the evidence suggests that this ability is supported both by structure that is available in the input (perceptual similarities among members of a given concept) and structure in the infant. In particular, there is evidence that even before they begin to learn words, infants have an impressive repertoire of core concepts involving objects, events, and relations (Baillargeon, 2000; Spelke, 2003). Some of their prelinguistic concepts are focused primarily on perceptual or sensory properties (e.g., RED, FAST, HAS EYES; see Quinn & Eimas, 2000); other prelinguistic concepts are more conceptual in nature. By 6 or 7 months, infants can identify distinct objects (e.g., a particular puppy) and can also categorize individuals into several different richly structured object categories at various levels of abstraction (e.g., basic-level categories like *dog*, and more abstract domain-level categories, like *animate*; Behl-Chadha, 1995; Mandler & McDonough,

1998; Quinn & Johnson, 2000; see S. A. Gelman & Kalish, Chapter 16, this *Handbook*, this volume, for a discussion of animacy; and Booth & Waxman, 2002b; Keil, 1994; Prasada, 2003; Spelke & Newport, 1998, for evidence pertaining to the early emergence of the concept ANIMATE). Infants also appear to represent individual actions within a host of richly structured event-based relations, including CAUSE, CONTAINMENT, and SUPPORT (Baillargeon, 2000; Leslie & Keeble, 1987; Michotte, Thines, & Crabbe, 1991; Oakes & Cohen, 1994; Wagner & Carey, 2003).

The richness and depth of the infants' early conceptual repertoire is impressive in and of itself. But it also raises a thorny problem for the infant as she breaks into a system of word learning: For if infants appreciate such a rich range of concepts and relations, and if each is a viable candidate for a word's meaning, then how do infants discover which of these candidates is to be mapped to the word that they have parsed (Quine, 1960)? In the next section, we consider the ways in which infants' sensitivity to the intentions of others helps them to solve this piece of the learning puzzle.

Interpreting the Intentions of Others

Neither the ability to identify a novel word nor the ability to represent individuals or concepts guarantees that the infant will successfully weave these linguistic and conceptual units together. To successfully map words onto their intended referents, the infant must also be able to infer something about the goals and intentions of the speakers around them. Research into this issue has flourished in the past decade, fueled in large part by an ingenious program of research aimed at uncovering what infants understand about the intentions of others and how they recruit their emerging social and pragmatic acumen to infer the intention of speakers in the task of word learning (see Woodward & Markman, 1998, for an excellent overview; also Baldwin & Moses, 2001; L. Bloom & Tinker, 2001; Jaswal & Markman, 2003; Meltzoff, 2002; Tomasello & Olgun, 1993; Woodward, 2004; Woodward & Guajardo, 2002). By 9 to 10 months of age, infants successfully and spontaneously follow speakers' eye-gaze and gestures (especially pointing), and they use these to home in on the intended focus in a naming episode: Infants are more likely to map a novel word to an object if the speaker is attending to that object than if her attention is directed elsewhere (Brooks & Meltzoff, 2002; Carpenter, Akhtar, & Tomasello, 1998; Hollich, Hirsh-Pasek, et al., 2000;

Meltzoff, Gopnik, & Repacholi, 1999; Moore, Angelopoulos, & Bennett, 1999; Woodward, 2003).

Conclusions about Initial Acquisitions

By the close of their 1st year, the foundations for word learning are in place. Infants have made significant headway in identifying the phonological units that will become their first words and in representing the conceptual units that will underlie their first meanings; and they are sensitive to the social and pragmatic cues that help them to weave these linguistic and conceptual units together (Baldwin & Baird, 1999; Baldwin & Markman, 1989; L. Bloom, 1998, 2000; Diesendruck, Markson, Akhtar, & Reudor, 2004; Echols & Marti, 2004; Fulker-son & Haaf, 2003; Gogate, Walker-Andrews, & Bahrick, 2001; Guajardo & Woodward, 2000; Tomasello & Olgun, 1993). In the next section, we consider how infants, armed with these foundational capacities, make their first forays into word learning.

FIRST STEPS INTO WORD LEARNING: A BROAD INITIAL LINK BETWEEN WORDS AND CONCEPTS

How can we best characterize infants' initial steps over the threshold into word learning? This issue has been a virtual magnet for attention on both the theoretical and empirical fronts. Some have argued forcefully that infants cross this threshold as *tabulae rasae*, with no links between their linguistic and conceptual units to serve as guides. In one especially influential version of this argument, Smith and her colleagues have claimed that early word learning is no different from any other kind of learning (Smith, 1999; Smith, Colunga, & Yoshida, in press). In this view, infants' first words are acquired in the absence of any guiding expectations, and it is only after infants have acquired a sizable productive lexicon that they begin to detect any links between linguistic and conceptual units (Smith, 1999). Moreover, in this view, words are tied tightly to perceptual experience, with little or no influence of conceptual relations. Others have argued with equal force for a very different view, asserting that infants harbor powerful, albeit general, expectations linking linguistic, perceptual, and conceptual units from the start (Balaban & Waxman, 1997; Booth & Waxman, 2003; Gopnik & Nazzi, 2003; Graham, Baker, & Poulin-Dubois, 1998; Poulin-Dubois,

Graham, & Sippola, 1995; Waxman & Booth, 2003; Waxman & Markow, 1995; Xu, 2002).

To adjudicate between these positions, we must start at the beginning, asking whether we can discern any links, however rudimentary, between the linguistic and conceptual systems of infants at the very onset of word learning. As noted, if such links exist, they will likely be less precise than those of mature speakers, because languages vary in the grammatical forms they represent and the way they recruit these forms to convey meaning. But it is certainly possible that infants begin with a broad language-general link that supports infants' first steps in lexical acquisition and that can then be more finely tuned as infants gain experience with the particular language being acquired.

Waxman and Markow (1995) used a novelty-preference design to discover whether infants ranging from 12 to 14 months of age harbor any links between linguistic and conceptual organization. During a *familiarization phase*, an experimenter offered the infant four different toys from a given object category (e.g., four animals), one at a time, in random order. This phase was immediately followed by a *test phase*, in which the experimenter simultaneously presented both (a) a new member of the now-familiar category (e.g., another animal) and (b) an object from a novel category (e.g., a fruit). Infants manipulated the toys freely throughout the task. Their total accumulated manipulation time served as the dependent measure. Each infant completed this task with four different sets of objects, two involving basic level categories (e.g., horses versus cats) and two involving superordinate level categories (e.g., animals versus fruit).

To identify any influence of novel words, infants were randomly assigned to one of three conditions that differed only during the familiarization phase of the experiment. Infants in the noun condition heard, for example, "See the *fauna*?" Those in the adjective condition heard "See the *faun-ish* one?" Those in a no-word control condition heard "See here?" At test, infants in all conditions heard precisely the same phrase ("See what I have?"). The experimenters presented novel words, rather than familiar ones, because their goal was to discover what links, if any, infants hold when it comes to mapping a new word to its meaning. If they had used familiar words (e.g., *dog*), performance could have been influenced by their understanding of those particular words, and could not speak to the more fundamental issue of the links between words and meaning.

The predictions were as follows: If infants noticed the category-based commonality among the four familiar-

ization objects, then they should reveal a preference for the novel object at test. If infants detected the presence of the novel words, and if these words directed their attention toward the commonalities among the objects presented during familiarization, then infants hearing novel words should be more likely than those in the no word control condition to reveal a novelty preference. Finally, if the initial link between words and concepts is general at the start, then infants in both the noun and adjective conditions should be more likely than those in the no word condition to form categories.

These predictions were borne out. Infants in the no-word control condition revealed no novelty preference, suggesting that they had not detected the category-based commonalities among the familiarization objects. In contrast, infants in both the noun and adjective conditions revealed reliable novelty preferences, indicating that they had successfully formed object categories.

This result provides clear evidence for an early, foundational link between word learning and conceptual organization. Infants in these experiments reliably detected the novel words, and these words held consequences for their conceptual organization. In essence, the words served as *invitations* to form categories (Brown, 1958). Providing infants with a common name (at this developmental point, either a noun or an adjective) for a set of distinct objects highlighted the commonalities among them and promoted the formation of object categories. More recent work has revealed that this invitation does more than simply highlight concepts that infants may already represent; it also supports the discovery of entirely novel concepts, comprised of entirely novel objects (P. Bloom, 2001; Booth & Waxman, 2002a; Fulkerson & Haaf, 2003; Gopnik, Sobel, Schulz, & Glymour, 2001; Maratsos, 2001; Nazzi & Gopnik, 2001). Moreover, this invitation has considerable conceptual force: Although novel words were presented only during the familiarization phase, their influence extended beyond the named objects, directing infants' attention to the new—and unnamed—objects present at test.

Specificity of the Initial Link

This demonstration of a broad initial link between words and concepts attracted considerable attention and raised several further questions, especially concerning the specificity of this phenomenon. On the linguistic side, researchers have asked whether infants' early expectation is specific to words, or whether it is apparent with sounds more generally. This question bears on issues of domain

specificity. On the conceptual side, researchers have explored whether the invitation is specific to the kinds of commonalities that underlie object categories or whether it also applies to a broader range of candidate meanings (e.g., property-based, event-related commonalities).

Words or Sounds?

A key question is whether the facilitative effect of novel words on infants' categorization stems specifically from the presentation of novel words or whether this might be the consequence of a more general, attention-engaging function associated with any auditory stimuli. To address this issue, several research programs have compared the effects of novel words to the effects of nonlinguistic stimuli (e.g., tones, melodies, mechanical noises produced by simple toys). The results are somewhat mixed. On the one hand, at 9 to 12 months of age, when infants have just begun to reliably parse words from the speech stream, novel words promote categorization, but novel tones (matched precisely to the naming phrase in amplitude, duration, and pause length) and other, more complex nonlinguistic stimuli (e.g., repetitive, nonlinguistic mouth sounds; a brief melodic phrase) fail to do so (Balaban & Waxman, 1997). This suggests that there is indeed something special about words at this early developmental moment (but see Gogate et al., 2001; Sloutsky & Lo, 1999).

This is not to say that nonlinguistic stimuli have no effect on object categorization. Under certain circumstances, nonlinguistic sounds (e.g., whistles, melodic phrases), gestures, and even pictograms appear to promote object categorization in infants and toddlers. But the key finding is that they do so only in certain restricted experimental contexts, and in particular when an experimenter makes it clear that her intention is to treat these nonlinguistic stimuli as object names. For example, if nonlinguistic stimuli are presented within familiar naming routines or if they are produced intentionally by an experimenter who is interacting directly with the infant and a salient object, then these nonlinguistic stimuli can promote object categorization (Fulkerson, 1997; Fulkerson & Haaf, 2003; Namy & Waxman, 1998, 2000, 2002; Woodward & Hoyne, 1999). In contrast, when these social and pragmatic cues are stripped away, nonlinguistic elements fail to support object categorization (Balaban & Waxman, 1997; Campbell & Namy, 2003; Fulkerson & Haaf, 2003).

This pattern of results is consistent with the position that infants take advantage of several kinds of cues to dis-

cover word meaning (Hall & Waxman, 2004; Hollich, Hirsh-Pasek, et al., 2000). When the cues converge with sufficient strength, nonlinguistic elements can be interpreted as "names for things." Absent these cues, nonlinguistic elements fail in this regard. Moreover, infants' willingness to accept nonlinguistic elements as names decreases over the course of the 2nd year of life, as they become aware that although nonlinguistic stimuli (including gestures) certainly augment spoken language, they do not typically function as category names (for a review of gesture, see Goldin-Meadow, Chapter 8, this *Handbook*, this volume; Namy, Campbell, & Tomasello, 2004). Thus, from the earliest stages of word learning, there appears to be something special about words. Infants interpret words, but not other sounds or gestures, as inherently connected to meaning.

Object Categories or a Broader Range of Concepts?

In addition to gaining clarity on what counts as a word at this early juncture, researchers have also explored more broadly the evidence on the conceptual side, asking whether infants initially link novel words exclusively to category-based commonalities (e.g., rabbits, animals), or whether this early link might encompass a wider range of commonalities, including property-based commonalities (e.g., color: pink things; texture: soft things) and event-based commonalities (e.g., flying; rolling).

Notice, however, that in all the experiments reviewed thus far, the only candidates for word meaning were individual objects or categories of objects. Yet, object categories represent only a small portion of the concepts that infants entertain and that words can denote. Therefore, to better characterize the scope of infants' initial expectation, it is necessary to examine a broader range of candidate meanings in word-learning experiments. With this goal in mind, Waxman and Booth (2001) went one step further, asking whether novel words highlight property-based commonalities (e.g., color, texture) as well as category-based commonalities among objects. The design of this series of experiments is described fully in the Acquisition of Nouns section later in this chapter. For the moment, we simply highlight one result from that series indicating that infants begin word learning with a broad expectation for candidate meanings. At 11 months of age, novel words (presented as either nouns or adjectives) directed infants' attention broadly to both category- and property-based commonalities.

This is an important finding because, thus far, only a handful of experimental studies have documented suc-

cessful word learning in infants at this age (Balaban & Waxman, 1997; Fulkerson & Haaf, 2003; Welder & Graham, 2001; Woodward, Markman, & Fitzsimmons, 1994). But even more important, the results revealed that infants begin the task of bona fide word learning equipped with a broad expectation that links content words (including both nouns and adjectives) to a broad range of candidate meanings (allowing for either category- or property-based commonalities).

Advantages of a Broad Initial Link

From the perspective of the learner, this general expectation offers an important developmental advantage. Because different languages make use of different sets of grammatical categories and because they use these to carve up semantic space in slightly different ways, it is to the learner's advantage to begin with only the most general expectations that highlight a range of commonalities and enable the learner to break into the system of word learning in the first place.

This broad initial link serves (at least) three essential functions. First, because words initially direct attention to a broad range of commonalities, they facilitate the formation of an expanding repertoire of concepts, and help to focus infants' attention on concepts that may otherwise have gone undetected. Second, this broad initial link between words and concepts provides infants with a means to establish a stable rudimentary lexicon. Finally, this initially broad expectation sets the stage for the evolution of the more precise expectations found in their native language.

LATER STEPS INTO WORD LEARNING: MORE SPECIFIC LINKS BETWEEN KINDS OF WORDS AND KINDS OF CONCEPTS

Our goal in this section is to ask how infants advance beyond an initially general expectation for words, how they establish a more precise set of expectations, and how they tease apart the distinct grammatical forms and discover their links to meaning.

Facing the linguistic domain, the question is when (and under what circumstances) infants begin to distinguish among the major grammatical forms (e.g., noun, adjective, verb) that are represented in their language. Facing the conceptual domain, the question is when they begin to map these grammatical forms to distinct kinds of meaning (e.g., category, property, actions, relations).

The Acquisition of Nouns

The evidence indicates that infants first tease out the nouns from among the other grammatical forms and map them specifically to category-based commonalities. We consider the conceptual consequences of this noun-to-category link, as well as the linguistic and conceptual forces supporting its emergence.

The Evolution of a Link between Nouns and Object Categories

The first evidence for the evolution of a more precise link between kinds of words and kinds of meaning comes from infants at roughly 13 to 14 months of age. Retaining the logic of the novelty-preference task described earlier, Waxman and Booth (2001, 2003) shifted the focus to include objects (e.g., purple animals) that shared both category-based commonalities (e.g., animal) and property-based commonalities (e.g., color: purple things). This design feature permitted them to examine infants' conceptual flexibility as well as the influence of novel words on conceptual organization. More specifically, they asked (a) whether infants could construe the very *same* set of objects (e.g., four purple animals) flexibly, either as members of an *object category* (e.g., animals) or as embodying an *object property* (e.g., color: purple), and (b) whether infants' construals were influenced systematically by novel words. For a discussion of the psychological distinction between category- versus property-based commonalities, see Waxman, 1999; Waxman & Booth, 2001; S. A. Gelman & Kalish, Chapter 16, this *Handbook*, this volume.⁶

⁶This approach is predicated on the assumption that there is, indeed, a principled psychological distinction between categories versus properties of objects. Most current theorists distinguish object categories (also known as *kinds* or *sortals*) from other types of groupings (e.g., *purple things*, *things to pull from a burning house*) on at least three (related) grounds: Object categories (1) are richly structured, (2) capture many commonalities, including deep, nonobvious relations among properties (as opposed to isolated properties), and (3) serve as the basis for induction (Barsalou, 1983; Bhatt & Rovee-Collier, 1997; S. A. Gelman & Medin, 1993; Kalish & Gelman, 1992; Macnamara, 1994; Medin & Heit, 1999; Murphy & Medin, 1985; Younger & Cohen, 1986). Although infants and children have less detailed knowledge about many object categories than do adults, they clearly expect named object categories to serve these functions (S. A. Gelman, 1996; Keil, 1994; Waxman, 1999; Welder & Graham, 2001).

This experiment consisted of three phases. Each infant completed the entire procedure four times, using four different sets of objects. In the *familiarization phase*, infants in all conditions viewed four distinct objects (e.g., four different purple animals), all drawn from the *same object category* (e.g., animal) and embodying the *same object property* (e.g., purple). These objects were presented two at a time, and the experimenter's comments when she presented them varied as a function of the infant's condition assignment. In the noun condition, she presented the two objects saying, for example, "These are *blickets*. This one is a *blicket* and this one is a *blicket*." In the adjective condition, she said, "These are *blickish*. This one is *blickish* and this one is *blickish*." In the no-word control condition, she said, "Look at these. Look at this one and look at this one."

In the *test phase*, they saw a category match (e.g., a blue horse; same category as familiarization objects, but new property) pitted directly against a property match (e.g., a purple spatula; same property as familiarization objects, but a new category). To assess *novelty-preference*, the experimenter placed the test pair easily within the infant's reach, saying, "Look at these." No labels were provided, and infant's attention to the objects was recorded. Next, to assess *word-extension*, the experimenter presented a target object (one of the original familiarization objects, e.g., a purple elephant), and pointed to it saying, "This one is a *blicket*" (noun condition), "This one is *blickish*" (adjective condition) or "Look at this one" (no-word condition). She then presented the two test objects, placing them easily within the infant's reach, saying, "Can you give me the *blicket*?" (noun condition), "Can you give me the *blickish* one?" (adjective condition) or "Can you give me one?" (no-word condition). By assessing both novelty-preference and word-extension, these researchers were able to ask whether infants' early expectations, previously evident in novelty-preference tasks only, are sufficiently robust to influence performance in the more active word-extension task.

Infants at 11 months revealed evidence for a broad initial expectation: They mapped novel words (either nouns or adjectives) to commonalities among objects (either category- or property-based commonalities; Waxman & Booth, 2003). In contrast, by 14 months, infants distinguished novel nouns from adjectives. They mapped novel nouns specifically to category-based (but not to property-based) commonalities among objects. Yet, at this same developmental moment, their mapping

for novel adjectives remained more general. As was the case at 11 months, 14-month-old infants typically tended to map novel adjectives broadly, either to category- or property-based commonalities. Although in some tasks, infants showed a more advanced pattern, mapping novel adjectives specifically to property-based (and not category-based) commonalities, this was a fragile effect, evident only under certain circumstances (Waxman & Booth, 2001).

In an independent line of research using the preferential-looking procedure, Echols has documented a similar developmental pattern (Echols & Marti, 2004). Focusing on infants' expectations for nouns and verbs, these researchers provide converging evidence that the link between nouns and object categories is first to emerge from a more general expectation. Infants in this task faced two video monitors. In the *familiarization phase*, infants watched as a novel object (e.g., an anteater) produced a novel action (e.g., opening/closing a cup). The infants saw this event first on one screen, then on the other, and then finally on both screens simultaneously. In the *test phase*, the scenes that were depicted changed, with one screen depicting the now-familiar object engaged in a novel action (e.g., the anteater spinning the cup) and the other depicting a novel object engaged in the now-familiar action (e.g., a manatee opening/closing the cup).

To identify whether the grammatical form of the novel word influenced infants' construal of these scenes, infants were randomly assigned to either a novel noun, novel verb, or no-word control condition. In the novel noun condition, infants heard, for example, "That's a *gep*; it's a *gep*." Those in the novel verb condition heard "It is *gepping*; it *geps*." At test, infants heard either "Look at the *gep*!" or "Look at it *gepping*" in the novel noun and novel verb conditions, respectively. If infants can distinguish novel nouns from verbs, and if they use grammatical form to infer novel words meanings, then infants hearing nouns should prefer the scene with the familiar object, and those hearing verbs should prefer the scene with the familiar action. And if infants' expectations regarding nouns emerges first, then infants hearing nouns should prefer the scene with the novel action, but infants hearing verbs should show no preference. This result would run parallel to those described earlier for nouns and adjectives (Waxman & Booth, 2001, 2003).

The results were consistent with the hypothesis that the link between nouns and object categories is the first to emerge in acquisition. At 13 months, infants in the

novel noun condition revealed a reliable preference for the familiar object, but those in the novel verb condition revealed no preference, looking equally to the two test screens. By 18 months, infants had acquired a more specific expectation for verbs. At this point, they mapped the novel nouns specifically to the familiar objects *and* the novel verbs specifically to the familiar actions (for related evidence, see Casasola & Cohen, 2000; Forbes & Poulin-Dubois, 1997).

Taken together, this research suggests that by 13 to 14 months, infants are sensitive to (at least some of) the relevant cues that distinguish among the grammatical forms, and they recruit these distinctions actively. At this developmental moment, they map nouns rather specifically to object categories, but their expectations for adjectives and verbs remain somewhat broad. Infants' sensitivity to the more specific expectations mapping these latter grammatical forms to their associated range of meanings represents a subsequent developmental achievement.

Summarizing to this point, we have argued that infants' broad initial expectations in word learning serve as a foundation for two discoveries: that there are distinct kinds of words (grammatical categories) in their language, and that there are correlations between these grammatical categories and the types of meaning that they convey. We suspect that these two discoveries go hand-in-hand, each adjusting gradually to the other, in a process akin to Quine's now-classic example of the child scrambling "up an intellectual chimney, supporting himself against each side by pressure against the others." (Quine, 1960, p. 93). We suspect that infants discover that there are distinct grammatical forms when they begin to notice the distinct patterns or grammatical frames in which distinct (kinds of) words occur (e.g., that some tend to be inflected or stressed, that some tend to be preceded consistently by (unstressed) closed class words, that some tend to occupy particular positions within phrases; Brent & Cartwright, 1996; Maratsos, 1998; Mintz, 2003; Mintz, Newport, & Bever, 2002).

Moreover, we have argued that as infants begin to scramble up the chimney of lexical acquisition, they first identify the nouns (from among the other grammatical forms) and map these specifically to object categories (from among the other types of commonalities, including property-based or action-based commonalities). Subsequent links (e.g., those for adjectives and verbs) will build on this fundamental base and will be fine-tuned as a function of experience with the specific correlations

between particular grammatical categories and their associated meanings in the language being acquired.

Further Evidence Concerning Nouns

The evidence for the early emergence of a link between nouns and object categories makes contact with an impressive array of literature focusing on the acquisition of nouns and their relation to object categories (see Woodward & Markman, 1998 for an excellent review; also see P. Bloom, 2000; Golinkoff et al., 2000; Hirsh-Pasek et al., 2004). Decades of devoted research on this topic have led to several important insights. Several research programs have focused on how children map *particular* nouns to their *particular* meaning. In this arena, researchers have discovered in infants and young children a strong tendency to interpret a novel noun (e.g., *dog*), applied to an individual object, as referring to a category of objects at the basic level within a conceptual hierarchy (Hall & Waxman, 1993; Markman & Hutchinson, 1984; Markman & Jaswal, 2004; Mervis, 1987; Rosch, Mervis, Gray, Johnson, & Boyes-Braem, 1976; Schafer & Plunkett, 1998; Waxman, 1990). Only after having established a name for the basic level category do children go on to interpret novel nouns as referring to categories at other hierarchical levels of abstraction (e.g., *terrier*, *mammal*, *animal*), or to individuals (e.g., *Rover*). This priority for naming objects at the basic level, which appears to be evident broadly across languages and cultures (Berlin, 1992; Berlin, Breedlove, & Raven, 1973), likely facilitates the process of word learning: This conceptual priority to name at the basic level effectively narrows the range of candidate meanings. Having established a basic level name, infants and children then go on to add names for categories at other hierarchical levels and to coordinate those names within semantic space (Diesendruck, Gelman, & Lebowitz, 1998; Diesendruck & Shatz, 2001; Imai & Haryu, 2004; Waxman & Senghas, 1992).

Other research has focused on how children discover the various *types* of nouns that are represented in their language (e.g., count nouns, mass nouns, proper nouns, generic nouns) and how these types map to meaning (Hall & Lavin, 2004; Markman & Jaswal, 2004; Prasada, 2000). Central to this endeavor has been an examination of cross-linguistic evidence, since languages differ in whether and how these distinctions are made within the nominal system (Bowerman & Levinson, 2001; Gathercole & Min, 1997; Gathercole, Thomas, & Evans, 2000; Imai, 1999; Imai & Gentner, 1997; Imai &

Haryu, 2004; Lucy & Gaskins, 2001; Wierzbicka, 1984). Current evidence with English-acquiring infants suggests that these distinctions among types of nouns may emerge toward the end of the 2nd year (Belanger & Hall, in press), at roughly the same time as the expectations for adjectives and verbs (Echols & Marti, 2004; Waxman & Booth, 2003).

Because the very rich research documenting an early talent for mapping nouns to meaning has been reviewed ably and elegantly elsewhere (P. Bloom, 2000; Gentner & Boroditsky, 2001; Golinkoff et al., 2000; Hall & Waxman, 2004; Woodward & Markman, 1998), we leave these issues aside to focus on newer advances.

The Noun Advantage

The evidence previously reviewed, documenting the early emergence of a link between nouns and categories of objects, resonates with the long-held observation that early word learning is characterized by an abundance of nouns relative to words from other grammatical categories (Caselli et al., 1995; Gentner & Boroditsky, 2001; Huttenlocher, 1974; Woodward & Markman, 1998; and see Bornstein et al., 2004 for an excellent cross-linguistic review). This observation has been the subject of some controversy. A number of researchers have claimed that this noun advantage is not universal, and have focused on the relative frequency of nouns versus verbs in the speech of children learning languages like Korean (Choi, 1998, 2000; Choi & Gopnik, 1995; Gopnik & Choi, 1995; Gopnik, Choi, & Baumberger, 1996) and Mandarin (Tardif, 1996; Tardif, Gelman, & Xu, 1999; Tardif, Shatz, & Naigles, 1997) in which verbs may be more salient in the input (Slobin, 1985; see also Sandhofer, Smith, & Luo, 2000). Others, however, have focused primarily on the relative frequency of nouns and verbs in mothers' reports of their children's speech, and have argued that children acquiring a wide variety of languages, including Dutch, French, Hebrew, Italian, Japanese, Kaluli, Korean, Mandarin, Navajo, Spanish, and Turkish, show an advantage for nouns over verbs, mirroring that reported for English-learning children (Au, Dapretto, & Song, 1994; Bassano, 2000; L. Bloom, Tinker, & Margulis, 1993; Camaiori & Longobardi, 2001; Fernald & Morikawa, 1993; Gentner, 1982; Goldfield, 2000; Kim, McGregor, & Thompson, 2000).

Despite these controversies, one conclusion is clear: Although the strength of the noun advantage may vary across languages and across vocabulary measures, there are no reported cases in which verb learning outstrips

noun learning. This early noun advantage calls for an explanation, and three have been put forth, each of which may account for some portion of the data.

The natural partitions/relational relativity hypothesis (Gentner, 1982; Gentner & Boroditsky, 2001; Gentner & Namy, 2004) argues that the noun advantage is a consequence of a conceptual or perceptual advantage in identifying objects in the world over relations among them. On this view, because objects come in tidy preindividuated packages, they are easy to identify and therefore serve as good candidates for word meaning. Because relational concepts (even for concrete, observable actions) are more nebulous, they are harder to identify. As a consequence, terms that refer to these relational meanings are learned later and are more variable across languages (Papafragou, Massey, & Gleitman, 2002). The natural partitions/relational relativity position, which focuses heavily on the conceptual and perceptual requirements of word learning, has been influential. However, it does not take into account that most nouns, even those concrete nouns that predominate in the early lexicon, do not refer to individual objects, but are instead extended quite spontaneously beyond the individuals on which they were learned. This observation is very important, because it means that infants' early words point to rather abstract concepts and not to tidy preindividuated packages (Waxman & Markow, 1995). This being the case, the question is whether *object concepts* are in some sense simpler than *relational concepts*, an issue that has yet to be resolved (Chierchia & McConnell-Ginet, 2000; Heim & Kratzer, 1998; Moltmann, 1997).

A second explanation for the noun advantage focuses more directly on cultural and linguistic factors. In brief, the claim is that the noun advantage may be related to cultural factors that make objects more salient than relations among them. On this view, cultural factors work in concert with other acoustic, prosodic, or syntactic factors that make nouns more salient than other grammatical forms in speech to children (S. A. Gelman & Tardif, 1998; Lavin, Hall, & Waxman, in press).

A third explanation for the noun advantage, to which we have already alluded, highlights the differences in the linguistic requirements underlying the acquisition of nouns compared with other grammatical categories (Fisher, Hall, Rakowitz, & Gleitman, 1994; Fisher & Tokura, 1996; Gillette, Gleitman, Gleitman, & Lederer, 1999; Gleitman, 1990; Mintz & Gleitman, 2002). Because adjectives and verbs are predicates that require arguments for their meaning, and because it is the nouns

that serve as these arguments, the acquisition of these grammatical forms and their links to meaning must be grounded in the prior acquisition of at least some nouns. Because nouns typically have fewer linguistic prerequisites, they can be learned first, and can then be used as a foothold for the subsequent acquisition of words from other grammatical categories.

More Than “Names for Things”: Consequences of Early Noun Learning

In recent years, researchers have begun to explore more broadly the *consequences* of acquiring nouns on infants' conceptual and linguistic representations. A growing body of evidence, based on several experimental paradigms, has converged to suggest that when infants acquire their first words, they acquire more than names for things. Noun learning engages and supports some of the most fundamental logical and conceptual capacities of the human mind, including the processes of object individuation, object categorization, and inductive inference. Infants' efficiency in identifying and processing nouns in the input also increases rapidly in infancy.

Conceptual Consequences: Individuation Object individuation, or the ability to track the identity of distinct individuals over time and place (Macnamara, 1982), is a fundamental conceptual and logical capacity. It permits us to know whether, for example, the dog we see now is the same dog we saw previously, or whether these are two different individuals. Under certain circumstances, infants have difficulty tracking the identity of two distinct objects (e.g., a ball and a duck; Van de Walle, Carey, & Prevor, 2000; Wilcox & Baillargeon, 1998; Xu, 1999; Xu & Carey, 1996). This was demonstrated in a series of experiments in which infants, seated before a stage with a small screen, watched as one object (e.g., a ball) emerged from one side of the screen and then returned. Next a different object (e.g., a duck) emerged from the other side of the screen and returned. After several such appearances and disappearances, the screen was lowered to reveal either one or two objects. If infants were able to track the identity of the two distinct objects, they should look longer on test trials revealing one object (the unexpected outcome) than on those revealing two (the expected outcome). Although 12-month-olds succeeded, 10-month-olds had difficulty tracking identity in this complex task (but see Wilcox, 1999; Wilcox & Baillargeon, 1998, for evidence that they succeed in simpler tasks).

However, Xu (1999) went on to examine the effect of naming each object as it appeared, and in so doing, documented a powerful role for naming in object individuation. Ten-month-old infants who were introduced to the same name for the two appearing and disappearing objects (e.g., “It's a toy!”) continued to have difficulty in this object individuation task. In contrast, those who heard distinct names for each object (e.g., “It's a ball. . . . It's a duck!”) succeeded. Apparently, then, providing distinct names for distinct objects highlights their uniqueness (rather than their commonalities) and supports very young infants' ability to trace their identity over time.

Converging evidence for this view comes from infants' performance in object categorization tasks. When objects (e.g., four different animals) are introduced with *distinct* (rather than common) names, infants fail to form categories (Graham, Kilbreath, & Welder, 2004; Waxman & Braun, 2005). It therefore appears that even for infants as young as 10 to 12 months of age, the conceptual consequences of word learning is nuanced. Providing the same name for a set of distinct individual objects highlights their commonalities and supports the formation of object categories, but does not support individuation. In contrast, providing *distinct* names for each individual highlights distinctions among them and promotes the process of object individuation (Van de Walle et al., 2000; Wilcox, 1999; Wilcox & Baillargeon, 1998; Xu, 1999). Thus, naming not only supports the establishment of a stable repertoire of object categories, but also provides infants with a means of tracing the identity of individuals within these categories.

Conceptual Consequences: Induction. One of the reasons that object categories have figured so largely in cognitive psychology, cognitive development, and cognitive science is that they have considerable inductive force. If we discover a property (e.g., bites if you pull its tail) that is true of one individual (e.g., Fido), we can infer that this property is also true of other members of the same object category (e.g., dogs). This is important because it permits us to extend our knowledge powerfully and systematically, taking us beyond our firsthand experience with distinct individuals and supporting category-based inferences. This inductive capacity is especially powerful when it comes to acquiring knowledge about nonobvious properties of objects.

There is now considerable evidence that, for adults and preschool-age children, naming strongly supports

category-based induction. Naming permits us to go beyond the perceptible commonalities that we can observe firsthand, and points us toward the deeper, perhaps hidden commonalities that characterize some of our most fundamental concepts (see Diesendruck, 2003; S. A. Gelman & Kalish, Chapter 16, this *Handbook*, this volume). More recent research reveals that naming may also support inductive inference in infants.

In an ingenious line of experimental work, Graham and her colleagues (Graham et al., 2004; Welder & Graham, 2001) have documented the role of naming in infants' inductive inference. In their tasks, an experimenter introduced 13-month-old infants to a target object. For half the infants, the experimenter named the target object with a novel noun; for the remaining infants, no names were provided. All infants then witnessed the experimenter perform an action with the object. Crucially, this action revealed a property of the object that was not available by visual inspection alone (e.g., that it made a particular noise when shaken). Infants were then provided with an opportunity to explore a series of other objects; no names were provided for these objects. The results were striking. In the absence of naming, infants generalized the hidden property narrowly, trying to elicit it only with test objects that strongly resembled the target object. In the novel noun condition, however, infants revealed a very different pattern. They now generalized the "hidden" property of the target object more broadly to other members of the object category, even if they did not bear as strong a perceptual resemblance to the target object (Booth & Waxman, 2002a; Gopnik & Sobel, 2000; Graham et al., 2004; Nazzi & Gopnik, 2001; Welder & Graham, 2001).

Thus, for infants as young as 13 months of age, nouns do more than merely support the establishment of object categories; they also lend inductive force and advance the acquisition of category-based knowledge.

Processing Consequences. In another exciting line of new research, investigators have begun to examine with precision the time-course underlying infants' processing of spoken words in real time. Although infants as young as 9 to 12 months of age can learn the meanings of (some) words, the efficiency with which they are able to process the words that they hear improves dramatically over the 2nd year of life (Fernald, McRoberts, & Swingley, 2001a; Fernald, Pinto, Swingley, Weinberg, & McRoberts, 1998; Swingley & Aslin, 2000; Swingley, Pinto, & Fernald, 1999). Swingley and Fernald (2002)

demonstrated this phenomenon in a series of innovative experiments. Infants in their experimental paradigm are presented with visual images of two familiar objects (e.g., a ball and a shoe). These are presented simultaneously, on two sides of a screen, while an experimenter directs the infant's attention to one of the objects by naming it (e.g., "Where is the ball?"). The likelihood that an infant will happen to be looking at the appropriate object at the moment that the experimenter mentions the noun is 50%. But the focus in this technique is on those infants who happen to be looking at the unnamed object when the naming event occurs (e.g., the shoe, in our example). Swingley and Fernald reasoned that if these infants understand the meaning of the noun, then they should switch their attention from the unnamed to the named object. They further reasoned that the latency of infants' switches could serve as an index of the infants' processing time for these familiar nouns. Analyses of infants' latency to switch revealed that their processing of familiar nouns increased markedly in the 2nd year of life. Moreover, they documented that infants begin to process words even as the words are being uttered. That is, they use partial information (e.g., the first half of a word) to begin to map that word to meaning (Fernald, Swingley, & Pinto, 2001b).

We suggest that infants' rapid gains in processing efficiency for familiar nouns is likely to facilitate several additional aspects of word learning as well. In particular, their increasing facility in recognizing familiar nouns should also help them to detect those circumstances in which a novel word has been uttered. This in turn will permit them to devote their resources (both conceptual and linguistic) toward identifying the meaning of that word. Infants' gains in processing efficiency for familiar nouns should also support their ability to notice the relations among words within an utterance, and to use these relations to establish the meaning of a novel word. In a clever demonstration, Goodman and her colleagues (J. C. Goodman, McDonough, & Brown, 1998) presented infants with sentences that contained a novel noun (e.g., "Mommy feeds the ferret"). Their results revealed that 2-year-olds successfully discovered the meaning of the novel nouns (e.g., ferret) based on their semantic and syntactic relations to the familiar words in the sentence.

Infants' increasing efficiency in processing spoken words may be related to other changes in word learning during the 2nd year of life. Recent evidence reveals that during this period, as infants become more proficient word learners, their patterns of neural activation in re-

sponse to familiar words shifts from a bilateral to a left-lateralized response (Mills, Coffey-Corina, & Neville, 1997). This suggests that they become more efficient in processing words. This increased efficiency facilitates word learning in general, and may be especially helpful in their efforts to assign distinct meanings to words that are close phonological neighbors (Hollich, Jusczyk, & Luce, 2000; Schafer, Plunkett, & Harris, 1999; Werker, Cohen, Lloyd, Casasola, & Stager, 1998; Werker & Fennell, 2004; Saffran et al., Chapter 2, this *Handbook*, this volume) and to words whose referents are absent.

Conclusions about Nouns

Infants as young as 13 months of age have already begun to discover some precise links between kinds of words and kinds of meaning. As they move from the broad initial link, they first tease apart the nouns from among the various other grammatical forms (e.g., adjectives, verbs) and map them specifically to objects and object categories (and not to object properties, including color, texture). This conclusion raises two (related) points.

First, the developmental advantage for acquiring nouns converges well with the view that learners must first identify the nouns and map them to entities in the world if they are to discover the other grammatical forms and their links to meaning (Fisher & Gleitman, 2002; Maratsos, 1998; Snedeker & Gleitman, 2004; Talmy, 1985; Wierzbicka, 1984). In addition to the conceptual and processing advantages conferred by the acquisition of nouns, there are important linguistic consequences of noun learning. In particular, the acquisition of nouns provides a gateway into the discovery of other grammatical categories and their mappings to meaning. More specifically, acquiring nouns enables the learner to build a rudimentary syntactic structure that contributes to the identification of other grammatical categories.

Second, it is now apparent that nouns are not the paradigm case for word learning. Their developmental trajectory and informational requirements differ markedly from those of the other major grammatical categories. Therefore, it is important to consider carefully the developmental trajectories of these other grammatical forms. Accordingly, we turn our focus to two such forms: adjectives and verbs.

The Acquisition of Adjectives

Although theoretical and empirical interest in the acquisition of the grammatical form *adjective* has lagged far

behind that of nouns (and even verbs), recent years have witnessed an increase in interest. The evidence thus far makes it clear that at least some of the processes underlying the acquisition of adjectives differ substantially from those underlying the acquisition of nouns. As discussed, substantially more developmental and cross-linguistic variation is associated with adjectives than with nouns (see the first section for cross-linguistic evidence pertaining to adjectives). Adjectives tend to appear later than nouns in the early lexicon, and the specific link between adjectives and properties of objects emerges later than the link between nouns and categories. In essence, then, the link between adjectives and properties of objects is elusive.

This developmental picture is somewhat surprising. After all, adjectives are prevalent in infant-directed speech and even from the first months of life, infants are exquisitely sensitive to the concepts marked by adjectives (e.g., sensory and perceptual properties, including color, size, texture, temperature). This being the case, the mappings from adjectives to properties of objects should be straightforward. This was the conclusion expressed by John Locke, who claimed, "Thus the same colour being observed to-day in chalk or snow, which the mind yesterday received from milk, it considers that appearance alone, makes it a representative of all of that kind; and having given it the name *whiteness*, it by that sound signifies the same quality wheresoever to be imagined or met with." (Locke, 1690/1975, Bk. II, chaps. xi, p. 9).

Yet, Locke's account fails to capture the developmental process. Although infants certainly detect many properties that are named by adjectives, and although they rely on these properties when reasoning about objects and events (Needham & Baillargeon, 1998; Wilcox, 1999), they somehow do not consider such properties to be primary candidates for word meaning. In fact, when presented with a novel adjective (*white*) in the context of a novel object (a white llama), infants and toddlers tend to interpret that adjective as a name for the object category (e.g., *llama*) rather than to a property (e.g., its color). This robust finding has been documented in children up to 3 years of age (Hall & Lavin, 2004; Markman & Jaswal, 2004). This interpretive error is telling, because children at this age certainly distinguish nouns from adjectives. Moreover, we know that they already have established a link between adjectives and object properties because when they are presented with familiar objects (objects for which they have

already acquired noun labels), they readily map novel adjectives to object properties rather than to categories. It is when they are presented with objects for which they have not yet acquired a noun label that they persist in mapping adjectives to categories, instead of to properties. Thus, children's interpretation of a novel adjective varies with the familiarity of the noun that it modifies. Further, their interpretive error (mapping a novel adjective to a category- rather than property-based commonality when the noun label for the category is unknown) suggests that there is a conceptual or linguistic priority for lexicalizing an object's category (and in particular, its basic level category) before any of its properties or parts (Hall & Waxman, 1993; Hall, Waxman, & Hurwitz, 1993; Imai & Haryu, 2004; Markman, 1989; Markman & Hutchinson, 1984).

To complicate developmental matters still further, even when they succeed in mapping an adjective to a property of an object, infants do not follow Locke's optimistic program. Instead of extending novel adjectives freely and liberally (e.g., extending *white* from cats to milk, snow, and mittens), their initial tendency is to extend adjectives very narrowly, only to other members of the same basic level category that share that property (e.g., extending *white* from one cat to another; Klibanoff & Waxman, 2000; Mintz & Gleitman, 2002; Waxman & Markow, 1998).

Why is the mapping from adjectives to object properties so elusive? In the following section, we address this question. We focus primarily on the early acquisition of adjectives referring to color and texture, because most of the recent developmental work has been centered here. However, not all adjectives are created equal. Some adjectives (e.g., *big* versus *small*) refer primarily to the poles of an entire dimension (e.g., size), whereas others pick out a range of values (e.g., *red*, *orange*, *yellow*) along the entire dimension (e.g., color; Landau & Gleitman, 1985). Although we will not treat this issue directly here, we point out that factors like these will probably have consequences for patterns of acquisition for most property terms.

Developmental Work

Several different approaches have been adopted to capture the developmental processes underlying infants' and young children's acquisition of adjectives (Gasser & Smith, 1998; Hall & Belanger, in press; Hall, Quantz, & Persoage, 2000; Mintz & Gleitman, 2002; Prasada, 1997; Waxman & Markow, 1998). These approaches

share some key design elements. To maximize the likelihood that infants will map the novel word to an object property, most experiments (a) introduce objects for which infants have already acquired a basic level noun label, (b) use properties that infants find salient (e.g., color; texture),⁷ and (c) present the novel adjectives within short syntactic frames, using the intonational contours of infant-directed speech. Yet despite these design features, infants and toddlers reveal an intriguing difficulty establishing the mappings for adjectives, and when they do succeed, their interpretations appear to depend on the nouns that they modify.

Linking Adjectives to Object Properties. Although there are slight hints suggesting that infants as young as 14 months have begun to map adjectives to object properties, the earliest systematic evidence comes from infants at 21 months. This is also the point at which infants begin to produce adjectives on their own (Fenson et al., 1994; Waxman & Markow, 1998). In a forced-choice task, infants were introduced to a single target (e.g., a yellow object) and asked to choose between two test objects. The matching test object shared a property-based commonality with the target (e.g., it was yellow). The contrasting test object embodied a contrasting value along that dimension (e.g., it was red). For half of the infants, the target (e.g., a yellow snake) and test objects (e.g., another yellow snake; a red snake) were members of the same basic level category. For the others, the target (e.g., a yellow dog) and test objects (e.g., a yellow snake, a red snake) were from different basic level categories. If infants map adjectives specifically to object properties, then infants hearing the target labeled with a novel adjective ("This is a(n) *X* one") should reveal a

⁷ Most investigations include texture (e.g., soft versus hard) because these property terms emerge fairly early in the lexicon (Fenson et al., 1994) and color (e.g., yellow versus green). Color represents an interesting case. Although color terms are almost universally marked as adjectives (Dixon, 1982; Wetzer, 1992), and although infants' color perception is remarkably similar to that of adults (Bornstein, Kessen, & Weiskopf, 1976), young children nonetheless appear to have a curious difficulty mapping specific color terms to their meaning (Bornstein, 1985a; Landau & Gleitman, 1985; Rice, 1980; Sandhofer & Smith, 1999, 2001; Soja, 1994). Most of the evidence has suggested that color terms emerge late, relative to other property terms, and that the initial mappings for color terms tend to be inconsistent (Bornstein, 1985b; but see Macario, 1991; Shatz, Behrend, Gelman, & Ebeling, 1996).

preference for the matching test object. If this effect is specific to adjectives, then infants hearing the target labeled with a novel noun (e.g., “This is an X”) or with no novel word (e.g., “Look at this one”) should reveal no such preference.

The results revealed clear competences as well as limitations. At 21 months, when the target and test objects were all drawn from the same familiar basic level category (e.g., all snakes), infants successfully extended novel adjectives (but not nouns) specifically to the test object sharing the same property. This indicates that they had distinguished adjectives from nouns and mapped them specifically to property-based commonalities. In sharp contrast, when the target (e.g., a dog) and test objects (e.g., snakes) were drawn from different basic level categories, infants were unable to accomplish this mapping.

Basic Level Categories as an Entry Point. This reliance on basic level object categories is not a fleeting phenomenon, evident only in very young word learners, or only with a small set of adjectives. It has also been documented in 3-year-olds performing word-extension tasks (Hall & Lavin, 2004; Klibanoff & Waxman, 2000; Markman & Jaswal, 2004), in adults performing online processing tasks (Allopenna, Magnuson, & Tanenhaus, 1998; Halff, Ortony, & Anderson, 1976; Medin & Shoben, 1988; Pechmann & Deutsch, 1982) and in connectionist models (Gasser & Smith, 1998). These findings are consistent with the observation that the precise meaning of a given adjective is influenced by the noun it modifies.

To see why this might be the case, consider a property term like *soft* or *red*. *Soft* slippers and *soft* ice-cream do not have the same texture; *red* hair and *red* Corvettes are not really the same color. This reflects that most adjectives must be related to a standard of comparison, and this standard is typically determined by the noun that the adjective modifies (Graff, 2000; Kennedy, 1997; Kennedy & McNally, in press; Rotstein & Winter, in press).⁸

Moreover, cross-linguistic evidence suggests that the semantic, syntactic, morphological, and lexical dependencies of adjectives on nouns may be universal. In languages that mark grammatical gender or number, ad-

jjectives must agree with the nouns they modify. This linguistic fact, coupled with the conceptual primacy of basic level categories, suggests that basic-level *nouns* may serve as an entry point for the acquisition of adjectives.

Moving beyond the Basic Level. Although novel adjectives may initially be interpreted within the context of familiar basic level categories, they are eventually extended more broadly. Children learn to extend *wet* to diapers, grass, finger-paintings; and *red*, to balloons, apples, shoes. What factors motivate this advance? The evidence suggests that to accomplish this task, infants integrate information from a wide range of sources, including cognitive, pragmatic, and linguistic cues. The importance of these additional cues is especially clear for infants acquiring languages (e.g., Japanese, Mandarin) where there are scant grammatical cues to distinguish nouns (count, mass, and proper nouns) from adjectives (Imai & Haryu, 2004). In such languages, where the grammatical cues are relatively weak, learners must depend more heavily on these additional sources of evidence if they are to assign words to grammatical categories and map them to meaning.

Current evidence suggests that several general cognitive processes are instrumental in discovering these mappings. The process of comparison operates in conjunction with naming to support children’s ability to extend adjectives across diverse basic level categories (Waxman & Klibanoff, 2000). Three-year-old children succeed in mapping novel adjectives beyond the basic level if they are first provided with an opportunity for comparison. For example, if they are permitted to compare two members of the same basic level category that differ only in the property of interest (e.g., a red versus a blue car), and if they are told that one is *blickish* and the other is not, children readily home in on the inference that *blickish* refers to the property and they go on to extend it broadly to other red objects, from a range of different basic level categories (Au, 1990; Heibeck & Markman, 1987; Waxman & Booth, 2001; Waxman & Klibanoff, 2000). Similarly, if they are permitted to compare two members of different basic level categories that share a particular property (e.g., a red car and a red cup), and if they are told that each is *blickish*, they infer that *blickish* refers to the property and extend it broadly to objects bearing that property from various basic level kinds (Mintz & Gleitman, 2002; Waxman & Klibanoff, 2000). In fact, it turns out that mothers provide just this kind of information when they are instructed to teach

⁸The standard of comparison for adjectives can also be set by context. For example, “my Fiat is a big car” may be true in the context of a discussion of Italian cars, but false in the context of a discussion of American cars.

their infants and toddlers the meaning of a novel adjective (Hall, Burns, & Pawluski, 2003; Manders & Hall, 2002). General cognitive processes may also help infants and children discover how reference to a particular dimension, like color or texture, is reflected in the lexicon (Sandhofer & Smith, 1999).

Pragmatic cues also facilitate adjectival mappings. Consider a scenario in which a novel animate object is introduced, saying, "This is *daxy*." This phrase is ambiguous, because *daxy* could be a proper noun, mass noun, or an adjective (Hall & Belanger, 2001; Hall & Lavin, 2004; Haryu & Imai, 2002; Imai & Haryu, 2004). Hall and his colleagues (Hall & Belanger, *in press*) demonstrated that 3-year-old children acquiring English resolve the ambiguity by attending to the number of individuals to which the word is applied. If it is applied only to a single novel animal (e.g., a llama), they restrict the word to that individual, suggesting that they interpreted it as a proper noun. However, if the word is applied to two different animals, then children extend it to other animals that share that property, suggesting that they interpreted it as an adjective. Imai and Haryu (2001, 2004) demonstrated that children acquiring Japanese show an overwhelming preference to interpret a novel word in an ambiguous phrase as referring to the basic level category. Once a basic level category term has been acquired, they go on to interpret a novel word in that same phrase as referring to a property of the object.

Finally, linguistic factors also contribute to the use of basic level categories as an entry point for adjectival acquisition. Mintz and Gleitman (2002) noted that in constructions like "This is a *blickish* one," the term *one* refers to an (unspecified) object category. Because in experimental tasks, this term is typically applied to a single individual (e.g., a dog), and because basic level object categories are so salient, such constructions are likely to support the extension of the novel adjective within, but not across, that (unspecified) basic level category. If this is the case, then replacing the unspecified pronoun *one* with a lexically specific head noun (e.g., "This is a *blickish* dog. Can you give me a *blickish* car?") should support a broader range of adjectival extension. The results revealed that in such cases, 2-year-olds successfully extended novel adjectives beyond the limits of basic level categories (Klibanoff & Waxman, 2000; Mintz & Gleitman, 2002). Providing the lexically specific head noun essentially blocked a basic level interpretation of the adjective because this noun provides explicit information indicating that a broader range of

extension (one that includes both a dog and a car) for the novel adjective is required.

Summarizing to this point, we have shown that in the absence of explicit (linguistic, pragmatic, or conceptual) evidence to the contrary, basic level kinds serve as the entry point for assigning meaning to a novel adjective (see Goldvarg-Steingold, 2003 for evidence that higher level categories may also serve this function). By enriching the conceptual, pragmatic, or linguistic information available, infants and children move beyond this entry point to extend adjectives broadly and appropriately across basic level kinds.

Cross-Linguistic Work

We have argued that cross-linguistic and developmental observations suggest (a) that the link between nouns and object categories, which emerges early in infants, may be a universal phenomenon, and (b) that the specific link between adjectives and their associated meaning, which emerge later in development, vary systematically as a function of the structure of the language under acquisition.

Empirical support for this position comes from recent research comparing monolingual children acquiring English, French, Italian, or Spanish (Hall, Waxman, Bredart, & Nicolay, 2003; Waxman, Senghas, & Benveniste, 1997). Although these languages are closely related, they provided an interesting set of cross-linguistic comparisons, primarily because of differences in the syntactic contexts and semantic functions associated with the grammatical form *adjective*. These differences permit us to examine how expectations for *adjectives* are shaped by the language being acquired.

To get a flavor for these differences, consider a cupboard holding several different coffee cups. Speakers of English and French distinguish the cups linguistically using a determiner, an adjective, and an overt noun (e.g., "a *blue* cup" or "the *blue* one"). In Italian and Spanish, although such constructions are sometimes apt, whenever the referent of the noun (cup) is recoverable from the context, it is omitted obligatorily from the surface of the sentence, leaving the determiner and adjective alone (e.g., "uno *azul*" or "a *blue*"). That is, in contexts where English speakers would say "the *blue* one," Spanish and Italian speakers allow the noun to be elided.

These constructions, known to linguists as *det-A* constructions, are ubiquitous in Italian and Spanish. Although *det-A* constructions also appear in English and French, they do so under highly restricted circum-

stances. Moreover, although *det-A* constructions are permissible in a slightly broader range of circumstances in French than in English, in both languages, this construction is relatively rare, and appears to be learned on a case-by-case basis rather than emerging as the product of a productive grammatical rule, as in Italian and Spanish (see Gathercole & Min, 1997, for other semantic/syntactic factors in Spanish and English, and their relation to acquisition; and Waxman et al., 1997, for a more detailed treatment of the *det-A* construction in these languages). Snyder et al. (2001) documented that Spanish-speaking children as young as 2 years of age produce *det-A* constructions broadly and spontaneously (see also, MacWhinney & Snow, 1990).

There are two important features to notice about the adjectives in *det-A* constructions. First, the adjectives in these constructions appear in syntactic contexts that appear to be identical to those where count nouns typically occur.⁹ Second, adjectives in these constructions appear to adopt a semantic function that is customarily associated with count nouns. *Det-A* constructions can refer to the named object *qua* object and can be extended to include other members of its object category, if these members also share the named property. Importantly, then, in Italian and Spanish there is considerable overlap in both the surface syntactic contexts and the semantic extensions for nouns and adjectives.

Does experience with these different languages lead to different outcomes in the expectations concerning the grammatical form *adjective*? As a first step in examining this hypothesis, Waxman and her colleagues (Waxman et al., 1997) conducted a cross-linguistic investigation involving preschool-age monolingual children acquiring either English, French, Italian, or Spanish. Each child “read” through a picture book with an experimenter (a native speaker of the child’s language). On each page, there were five pictures: a target (e.g., a cow), two category-based alternatives (e.g., a fox and a zebra), and two thematically related alternatives (e.g., a barn and milk). Children were assigned to one of three conditions. In the no-word condition, the experimenter pointed to the target and said, “See this? Can you find another one?” In the novel noun condition, she said, for example, “See this *fopin*? Can you find another *fopin*?”

In the novel adjective condition, she said, “See this *fopish* one? Can you show me another one that is *fopish*?”

The predictions were straightforward. (a) If a link between nouns and object categories is universal, then all children should extend the novel nouns to the category-based test objects; (b) If cross-linguistic differences regarding the grammatical form *adjective* have consequences on acquisition, then children’s extensions of the novel adjectives should vary as a function of native language. In Italian and Spanish, where adjectives are permitted to adopt some of the syntactic and semantic features associated with nouns, children may extend novel adjectives (like nouns) to other members of the same category. In contrast, in English and in French, where this nominal interpretation of novel adjectives is not available, children should fail to extend novel adjectives to category members and should perform at chance levels.

The results were consistent with these predictions. Children from each language community consistently extended the novel nouns to the category-based alternatives. But performance in the *novel adjective* condition varied systematically as a function of language. As predicted, children acquiring French and English performed at the chance level, while those acquiring Italian and Spanish extended novel adjectives (like novel nouns) to the category-based alternatives. Although this taxonomic inclination was less pronounced for adjectives than for nouns, it was quite robust, holding up in children ranging from 3 to 7 years of age. Perhaps most striking, these children extended novel adjectives to the category-based alternatives not only when they were presented in *det-A* phrases (and therefore could have been either nouns or adjectives), but also when they were presented in phrases incorporating an overt noun (e.g., *cosa*). Thus, even when the syntactic contexts were unambiguously adjectival and fully comparable to those in English and French, Italian- and Spanish-speaking children extended the novel adjectives on the basis of category membership.

These results suggest that children’s expectations for adjectives are tailored by features of the particular language being acquired. For children acquiring English or French, languages in which nouns (but not adjectives) can refer to objects and can be extended to other category members, children build an expectation that nouns (but not adjectives) can take on this semantic function. For children acquiring Italian and Spanish, experience steers the acquisition process along a slightly different

⁹The adjectives in these *det-A* phrases retain their syntactic status as adjectives (see Kester, 1994; Snyder, 1995; and Waxman et al., 1997, for the relevant diagnostics).

developmental course, permitting children to build an expectation that both nouns and adjectives can be extended on the basis of category membership.

This suggests one way in which language-specific experience shapes the acquisition of the predicate forms. In future work, it will be important to examine these effects in a wider range of languages and to explore the developmental implications of this distributional overlap for infants' ability to distinguish nouns from adjectives.

Conclusions about Adjectives

We have conveyed several insights into the acquisition of adjectives. Although adjectives are plentiful in the input that children hear, and although even infants are sensitive to the properties that are typically encoded by early adjectives (e.g., color, texture, size, temperature, temperament), mapping adjectives to their associated meaning is surprisingly elusive. The mapping for adjectives emerges later than that for nouns and varies as a function of the structure of the ambient language. Moreover, there is a linguistic or conceptual priority to name an object's kind (and especially its basic level category) before marking its properties, however salient those properties may be.

The acquisition of the grammatical form *adjective* appears to rest on the prior acquisition of (at least some) nouns and to require a richer set of linguistic and conceptual cues than nouns (Mintz & Gleitman, 2002; Waxman & Klibanoff, 2000). Moreover, the interpretation of any particular adjective appears to depend (at least in the initial stages of acquisition) on the particular noun that it modifies. These observations have led to the conclusion that early noun learning serves as a gateway for the acquisition of adjectives. We also suggest that noun learning serves as a gateway for the acquisition of verb meaning.

The Acquisition of Verbs

Because not all words share the same grammatical and conceptual requirements, we expect to find differences in the information that learners use to acquire different kinds of words. Most nouns are not argument taking but most verbs are; it may therefore be the case that identifying a verb requires prior identification of the phrases that serve as its arguments. Noun phrases serve this function by helping the learner identify the event denoted by the verb from the extralinguistic context. From

this perspective, early noun learning sets the stage for the subsequent acquisition of other grammatical categories like verbs (Gleitman, 1990). Learning the nouns enables the learner to project noun phrases in the syntax. These noun phrases represent the scaffolding on which infants assemble a rudimentary representation of the structure of the native language (Fisher et al., 1994; Fisher & Tokura, 1996; Naigles, 2002) and this, in turn, provides a foundation for the acquisition of the other essential grammatical forms. The critical idea is that a learner who can identify the nouns in a sentence can build noun phrases, which then serve as the arguments of the verb. Identifying the arguments of the verb leads to a rudimentary syntactic structure which, in turn, is informative of the meaning of the verb. On this view, verb learning is dependent on syntactic structure, which can be partially identified through the identification of the nouns in the sentence.

Informational Differences between Nouns and Verbs

One of the strongest pieces of evidence that the informational requirements for learning verbs are steeper than those for nouns comes from experiments with adult participants in a simulated word-learning environment (Gillette et al., 1999; Snedeker & Gleitman, 2004). Adults were presented a series of videotaped scenes depicting the visual context of a parent uttering a word to their child, but with the sound removed. The participants' task was to identify the word that was uttered by the parent. Participants were divided into several conditions that differed by how much information they received about the linguistic context of the utterance. Participants experienced either (a) just the visual scene, (b) the scene plus the nouns that co-occurred with the novel word, (c) the syntactic frame with nonsense words replacing all the content words, (d) the syntactic frame with co-occurring nouns, or (e) all this information together. Crucially, the proportion of words that were correctly identified and the type of words that were identifiable changed significantly as a function of information type. When presented with no information beyond the visual scene, participants correctly identified nouns more often than they correctly identified verbs. Although participants were least successful at identifying verbs when only the visual scene was presented, they improved as the amount of syntactic information increased. Syntactic information was more effective than the co-occurring nouns in leading participants to the right answer, and the combination of these cues was

more effective than either of these alone. These results lend support to the idea that successful verb learning requires information beyond the observation of extralinguistic context. In particular, syntactic argument structure and the co-occurrence of known nouns serving as syntactic arguments were crucial to adults' success in identifying the missing verbs.

Children's Use of Syntax to Learn Verb Meanings

In addition to these simulations with adult learners, there is by now a wealth of evidence identifying the crucial role of syntax in helping children identify the meanings of novel verbs. Naigles (1990) used the preferential looking paradigm to investigate this issue. Two-year-olds saw a videotaped scene depicting the following two actions simultaneously: A duck forces a rabbit to squat by pushing on its head, while the duck and rabbit each wheel their free arm in a circle. Notice that there is a causal interpretation of the observed event ("to force to squat") and a noncausal interpretation ("to rotate one's arm"). While both interpretations involve two participants, only under one of these interpretations are the two in a causer-to-caused relation. While watching this scene, half the infants heard a disembodied voice say "The duck is biffing the bunny" while the other half heard "The duck and the bunny are biffing." Each utterance thus mentions two entities, but only in the first one do the two entities show up in two different argument positions ("the duck and the bunny" is a single complex noun phrase occupying one argument position; namely, the subject position). This video was then removed and the voice said, "Find biffing now!" Two new videos now appeared, one displayed to the left of the watching child, the other to the right. In one, the duck was shown forcing the rabbit to squat but without arm-wheeling. In the other, the duck and rabbit were shown standing side by side wheeling their arms. Infants attended longest to the scene that matched the syntax. When the novel verb was presented as a transitive verb ("the duck is biffing the bunny"), infants took that verb to refer to the causative event in which the duck causes the bunny to squat. When the novel verb was presented as an intransitive ("the duck and the bunny are biffing"), they looked longest at the noncausative action in which the characters were wheling their arms. Evidently the syntactic structure was decisive in cueing which aspect of the complex initial scene was relevant to the interpretation of *biffing* (Naigles, 1990; see also Fisher et al., 1994; Naigles,

1996; Naigles & Kako, 1993). This work demonstrates that 2-year-olds can use the syntax to assign a meaning to a novel verb.

Bunger and Lidz (2004) used the preferential looking paradigm to show that syntax can be useful not only in distinguishing which of two simultaneously occurring events is labeled by a novel verb, as in Naigles' studies, but also in distinguishing which aspect of a single internally complex event is so labeled. The relevant case also involved causative events that, although typically expressed as one lexical unit (e.g., *kill*, *roll*), can be decomposed into two subevents (Dowty, 1979; Hale & Keyser, 1993; Jackendoff, 1990; Levin & Rappaport-Hovav, 1995; McCawley, 1968). The conceptual structure of a causative event can be represented as in (2), with open argument positions to be filled by the causer of the event and the affected entity:

(2) [[X DO SOMETHING] CAUSE [Y BECOME STATE]].

The first subpart of this structure [X DO SOMETHING] specifies the causing subevent, or the means, and the second subpart [Y BECOME STATE] specifies the resulting change of state. For example, a verb like *bounce* (a) can be represented as in (b):

(3) a. The girl bounced the ball.

b. [[The girl HITS THE BALL] CAUSE [the ball BECOME BOUNCING]]

Bunger and Lidz (2004) asked three questions. First, do young children have internally complex representations like (2) for the concepts labeled by causative verbs? Second, can different syntactic structures differentially direct children's attention to these subevents (thereby influencing their interpretation of a novel verb used to describe the event). Third, are children limited to using syntax to distinguish between multiple distinct events in the world as in Naigles (1990), or can they also use it to parse single events that are internally complex.

To answer these questions, they conducted a preferential looking study in which 2-year-old children saw internally complex causative events labeled by a novel verb occurring in distinct syntactic structures. Children were first familiarized to an event of direct causation (e.g., a girl bouncing a ball) described by a novel verb. The syntactic frame in which the novel verb was presented varied across children in four ways: control ("Look at that"), transitive ("The girl is pimming the ball"),

unaccusative¹⁰ (“The ball is pimming”), or multiple frame (transitive + unaccusative: “The girl is pimming the ball.” “Do you see the ball pimming?”). This training phase was followed by a test phase, identical for all conditions, in which children heard the novel verb (“Where’s pimming now?”) while they saw, on opposite sides of the screen, the separate subevents depicting the means (the girl patting a ball, but no bouncing) and the result (the ball bouncing with the girl standing idly by) of the complex causative presented during training.

Because the unaccusative variant of a causative verb labels the result subevent without making reference to the means, Bunger and Lidz (2004) predicted that children in the unaccusative and multiple-frame conditions would be more likely than children in the transitive and control conditions to interpret the novel verb as referring to the result subevent. This prediction was borne out. At test, children in the control and transitive conditions showed no significant preference for either subevent. Crucially, however, children in the unaccusative and multiple-frame conditions demonstrated a significant preference for the result subevent. Thus, the syntactic context in which novel verbs were presented guided children’s interpretations of those verbs, even when the verbs referred to subparts of internally complex events.

In an interesting refinement, Fisher and her colleagues (Fisher et al., 2004; Fisher & Tokura, 1996) asked whether these kinds of syntactic bootstrapping effects result from the syntax *per se*, or whether they might result from children’s knowledge of the meanings of the co-occurring nouns. Her method was to provide children with structural cues without providing contentful noun phrases. Two- and three-year-old children saw two same-gender individuals participating in a single event. For example, a woman was being twirled in a swivel chair by another woman, by the stratagem of pulling on a long ribbon attached to the former woman’s waist. The children were asked to “Show me the one who’s pilking around” or “Show me the one who’s pilking her around” by pointing to one of the depicted women. These children used the number and position of noun phrases in the sentence to determine which of the two women was being referred to, even though these

noun phrases were just pronouns. When they heard the transitive sentence, they picked the woman doing the twirling; that is, they interpreted the two-noun phrase sentence as describing the causal aspect of the observed event; symmetrically, when they heard the intransitive sentence, they picked the woman being twirled. Thus, we see that although the identification of nouns can help to build a syntactic structure, it is this structure, and not only the semantic information contained in the nouns, that guides children’s acquisition of novel verbs. This conclusion does not mean that verb learning is independent of noun learning. Rather, to the extent that learning nouns leads to learning verbs, this support is mediated through the projection of syntactic structure.

An additional kind of evidence for children’s use of syntax to guide verb learning comes from their interpretations of known verbs in novel syntactic contexts (Lidz, 1998; Naigles, Fowler, & Helm, 1992; Naigles & Kako, 1993). In these experiments 2-, 3-, and 4-year-old children used objects from a Noah’s ark playset to act out sentences presented to them by an experimenter. Some of the sentences were grammatical, whereas others were ungrammatical in English, but represented structures that are possible in some language. Some sentences added an argument to an intransitive verb, as in “the zebra comes the giraffe to the ark,” while others subtracted a required argument from a transitive verb, as in “the zebra brings to the ark.” While children uniformly provided accurate enactments of the grammatical sentences, their behavior in response to the ungrammatical sentences was crucial in providing a window into the learning process. For these sentences, children essentially had two choices. They could ignore the additional or missing argument, relying on their knowledge of the verb. Alternatively, they could integrate the novel structure into their interpretation, modifying their interpretations of these known verbs. These children adopted the latter strategy. When presented with a sentence like “The zebra comes the giraffe to the ark,” children acted out a scene in which the zebra brings the giraffe to the ark, showing that the extra argument is interpreted as a causal agent. By the same token, “The giraffe brings to the ark” was acted out with the giraffe coming to the ark, with no causal agent.

These studies show that children use the number of noun phrase arguments to broaden the scope of the events that they think a known verb refers to. Although *come* expresses only motion toward a location in the adult language, if this verb is presented with an additional syntactic argument, children who have not yet set-

¹⁰The term “unaccusative” refers to an intransitive verb whose subject behaves in some ways like an object, as in pairs like “the navy sank the boat” versus “the boat sank” (see Burzio, 1986; Levin & Rappaport-Hovav, 1995; Perlmutter & Postal, 1984, for discussion).

tled on a fixed representation of the verb's meaning will take that additional syntactic argument as evidence that the verb can also express caused motion. These studies provide clear evidence for the power of syntax in licensing inferences about verb meaning. Moreover, they enable us to ask whether children are constrained in how they extend known verbs into novel contexts. We now turn to this question.

Cross-Linguistic Evidence and Constraints on Verb Learning

The fact that children can use syntax as one source of information in learning novel verbs allows us to ask questions not only about how children learn verbs but also about the existence of constraints on verb learning. We can ask whether children are limited in their verb learning by the kinds of constraints that appear to hold across diverse languages. The research strategy is to look for cross-linguistically stable generalizations and then ask whether children's learning reflects those generalizations. The idea behind this strategy is that linguistic universals derive from principled constraints on what a possible human language is. Thus, to the extent that these constraints can be found in verb learners, we add to the evidence in support of them. From another perspective, cross-linguistically stable generalizations provide us with hypotheses about constraints on verb learning that can then be tested on children who are developing a lexicon. Moreover, to the extent that a property of verb meaning or linking can vary cross-linguistically, we expect to find that property to be highly sensitive to aspects of the linguistic environment, since it will depend not on principled constraints from the learner, but on the observation of the particular language being learned (the linguistic input).

Syntactic and Semantic Types of Arguments.

The method of testing children's extensions of known verbs to novel contexts has been used to investigate children's knowledge of the connection between syntactic and semantic types of arguments and the range of possible verb meanings (Lidz, Gleitman, & Gleitman, 2004). The rationale for this manipulation is based on the observation that some aspects of the mapping from event participants to syntactic categories are universal, while other aspects are more variable both within and across languages. A propositional argument can be realized as a tensed clause (*John thinks that Mary will win*) or an infinitival clause (*John expects Mary to win*) but not as a noun phrase referring to an in-

dividual (**John thinks the winner*).¹¹ The choice of tensed or untensed clause, however, is subject to lexical variability and must be learned on a verb-by-verb basis. Similarly, some change-of-state verbs that can occur with one argument (*the vase dropped*) can also occur with two (*I dropped the vase*), while others do not allow this alternation (*the vase fell*; **I fell the vase*). But, verbs in this class never have their arguments realized as sentential complements (**John falls that it is Bill*; **John drops Bill to be here*).

Given the existence of principled constraints on the syntax-semantics mapping (e.g., that verbs denoting relations between individuals and propositions can take clausal arguments), as well as lexically specific constraints (e.g., that *think* takes a tensed sentence complement but not an infinitival complement), we can ask whether children are limited in the ways that they are willing to extend known verbs in accordance with these constraints. To do this, Lidz et al. (2004) examined 3-year-old children's understanding of known verbs in syntactic contexts that are permitted by language, but not by the language they happen to be learning (*the zebra falls the giraffe*; *the zebra thinks the giraffe to go to the ark*) and compared this with their understanding of known verbs in syntactic contexts that are not permitted by any language (**the zebra falls that the giraffe goes to the ark*; **the zebra thinks the giraffe*). The reasoning behind this manipulation was the following: If children are constrained to allow only those mappings that are allowed by language in general, then they should distinguish these two types of extensions. Children should be willing to extend verbs in ways that are possible in principle, but happen not to occur for those particular verbs in their language. They should be unwilling to extend verbs in ways that are in conflict with the principles of syntax-semantics mapping that are found across all languages.

This expectation was met. Lidz et al. (2004) found that children relied on the syntactic structure to guide their enactments only when the novel verb-sentence pairing was a possible pairing in principle (although not in English). In the cases in which the novel syntactic structure would violate principles of syntax to semantic mapping (like **the zebra falls that the giraffe goes to the ark*), children performed actions that relied more heavily on what they already knew about the verb. In other words, children accepted extensions of known verbs into

¹¹ The asterisk (*) is used to indicate that a sentence is grammatically anomalous.

new syntactic frames only when the verb-frame pairing was one that might have been possible. This finding suggests that children's knowledge of the syntax-semantics mapping guides their acquisition of novel verbs even when their lexical representations for certain verbs have not yet solidified. Some aspects of the syntax to semantics mapping do not have to be learned but rather guide learners' hypotheses from the start.

Universals in the Expression of Causativity. The domain of causation, because it has some universal components and some cross-linguistically variable components, has provided another opportunity to isolate the relative contributions of linguistic constraints and linguistic experience. As noted, many change-of-state verbs (e.g., *break*) have both a transitive and intransitive use that differ with respect to causativity. The transitive version (4a) includes an argument to play the role of causer, whereas the intransitive version (4b) does not:

- (4) a. Kim broke the vase.
 b. The vase broke.

This relation between transitivity and causativity is found in all languages (Comrie, 1985; Haspelmath, 1993, among others). One thing that does vary cross-linguistically is whether the alternation is morphologically marked. In many languages, the intransitive variants are basic, and an additional causative morpheme is used to indicate causation. In other languages, the transitive variants are basic and an additional anti-causative morpheme indicates the lack of causation. In still other languages, both strategies exist for different verbs. Thus, the addition and subtraction of arguments is used universally to mark causative status, whereas the use of verbal affixes to mark causative status varies both cross-linguistically and within a language.

This state of affairs presents an interesting research question—whether children use argument number as a cue to causativity because this cue is reliably present in their language or because they are predisposed to do so. Lidz, Gleitman, and Gleitman (2003) pitted the universal property of argument number against the cross-linguistically variable property of morphology in Kannada, a language with causative morphology, to distinguish the effect of inherent constraints on the learner from the effect of the language environment. Do children use argument number as a cue to causal verb meaning as a result of observing this relationship in the input? Or is this

relationship in the input because all language learners expect their language to express it?

Kannada is an appropriate probe language because of its abundant use of the morphological cue to causativity. In Kannada, any verb can be made causative through the addition of a causative morpheme. Moreover, whenever this morpheme is present, the causal interpretation is entailed. Finally, in Kannada, as in all languages, many verbs with two arguments are not interpreted causally. Given this pattern of facts, the causative morpheme is a more reliable cue for causation than is the number of arguments.

Because the presence of the causative morpheme guarantees a causal interpretation but the presence of two arguments is only probabilistically associated with causal interpretation, Kannada can offer some insight into the origins of the connection between argument number and causal interpretation.

Lidz et al. (2003) used the Noah's ark methodology described earlier with 3-year-old children learning Kannada as their first language. Children were presented with known verbs with either one or two noun phrase arguments and either with or without the causative morpheme. The predictions were as follows. If children use the most reliable cues in their language input to determine the syntax to semantics mapping, we would expect children learning Kannada to rely more heavily on the causative morpheme as an expression of causativity than on the number of arguments. On the other hand, if children are guided by expectations about the syntax-semantics mapping that are based on the universal grammatical principles, they should rely more heavily on argument number than causative morphology. In the latter case, children would be expected to override the most reliable cue in the input in favor of the less reliable cue determined by inherent grammatical constraints.

The data were clear. Three-year-old Kannada-learning children treated argument number but not morphology as an indication of causativity, despite the fact that the latter is the more reliable cue in their language. In sum, children acted out two-noun-phrase sentences as causative and one-noun-phrase sentences as noncausative, independent of the presence or absence of the causative morpheme.

In effect, these children ignored the more reliable morphological cue to verb meaning and instead relied on the syntactic cue (noun phrase number). This result provides evidence for the priority of the principle aligning noun phrases with semantic participants. The observation that learners discarded the best cue in favor of a

weaker one reveals the active role that learners play in acquiring verb meanings. Learners use argument number as a cue to verb meaning not because it is there in the input, but because they expect to find it there.¹²

Universals and Constraints on Locative Verbs.

Yet another source of evidence for inherent constraints on syntax semantics mapping comes from studies of locative verbs—verbs expressing the movement of some object (the figure) to a location (the ground). Verbs that describe the manner of motion (*pour, spill, shake*) require the figure to occur as the direct object, whereas verbs that describe a change of state (*fill, cover, decorate*) require the ground to occur as the direct object (Rappaport & Levin, 1988):

- (5) a. Edward poured water into the glass.
(figure frame)
- b. *Edward poured the glass with water.
(ground frame)
- c. *Edward filled water into the glass.
(figure frame)
- d. Edward filled the glass with water.
(ground frame)

Studies of the acquisition of these verbs find that children use this syntax-semantics mapping to guide their interpretations and productions (Gropen, Pinker, Hollander, & Goldberg, 1991a, 1991b; Pinker, 1989). However, it has also been observed that children make some errors in production in this domain. Bowerman (1982) found evidence of children using the figure frame inappropriately with change of state verbs in their spontaneous productions. This effect was replicated by Gropen et al. (1991a) and Kim, Landau, and Phillips (1999) in elicited production studies.

Importantly, however, in none of these studies were children reported to have made errors in which they used manner of motion verbs with the ground frame. This asymmetry is important because it mirrors the cross-linguistic variation in this domain. Kim et al. (1999) exam-

ined a wide range of unrelated languages and found that locative change of state verbs vary cross-linguistically in whether they can occur in the figure frame. However, no language was found in which manner of motion verbs can occur in the ground frame. Thus, children's errors are limited to the places where languages can vary. In cases where there are universal constraints on linking patterns, children obey those constraints throughout acquisition. In cases where there are no such constraints, children must rely on their input to guide acquisition.

The Role of Input in Verb Learning

We have seen (a) that children use syntax to guide their acquisition of novel verbs, and (b) that inherent constraints guide children's use of syntax in this regard. However, we also expect to find children showing a sensitivity to the input exactly when inherent constraints from the learner do not exist. In determining a division of labor between the child's internally generated constraints and the child's experience with the language environment, we expect to find sensitivity to the input just in those cases in which the child has no internally generated expectations about verb meaning and verb syntax. This is what we find.

One study showing children's sensitivity to the input in verb learning involved the verb extension methodology discussed earlier. Naigles et al. (1992) examined 2- to 5-year-old children's extensions of motion verbs like *come*, *go*, *bring*, and *take* into syntactic frames where these verbs do not occur. As in the studies previously discussed, these authors found that children, but not adults, adjusted their meanings of these verbs to fit the syntactic context. Thus, when *come* was presented transitively (*the zebra comes the giraffe to the ark*), children treated it as expressing the causal event in which the zebra brings (= cause to come) the giraffe to the ark. Adults on the other hand seemed to interpret the sentence as an error and repaired the syntax, acting out a noncausal scenario (e.g., the zebra and the giraffe come to the ark). Interestingly, the transition to adult behavior varied as a function of age and, most importantly, as a function of verb frequency. In particular, intransitive *bring* and *take* were repaired earlier than transitive *come* and *go*. This finding is important because the intransitive (ungrammatical) variants of *bring* and *take* express the same meanings as the intransitive (but grammatical) variants for *come* and *go*. Likewise, the transitive (ungrammatical) variants of *come* and *go* express the same meanings as the transitive (grammatical) variants of

¹² Kannada-speaking adults eventually do acquire this special ("language specific") feature of their language. To say that they did not would mean that the Kannada language had changed. So it is reassuring to find, as we did, that Kannada adults show sensitivity both to argument number and to the causative morpheme when they participate in the Noah's ark experiment.

bring and *take*. Thus, the learner at some point should recognize that these verbs represent suppletive pairs (e.g., *come* = *bring*; and *go* = *take*, modulo the difference in causation) and stop allowing the intransitives to be used transitively and vice versa. But, importantly, what Naigles et al. found was that the repairs did not all begin at the same time. Instead, the more frequent verbs (*come* and *go*) were repaired later than the less frequent verbs (*bring* and *take*). This can be understood as the effect of frequency on suppletion. The higher frequency items allow children to build stable lexical representations earlier. Thus, these representations block the use of other words to express those same meanings. *Bring* is disallowed as an intransitive because the child has learned that *come* expresses that meaning. Experience with a given verb determines the learner's willingness to accept other verbs as expressing that same meaning. Most importantly, from the present perspective, the effect of experience appears here because there are no expectations or constraints from children to tell them whether a verb like *come* can or cannot be used transitively. This must come from experience.

Other studies also highlight the importance of children's sensitivity to the input in verb learning (e.g., Childers & Tomasello, 2002; Naigles & Hoff-Ginsberg, 1998; Snedeker & Trueswell, in press; Tomasello, 1992, among others). These studies tell us that for properties of verb representation that can vary within a language, children are extremely sensitive to the frequency of occurrence of those representations. As expected, when there are no constraints from the child on what the verb's representation should be like, the linguistic environment exerts a strong influence.

Conclusions about Verbs

We have conveyed several messages about the state of the art in verb learning. First, because verbs have complex representations that depend on the prior acquisition of certain other linguistic properties (minimally, the recognition of syntactic arguments), they are acquired later than nouns. Second, by paying attention to the details of how verbs are represented in the minds of adult speakers and whether these details can and cannot vary across languages, we can develop very clear predictions about the kinds of constraints on verb learning that we should find in children. In cases where cross-linguistic evidence suggests that a linking may be universal, we suspect that inherent constraints may be at play and therefore that we should be able to see these constraints

in experimental manipulations with young learners. Where properties of representation can vary, however, we expect to find little evidence of inherent constraints. Instead, we expect to see a strong influence of the linguistic environment. As we have argued throughout this chapter, the important question in language acquisition and in word learning is not whether there are inherent constraints on learners. Rather, the crucial questions are where we expect to see the effects of constraints, where we expect to see the effects of experience, and how constraints interact with experience to guide acquisition.

THE FUTURE OF WORD-LEARNING RESEARCH

The study of word learning must take into account the variety of word types found in natural languages. In this chapter, we have focused on the acquisition of the major grammatical categories—noun, adjective, and verb—highlighting that nouns tend to emerge first in language acquisition and serve as the foundation for the discovery of the other grammatical forms and their meanings.

The kinds of words that we have examined, however, only scratch the surface of those found in natural languages. Languages include words that quantify over individuals (*a*, *the*, *every*, *two*), words that compare sets of individuals (*most*, *more*, *less*), words that refer back to previously mentioned entities (*he*, *she*, *one*, *herself*), words that quantify over events (*always*, *sometimes*), words that describe the manner of an event (*quickly*, *repeatedly*), and so on. As we have suggested, each kind of word points to a restricted range of concepts. Moreover, the relation between linguistic and conceptual structure is bidirectional. Distinct grammatical forms highlight distinct kinds of meaning; but at the same time, linguistic structure is in many ways derived from the meaning of the words involved. Differences in meaning therefore lead to differences in syntax. Consequently, examining the role of syntax in word learning is crucial, as the syntax provides a surface cue that the learner can use to infer the meaning of the word and that the developmental researcher can use to infer what might count as knowledge of the word.

We have also underscored the argument that the field of word learning must be sensitive to cross-linguistically stable and cross-linguistically variable properties of words and grammatical categories. Cross-linguistic research can be instrumental in developing hypotheses

both about the kinds of structures within the learner that guide acquisition and about the kinds of linguistic input that shape word learning. A maximally general theory of word learning must still be constrained enough to explain the speed with which children grow a lexicon and flexible enough to allow this growth to occur in a wide range of linguistic environments. By placing word learning firmly within the context of development and of comparative linguistics, we have provided a foundation for future research in which we consider the full range of words represented in human language and the full range of concepts to which these apply. Current word-learning research reveals that learners exhibit some general sensitivities and expectations at the onset of acquisition that later become tuned to the child's particular language environment.

We began this chapter with a reference to Janus, the god of gateways and transitions. We have argued throughout this chapter that word learning resides on the boundary between conceptual and linguistic knowledge and that word learning represents a doorway through which constraints from the learner interact with the vagaries of linguistic environment. We end with a final reference to Janus. Word-learning research now stands at an important threshold, having reached a point where a focus on noun learning can be replaced with a broader, more inclusive, conception of the range of concepts and grammatical knowledge involved in word learning. Crossing this threshold will require the field to continue to integrate ideas, methods, and generalizations from developmental psychology, cognitive psychology, and comparative linguistics.

Gesture Offers Unique Insight into a Child's Knowledge	350

A student waves her arm wildly when the teacher asks a question. Another shrinks into her seat while trying hard not to make eye contact. Both are letting the teacher know whether they want to answer the question. Such acts are part of what is called *nonverbal communication*. A wide-ranging array of behaviors count as nonverbal communication—the home and work environments we create; the distance we establish between ourselves and our listeners; whether we move our bodies, make eye contact, or raise our voices—all collaborate to send messages about us (Knapp, 1978). But these messages, while important in framing a conversation, are not the conversation itself. The student's extended arm or averted gaze does not constitute the answer to the teacher's question but simply reflects the student's attitude toward answering that question.

Preparation of this chapter was supported in part by grant R01 DC00491 from NIDCD and grants R01 HD47450 and P01 HD40605 from NICHD.

CONCLUSION	365
REFERENCES	365

According to Argyle (1975), nonverbal behavior expresses emotion, conveys interpersonal attitudes, presents one's personality, and helps manage turn-taking, feedback, and attention (see also Wundt, 1900/1973). Argyle's characterization fits with most people's intuitions about the role nonverbal behavior plays in communication. But people do not instinctively realize that nonverbal behavior can reveal thoughts as well as feelings. The striking omission from Argyle's list is that it gives absolutely no role to nonverbal behavior in conveying a message—only a role in conveying the speaker's attitude toward the message or in regulating the interaction between speaker and listener.

This is the traditional view. Communication is divided into content-filled verbal and affect-filled nonverbal components. Kendon (1980) was among the first to challenge this view, arguing that at least one form of nonverbal behavior—gesture—cannot be separated from the content of the conversation. As McNeill (1992) has shown in his groundbreaking studies of gesture and

speech, the hand movements we produce as we talk are tightly intertwined with that talk in timing, meaning, and function. To ignore the information conveyed in these hand movements, these gestures, is to ignore part of the conversation.

This chapter is about children's use of gesture—how they produce gestures of their own and understand the gestures that others produce. I focus on gesture as opposed to other forms of nonverbal behavior precisely because gesture has the potential to reveal information about how speakers think, information that is not always evident in their words. I begin by situating gesture within behaviors traditionally identified as nonverbal. Because gesture is intimately tied to speech, I next chart its development not only in children whose language-learning follows a typical course but also in children for whom language-learning has gone awry. We will see that gesture is remarkably versatile and assumes a new form when circumstances require it to assume a new function. Gesture is shaped by the functions it serves, not by the modality in which it is produced, and thus has the potential to tell us about those functions. I then show that gesture fulfills its potential, providing insight into a child's thoughts and, at times, offering a unique picture of those thoughts. In the remainder of the chapter, I explore the mechanisms and functions of gesture: What makes us gesture, and what purpose does gesture serve? I focus, in particular, on whether gesture plays a role in communication and thinking and, as a result, has an impact on cognitive change—whether gesture goes beyond reflecting a child's thoughts to having a hand in shaping those thoughts.

SITUATING GESTURE WITHIN THE REALM OF NONVERBAL BEHAVIOR

In 1969, Ekman and Friesen proposed a scheme for classifying nonverbal behavior and identified five types:

1. *Affect displays*, whose primary site is the face, convey the speaker's emotions, or at least those emotions that the speaker does not wish to mask (Ekman, Friesen, & Ellsworth, 1972).
2. *Regulators*, which typically involve head movements or slight changes in body position, maintain the give-and-take between speaker and listener and help pace the exchange.

3. *Adaptors* are fragments or reductions of previously learned adaptive hand movements that are maintained by habit; for example, smoothing the hair, pushing glasses up the nose even when they are perfectly positioned, holding or rubbing the chin. Adaptors are performed with little awareness and no intent to communicate.
4. *Emblems* are hand movements that can be produced with speech or without it. They have conventional forms and meanings; for example, the "thumbs up," the "okay," the "shush." Speakers are always aware of having produced an emblem and produce them to communicate with others, often to control their behavior.
5. *Illustrators* are hand movements that are directly tied to speech and often illustrate that speech; for example, a child says that the way to get to her classroom is to go upstairs and, at the same time, bounces her hand upward.

The focus in this chapter is on the last category—illustrators—called *gesticulation* by Kendon (1980) and plain old *gesture* by McNeill (1992), the term I use here. Gestures can mark the tempo of speech (beat gestures), point out referents of speech (deictic gestures), or exploit imagery to elaborate the contents of speech (iconic or metaphoric gestures). Gestures sit somewhere between adaptors and regulators at one end and emblems at the other end of the awareness spectrum. People are almost never aware of having produced an adaptor or regulator and are almost always aware of having produced an emblem. Because gestures are produced along with speech, they take on the intentionality of speech. Gestures are produced in the service of communication and, in this sense, are deliberate, but they rarely come under conscious control.

Gestures differ from emblems in other ways (McNeill, 1992). Gestures depend on speech; emblems do not. Indeed, emblems convey their meanings perfectly well when produced without any speech at all. In contrast, the meaning of a gesture is constructed in an ad hoc fashion in the context of the speech it accompanies. In the earlier example, the bouncing-upward gesture referred to taking the stairs. If that same movement were produced in the context of the sentence "production increases every year," it would refer instead to yearly incremental increases. In contrast, emblems have a constant form-meaning relation that does not depend on the vagaries of the conversation. The thumbs-up emblem means "things are good" independent of the particular

sentence it accompanies and even if not accompanied by any sentence whatsoever. Emblems are also held to standards of form. Imagine making the thumbs-up sign with the pinky, instead of the thumb—it just doesn't work. But producing the bouncing-upward gesture with either a pointing hand, an open palm, or even an O-shaped hand seems perfectly acceptable. In this sense, emblems (but not gestures) are like words, with established forms that members of the community can understand and critique in the absence of context or explanation.

It is precisely because gestures are produced as part of an intentional communicative act (unlike adaptors) and are constructed at the moment of speaking (unlike emblems) that they are of interest to us. They participate in communication, yet they are not part of a codified system. As such, they are free to take on forms that speech cannot assume or, for a child who has not yet mastered a task, forms that the child cannot yet articulate in speech.

THE DEVELOPMENT OF GESTURE IN LANGUAGE-LEARNING CHILDREN

Children typically use gesture before they are able to speak and become gesture producers early in development.

Becoming a Gesture Producer

At a time in their development when children are limited in what they can say, gesture offers an additional avenue of expression, one that can extend the range of ideas that a child can express. And young children take advantage of this offer (Bates, 1976; Bates, Benigni, Bretherton, Camaioni, & Volterra, 1979; Petit, 1988). In a group of 23 children learning Italian, all 23 used gestures at 12 months (only 21 used words; Camaioni, Caselli, Longobardi, & Volterra, 1991). Moreover, the children's gestural vocabularies, on average, were twice the size of their speech vocabularies (11 gestures versus 5.5 words). Strikingly, even deaf children acquiring sign language produce gestures, and at the earliest stages of language-learning, they produce more gestures than signs (Capirci, Montanari, & Volterra, 1998).

Gesture Is an Early Form of Communication

Children typically begin to gesture between 8 and 12 months (Bates, 1976; Bates et al., 1979). They first use deictics, pointing or hold-up gestures, whose meaning is given entirely by the context and not by their form. For

example, a child of 8 months may hold up an object to draw an adult's attention to it and then, several months later, point at the object. In addition to deictic gestures, children produce the conventional gestures common in their cultures such as nods and side-to-side headshakes. Finally, at about a year, children begin to produce iconic gestures, although the number tends to be small and variable across children (L. P. Acredolo & Goodwyn, 1988). A child might open and close her mouth to represent a fish or flap her hands to represent a bird (Iverson, Capirci, & Caselli, 1994). Children do not begin to produce beat or metaphoric gestures until much later in development (McNeill, 1992).

Deictic gestures and iconic gestures offer children a relatively accessible route into language. Pointing gestures precede spoken words by several months for some children. These early gestures are unlike nouns in that an adult must follow the pointing gesture's trajectory to its target to figure out which object the child means to indicate. In this sense, they more closely resemble the context-sensitive pronouns "this" or "that." Despite their reliance on the here-and-now, pointing gestures constitute an important early step in symbolic development and pave the way for learning spoken language. Iverson, Tencer, Lany, and Goldin-Meadow (2000; see also Iverson & Goldin-Meadow, 2005) observed five children at the earliest stages of language-learning, and calculated how many objects a child referred to using speech only ("ball"), gesture only (point at ball), or both ("ball" and point at ball, produced either at the same time or at separate moments). The children referred to a surprisingly small percentage of objects in speech only, and an even smaller percentage in both speech and gesture. Over half of the objects the children mentioned were referred to *only* in gesture. This pattern is consistent with the view that gesture serves a bootstrapping function in lexical development—it provides a way for the child to refer to objects in the environment without having to produce the appropriate verbal label.

Unlike a pointing gesture, the form of an iconic gesture captures aspects of its intended referent. Its meaning is consequently less dependent on context. These gestures therefore have the potential to function like words, and according to Goodwyn and Acredolo (1998, p. 70), they do just that. Children use their iconic gestures to label a wide range of objects (tractors, trees, rabbits, rain). They use them to describe how an object looks (big), how it feels (hot), and even whether it is there (all gone). They use them to request objects (bottle) and actions (out). However, there are differences

across children in how often they use iconic gestures, and also in whether they use these gestures when they cannot yet use words. Goodwyn and Acredolo (1993) compared the ages at which children first used words and iconic gestures symbolically. They found that the onset of words occurred at the same time as the onset of gestures for only 13 of their 22 children. The other 9 began producing gestural symbols at least 1 month before they began producing verbal symbols; some began as much as 3 months before. Importantly, none of the children produced verbal symbols before they produced gestural symbols. In other words, none of the children found words easier than gestures, but some did find gestures easier than words.

Not surprisingly, children stop using symbolic gestures as words as they develop. They use fewer gestural symbols once they begin to combine words with other words, whether the language they are learning is English (L. P. Acredolo & Goodwyn, 1985, 1988) or Italian (Iverson et al., 1994). There appears to be a shift over developmental time: At the beginning, children seem to be willing to accept either gestural or verbal symbols, but as they develop, children begin to rely more heavily on verbal symbols. Namy and Waxman (1998) have found experimental support for this developmental shift. They tried to teach 18- and 26-month-old English-learning children novel words and novel gestures. Children at both ages learned the words, but only the *younger* children learned the gestures. The older children had already figured out that words, not gestures, carry the communicative burden in their worlds.

Children thus exploit the manual modality at the very earliest stages of language-learning. Perhaps they do so because the manual modality presents fewer burdens. It certainly seems easier to produce a pointing gesture to indicate a bird than to articulate the word *bird*. It may even be easier to generate a wing-flap motion than to say “bird.” Children may need more motor control to make their mouths produce words than to make their hands produce gestures. Whatever the reason, gesture seems to provide an early route to first words, at least for some children.

Even though they treat gestures like words in some respects, children rarely combine their gestures with other gestures, and if they do, the phase tends to be short-lived (Goldin-Meadow & Morford, 1985). But children frequently combine their gestures with words, and they produce these word-plus-gesture combinations well before they combine words with words. Children’s earliest gesture-speech combinations contain gestures that convey

information redundant with the information conveyed in speech; for example, pointing at an object while naming it (de Laguna, 1927; Greenfield & Smith, 1976; Guillaume, 1927; Leopold, 1949). The onset of these gesture-speech combinations marks the beginning of gesture-speech integration in the young child’s communications.

Gesture Becomes Integrated with Speech during the One-Word Period

The proportion of a child’s communications that contains gesture seems to remain relatively constant throughout the single-word period. What changes over this time period is the relationship gesture holds to speech. At the beginning of the one-word period, three properties characterize children’s gestures:

1. Gesture is frequently produced alone; that is, without any vocalizations at all, either meaningless sounds or meaningful words.
2. On the rare occasions when gesture is produced with a vocalization, it is combined only with meaningless sounds and not with words; this omission is striking given that the child is able to produce meaningful words without gesture during this period.
3. The few gesture-plus-meaningless sound combinations that the child produces are not timed in an adult fashion; the sound does not occur on the stroke or the peak of the gesture (cf. Kendon, 1980; McNeill, 1992).

During the one-word period, two notable changes take place in the relationship between gesture and speech (Butcher & Goldin-Meadow, 2000). First, gesture-alone communications decrease, and in their place, the child begins to produce gesture-plus-meaningful-word combinations for the first time. Gesture and speech thus begin to have a *coherent semantic* relationship. Second, gesture becomes synchronized with speech, not only with the meaningful words that compose the novel combinations but also, importantly, with the old combinations that contain meaningless sounds (in other words, temporal synchronization applies to both meaningful and meaningless units and is therefore a separate phenomenon from semantic coherence). Thus, gesture and speech begin to have a *synchronous temporal* relationship. These two properties—semantic coherence and temporal synchrony—characterize the integrated gesture-speech system found in adults (McNeill, 1992) and appear to have their origins during the one-word period.

This moment of integration is the culmination of the increasingly tight relation that has been evolving between hand and mouth (Iverson & Thelen, 1999). Infants produce rhythmic manual behaviors prior to the onset of babbling. These manual behaviors entrain vocal activity so that the child's vocalizations begin to adopt the hand's rhythmical organization, thus assuming a pattern characteristic of reduplicated babble (Ejiri & Masataka, 2001). These rhythmic vocalizations become more frequent with manual behaviors and less frequent with nonmanual behaviors. Thus, by 9 to 12 months, when children produce their first words and gestures, the link between hand and mouth is strong, specific, and stable, and ready to be used for communication (Iverson & Fagan, 2004).

Moreover, the onset of gesture-speech integration sets the stage for a new type of gesture-speech combination—combinations in which gesture conveys different information from that conveyed in speech. For example, a child can gesture at an object while describing the action to be done on that object in speech (pointing to an apple and saying “give”) or gesture at an object while describing the owner of that object in speech (pointing at a toy and saying “mine”; Goldin-Meadow & Morford, 1985; Greenfield & Smith, 1976; Masur, 1982, 1983; Morford & Goldin-Meadow, 1992; Zinober & Martlew, 1985). This type of gesture-speech combination allows a child to express two elements of a proposition (one in gesture and one in speech) at a time when the child is not yet able to express those elements in a single spoken utterance. Children begin to produce combinations in which gesture conveys different information from speech (point at box + “open”) at the same time as, or later than—but *not* before—combinations in which gesture and speech convey the same information (point at box + “box”; Goldin-Meadow & Butcher, 2003; see also Iverson & Goldin-Meadow, 2005). Thus, combinations in which gesture and speech convey different information are not produced until *after* gesture and speech become synchronized, and thus appear to be a product of an integrated gesture-speech system (rather than a product of two systems functioning independently of one another).

In turn, combinations in which gesture and speech convey different information predict the onset of two-word combinations. Goldin-Meadow and Butcher (2003) found in six English-learning children that the correlation between the age of onset of this type of gesture-speech combination and the age of onset of two-

word combinations was high ($r_s = .90$) and reliable. The children who were first to produce combinations in which gesture and speech conveyed different information were also first to produce two-word combinations. Importantly, the correlation between gesture-speech combinations and two-word speech was specific to combinations in which gesture and speech conveyed *different* information. The correlation between the age of onset of combinations in which gesture and speech conveyed the *same* information and the age of onset of two-word combinations was low and unreliable. It is the *relation* that gesture holds to speech that matters, not merely gesture's presence (see also Ozcaliskan & Goldin-Meadow, 2005b).

In sum, once gesture and speech become integrated into a single system (as indexed by the onset of semantically coherent and temporally synchronized gesture-speech combinations), the stage is set for the child to use the two modalities to convey two distinct pieces of a single proposition within the same communicative act. Moreover, the ability to use gesture and speech to convey different semantic elements of a proposition is a harbinger of the child's next step—producing two elements within a single spoken utterance, that is, producing a simple sentence (see also Capirci et al., 1998; Goodwyn & Acredolo, 1998; Iverson & Goldin-Meadow, 2005).

Gesture Continues to Play a Role in Communication over the Course of Development

The findings described thus far suggest that gesture and speech become part of a unified system sometime during the one-word period of language development. Over time, children become proficient users of their spoken language. At the same time, rather than dropping out of children's communicative repertoires, gesture continues to develop and play an important role in communication. Older children frequently use hand gestures as they speak (Jancovic, Devoe, & Wiener, 1975), gesturing when asked to narrate a story (e.g., McNeill, 1992), give directions (e.g., Iverson, 1999), or explain their reasoning on a series of problems (e.g., Church & Goldin-Meadow, 1986).

As in earlier stages, older children often use their hands to convey information that overlaps with the information conveyed in speech. Take, for example, a child participating in a Piagetian conservation task. The child is asked whether the amount of water changed when it was poured from a tall, skinny container into a

short, wide container. The child says that the amount of water did change “cause that’s down lower than that one,” while first pointing at the relatively low water level in the short, wide container and then at the higher water level in the tall, skinny container (Figure 8.1a). The child is focusing on the height of the water in both speech and gesture and, in this sense, has produced a *gesture-speech match*.

However, children also use their gestures to introduce information that is not found in their speech. Consider another child who gave the same response in speech, “cause this one’s lower than this one,” but indicated the *widths* (not the heights) of the containers with her hands

(two C-shaped hands held around the relatively wide diameter of the short, wide container, followed by a left C-hand held around the narrower diameter of the tall, skinny container; Figure 8.1b). In this case, the child is focusing on the height of the water in speech, but on its width in gesture, and has produced a *gesture-speech mismatch* (Church & Goldin-Meadow, 1986).

As in the early stages of language development (see Goldin-Meadow & Butcher, 2003; Iverson & Goldin-Meadow, 2005), gesture and speech adhere to the principles of gesture-speech integration described by McNeill (1992), even when the two modalities convey different information. Consider the child in Figure 8.1b. She says

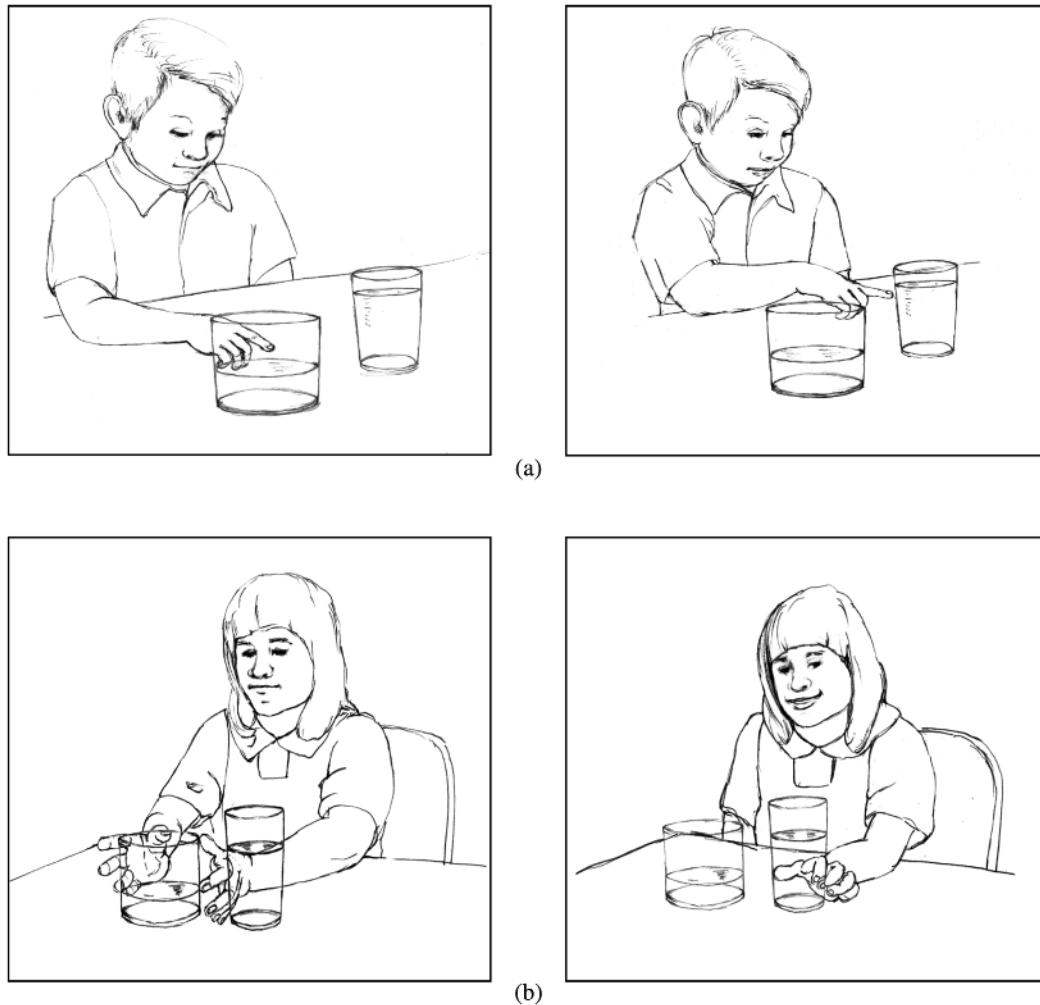

Figure 8.1 Examples of children explaining why they think the amount of water in the two containers is different. Both children say that the amount is different because the water level is lower in one container than the other. The child in the top two pictures (a) conveys the *same* information in gesture (he indicates the height of the water in each container)—he has produced a *gesture-speech match*. The child in the bottom two pictures (b) conveys *different* information in gesture (she indicates the width of each container)—she has produced a *gesture-speech mismatch*.

the amount is different because the water in the short wide container is “lower” while indicating the width of the container in her gestures. Although this child is expressing two different pieces of information in gesture and speech, she is nevertheless describing the same object in the two modalities. Moreover, the timing of the gesture-speech mismatch also reflects an integrated system. The child produces the width gesture as she says “this one’s lower,” thus synchronously expressing her two perspectives on the container.

Further evidence that gesture-speech mismatches reflect an integrated system comes from the fact that, as in the transition from one- to two-word speech, the relationship between gesture and speech is a harbinger of the child’s next step. Children who produce many gesture-speech mismatches when explaining their solutions to a task appear to be in a transitional state with respect to that task—they are more likely to profit from instruction and make progress in the task than children who produce few mismatches. Thus, the child in Figure 8.1b is more likely to profit from instruction in conservation than the child in Figure 8.1a (Church & Goldin-Meadow, 1986). Gesture can serve as an index of readiness-to-learn not only for conservation but for other tasks as well: mathematical equivalence as it applies to addition (Perry, Church, & Goldin-Meadow, 1988), balancing a beam on a fulcrum (Pine, Lufkin, & Messer, 2004) and, as described, making the transition from one- to two-word speech (Goldin-Meadow & Butcher, 2003; Iverson & Goldin-Meadow, 2005). If gesture and speech were independent of one another, their mismatch would be a random event and, as a result, should have no cognitive consequence whatsoever. The fact that gesture-speech mismatch is a reliable index of a child’s transitional status suggests that the two modalities are, in fact, *not* independent of one another (Goldin-Meadow, Alibali, & Church, 1993).

Importantly, gesture-speech mismatch is not limited to a particular age, nor to a particular task. Communications in which gesture conveys different information from speech have been found in a variety of tasks and over a large age range:

- Eighteen-month-old infants going through their vocabulary spurt (Gershkoff-Stowe & Smith, 1997).
- Preschoolers reasoning about a board game (M. A. Evans & Rubin, 1979) and learning to count (T. A. Graham, 1999).

- Elementary school-age children reasoning about conservation (Church & Goldin-Meadow, 1986) and mathematics (Perry et al., 1988) problems.
- Middle-schoolers reasoning about seasonal change (Crowder & Newman, 1993).
- Children and adults reasoning about moral dilemmas (Church, Schonert-Reichl, Goodman, Kelly, & Ayman-Nolley, 1995) and explaining how they solved Tower of Hanoi puzzles (Garber & Goldin-Meadow, 2002).
- Adolescents predicting when rods of different materials and thicknesses will bend (Stone et al., 1992).
- Adults reasoning about gears (Perry & Elder, 1997) and problems involving constant change (Alibali, Bassok, Olseth, Syc, & Goldin-Meadow, 1999).
- Adults describing pictures of landscapes, abstract art, buildings, people, machines, and so on (Morrel-Samuels & Krauss, 1992) and narrating cartoon stories (Beattie & Shovelton, 1999a; McNeill, 1992; Rauscher, Krauss, & Chen, 1996).

Moreover, communications in which gesture and speech convey different information can be frequent within an individual. At certain points in their acquisition of a task, children have been found to produce gesture-speech mismatches in over half of their explanations of that task (Church & Goldin-Meadow, 1986; Perry et al., 1988; Pine et al., 2004).

Thus, gesture continues to accompany speech throughout childhood (and adulthood), forming a complementary system across the two modalities. At all ages, gesture provides a medium for conveying ideas that is analog in nature. It is also a medium that is not codified and therefore not constrained by rules and standards of form, as is speech.

Becoming a Gesture Comprehender

Not only do children produce gestures, they also receive them. There is good evidence that by 12 months, infants can understand the gestures that others produce (e.g., at 12 to 15 months, children look at a target to which an adult is pointing; Butterworth & Grover, 1988; Leung & Rheingold, 1981; Murphy & Messer, 1977). But do young children integrate the information they get from the pointing gesture with the message they are getting from speech?

Allen and Shatz (1983) asked 18-month-olds a series of questions with and without gesture, for example, “what says meow?” uttered while holding up a toy cat or cow. The children were more likely to provide some sort of response when the question was accompanied by a gesture. However, they were no more likely to give the *right* response, even when the gesture provided the correct hint (holding up the cat versus the cow). From these observations, we might guess that, for children of this age, gesture serves merely as an attention-getter, not as a source of information.

Macnamara (1977) presented children of roughly the same age with two gestures—the pointing gesture or the hold-out gesture (extending an object out to a child, as though offering it)—and varied the speech that went with each gesture. In this study, the children responded to the gesture, although nonverbally; they looked at the objects that were pointed at and reached for the objects that were held out. Moreover, when there was a conflict between the information conveyed in gesture and speech, the children went with gesture (e.g., if the pointed-at object was not the object named in the speech, the child looked at the object indicated by the gesture).

From these studies, we know that very young children notice gesture and can even respond appropriately to it. However, we do not know whether very young children can integrate information across gesture and speech. To find out, we need to present them with information that has the possibility of being integrated. Morford and Goldin-Meadow (1992) did just that in a study of children in the one-word stage. The children were given “sentences” composed of a word and a gesture, for example, “push” said while pointing at a ball; or “clock” said while producing a *give* gesture (flat hand, palm facing up, held at chest level). If the children could integrate information across gesture and speech, they ought to respond to the first sentence by pushing the ball and to the second by giving the clock. If not, they might throw the ball or push some other object in response to the first sentence, and shake the clock or give a different object in response to the second sentence. The children responded by pushing the ball and giving the clock; that is, their responses indicated that they were able to integrate information across gesture and speech. Moreover, they responded more accurately to the “push” + point at ball sentence than to the same information presented entirely in speech—“push ball.” For these one-word children, gesture + word combinations were *easier*

to interpret than word + word combinations conveying the same information.

One more point deserves mention—the gesture + word combinations were more than the sum of their parts. Morford and Goldin-Meadow (1992) summed the number of times the children pushed the ball when presented with the word “push” alone (0.7) with the number of times the children pushed the ball when presented with the point at ball gesture on its own (1.0). That sum was significantly smaller than the number of times the children pushed the ball when presented with the “push” + point at ball combination (4.9). The children needed to experience *both* parts of the gesture + word combination to produce the correct response. Gesture and speech together evoked a different response from the child than either gesture alone or speech alone.

Kelly (2001) found the same effect in slightly older children responding to more sophisticated messages. The situation was as natural as possible. A child was brought into a room and the door was left ajar. In the speech only condition, the adult said, “it’s going to get loud in here” and did nothing else. In the gesture only condition, the adult said nothing and pointed at the open door. In the gesture + speech condition, the adult said, “it’s going to get loud in here” while pointing at the door. The adult wanted the child to get up and close the door, but he didn’t indicate his wishes directly in either gesture or speech. The child had to make a pragmatic inference to respond to the adult’s intended message.

Even 3-year-olds were able to make this inference, and were much more likely to do so when presented with gesture + speech than with either part alone. Kelly (2001) summed the proportion of times the 3-year-olds responded correctly (they closed the door) when presented with speech alone (.12) and when presented with gesture alone (.22). That sum (.34) was significantly smaller than the proportion of times the children responded correctly when presented with gesture + speech (.73). Interestingly, 4-year-olds did not show this emergent effect. Unlike younger children who needed both gesture and speech to infer the adult’s intended meaning, 4-year-olds could make pragmatic inferences from either speech or gesture on its own. Thus, for 3-year-olds (but not 4-year-olds), gesture and speech must work together to codetermine meaning in sentences of this type. Gesture on its own is ambiguous in this context, and needs speech (or a knowing listener) to constrain its meaning. However, speech on its own is ambiguous in the same way, and

needs gesture to constrain its meaning. It appears to be a two-way street.

Not surprisingly, older children are also able to get meaning from gesture. Moreover, they look like adults in their ability to do so (to be discussed later in this chapter). Kelly and Church (1997) asked 7- and 8-year-old children to watch the videotapes of other children participating in conservation tasks. In half of the examples, the children on the videotape produced gestures that conveyed the same information as their speech (gesture-speech matches; see Figure 8.1a); in the other half, they produced gestures that conveyed different information from their speech (gesture-speech mismatches; Figure 8.1b). The children in the study simply described to the experimenter how they thought the child in the videotape explained his or her answer. The child observers were able to glean substantive information from gesture, often picking up information that the child in the videotape had produced *only* in gesture. If asked to assess the child in Figure 8.1b, children would attribute knowledge of the widths of the containers to the child although she had expressed width only in her gestures.

Children thus get meaning from the gestures that accompany speech. Moreover, those meanings affect how much information is gleaned from the speech. Goldin-Meadow, Kim, and Singer (1999; see also Goldin-Meadow & Singer, 2003) found that teachers' gestures can affect the way their students interpret their *speech* in a math tutorial—at times gesture helps comprehension; at other times, gesture hurts it. Children were *more* likely to repeat a problem-solving strategy the teacher produced in speech when that speech was accompanied by a matching gesture than when it was accompanied by no gesture at all. Consequently, when gesture conveys the same message as speech, perhaps not surprisingly, it helps the child arrive at that message. Conversely, children were *less* likely to repeat a strategy the teacher produced in speech when that speech was accompanied by a mismatching gesture than when it was accompanied by no gesture at all. When gesture conveys a different message from speech, it may detract from the child's ability to arrive at the message presented in speech.

The Gestural Input Children Receive

Very little is known about the gestures that children receive as input during development. Bekken (1989) observed mothers interacting with their 18-month-old

daughters in an everyday play situation and examined the gestures that those mothers produced when talking to their children. She found that mothers gestured less frequently overall talking to a child compared with talking to an adult, but produced proportionately more simple pointing gestures. Shatz (1982) similarly found that, when talking to young language-learning children, adults produce a small number of relatively simple gestures (pointing gestures rather than metaphoric and beat gestures).

Iverson, Capirci, Longobardi, and Caselli (1999) observed Italian mothers interacting with their 16- to 20-month-old children, and found that the mothers gestured less than their children did. However, when the mothers did gesture, their gestures co-occurred with speech, were conceptually simple (pointing or conventional gestures), referred to the immediate context, and were used to reinforce the message conveyed in speech. In other words, the mothers' gestures took on a simplified form reminiscent of the simplified "motherese" they used in speech. In addition, the mothers varied widely in their overall production of gesture and speech, some talking and gesturing quite a bit and others less so. And those differences were relatively stable over time despite changes in the children's use of gesture and speech (see Ozcaliskan & Goldin-Meadow, 2005a).

Namy, Acredolo and Goodwyn (2000) found that the number of gestures parents produced during a book-reading task with their 15-month-old children was highly correlated with the number of gestures the children themselves produced. L. P. Acredolo and Goodwyn (1985, 1988; Goodwyn & Acredolo, 1993) found that the majority of gestures acquired by infants are derived from gestural or motor routines that parents engage in with them, either deliberately (e.g., the itsy-bitsy spider song which is routinely accompanied by a finger gesture depicting a spider crawling motion) or unwittingly (e.g., sniffing a flower). In a cross-cultural analysis, Goldin-Meadow and Saltzman (2000) found that Chinese mothers gestured significantly more when talking to their orally trained deaf children (and to their hearing children) than did American mothers. In turn, the Chinese deaf children produced more gestures than the American deaf children (Wang, Mylander, & Goldin-Meadow, 1993).

Moreover, evidence from experimental situations suggests that the gestures adults produce are not just correlated with child gesture but can have an impact on

child language-learning. Children are significantly more likely to learn a novel word if it is presented with gesture than without it (Ellis Weismer, & Hesketh, 1993). When parents are asked to teach their children in the one-word stage gestures for objects and actions, children not only learn the gestures, but increase their verbal vocabularies as well (L. P. Acredolo, Goodwyn, Horrobin, & Emmons, 1999; Goodwyn, Acredolo, & Brown, 2000), suggesting that, at least at this stage, appropriately used gesture can facilitate word learning.

The gestures that parents produce seem to have an impact on how often children gesture and may even influence the ease with which children learn new words. However, parental gesture cannot be essential for either development. Children who are blind from birth not only are capable language-learners (Andersen, Dunlea, & Kekelis, 1984, 1993; Dunlea, 1989; Dunlea & Andersen, 1992; Landau & Gleitman, 1985; Iverson et al., 2000), but also gesture when they talk even though they have never seen anyone gesture. On certain tasks, congenitally blind children produce gestures at the same rate and in the same distribution as sighted children (Iverson & Goldin-Meadow, 1997, 1998). Children do not have to see gesture in order to use it.

GESTURE WHEN LANGUAGE-LEARNING GOES AWRY

Some children cannot easily learn the spoken language that surrounds them and end up being language-delayed. Other children, although potentially able to learn language, are deprived of a usable model for language; for example, deaf children who cannot learn to speak and are not exposed to sign. The question we address in this section is whether children who cannot and children who do not learn language turn to gesture.

When Children *Cannot* Learn Language

Thal, Tobias, and Morrison (1991) observed a group of children in the one-word stage of language acquisition who were in the lowest 10% for their age group in terms of size of productive vocabulary. They characterized the children's verbal and gestural skills at the initial observation session when the children ranged in age from 18 to 29 months, and then observed each child again, 1 year later. They found that some of the children were no longer delayed at the 1-year follow-up; they had caught

up to their peers. The interesting point about these so-called late bloomers is that they had actually shown signs of promise a year earlier, and they showed this promise in gesture. The late bloomers had performed significantly better on a series of gesture tests taken during the initial observation session than did the children who, a year later, were still delayed. Indeed, the late bloomers' gesture performance was no different from normally developing peers. Thus, children whose language development was delayed but whose gestural development was not had a better prognosis than children who were delayed in both language and gesture. At the least, gesture seems to reflect skills that can help children recover from language delay—it may even serve as one of those skills.

However, gesture may not be at the forefront for all moments of language development and for all learners. Iverson, Longbardi, and Caselli (2003) observed five children with Down syndrome (mean age 48 months) and matched them on language level, essentially vocabulary size, with five typically developing children (mean age 18 months). The typically developing children showed the pattern found by Goldin-Meadow and Butcher (2003): a large number of combinations in which gesture conveys information that is different from the information conveyed in speech, the gesture + speech combination that heralds the onset of two-word speech. However, the children with Down syndrome did not show this pattern. Thus, at this particular stage of development, the Down syndrome children did not display a gestural advantage, suggesting that they were not yet ready to produce two-word utterances.

What happens to children whose language continues to be delayed at later stages of development? Some children fail to acquire age-appropriate language skills, yet they seem to have no other identifiable problems (no emotional, neurological, visual, hearing, or intellectual impairments). Children who meet these criteria are diagnosed as having Specific Language Impairment (SLI). J. L. Evans, Alibali, and McNeil (2001) studied a group of SLI children ranging in age from 7 to 9.5 years. They asked each child to participate in a series of Piagetian conservation tasks, and compared their performance with a group of normally developing children who were matched to the SLI children on number of correct judgments on the tasks. The task-matched normally developing children turned out to be somewhat younger (7 to 8) than the children with SLI (7 to 9.5).

The question that J. L. Evans and her colleagues (2001) asked was whether the children with SLI would turn to gesture to alleviate the difficulties they had with spoken language. They found that the SLI children did *not* use gesture more often than the task-matched children without SLI. However, the children with SLI were far more likely than the task-matched children to express information in their explanations that could *only* be found in gesture. Thus, when given a water conservation task, an SLI child might behave like the child in Figure 8.1b, indicating the height of the container in words but its width in gesture. If we consider information encoded in *both* gesture and speech, the child in Figure 8.1b has expressed the essential components of a conserving explanation—the tall container is not only taller than the short container but it is also thinner (the two dimensions can compensate for each other). When J. L. Evans and colleagues coded gesture and speech together, the children with SLI ended up producing significantly more conserving explanations than the task-matched children without SLI. It may not be surprising that the children with SLI knew more about conservation than their task-matched peers—they were older. However, all the extra knowledge that the SLI children had was in gesture. The children seemed to be using gesture as a way around their difficulties with speech.

Throughout development, speakers seem to be able to use gesture to detour around whatever roadblocks prevent them from expressing their ideas in words. These detours may not always be obvious to the ordinary listener, to the researcher, or even to the clinician. They may reside, not in how much a speaker gestures, but in the type of information the speaker conveys in those gestures. The gestures the SLI children produced did not form a substitute system replacing speech. Rather, the children's gestures seemed no different from the gestures that any speaker produces along with talk. The children with SLI appear to be exploiting the gesture-speech system that all speakers employ, and using it to work around their language difficulties.

When Children Do Not Learn Language

We turn next to a situation in which children do not learn a spoken language, not because they are unable to acquire language, but because they are unable to hear. It turns out to be extremely difficult for deaf children with profound hearing losses to acquire spoken language. But if these children are exposed to sign language, they learn

that language as naturally and effortlessly as hearing children learn spoken language (Lillo-Martin, 1999; Newport & Meier, 1985). However, most deaf children are not born to deaf parents who could provide them with input from a sign language from birth. Rather, 90% of deaf children are born to hearing parents (Hoffmeister & Wilbur, 1980). These parents typically do not know sign language and would prefer that their deaf children learn the spoken language that they and their relatives speak. As a result, many profoundly deaf children of hearing parents are sent to oral schools for the deaf—schools that focus on developing a deaf child's oral potential, using visual and kinesthetic cues and eschewing sign language to do so. Most profoundly deaf children do not achieve the proficiency in spoken language that hearing children do. Even with intensive instruction, deaf children's acquisition of speech is markedly delayed when compared either with the acquisition of speech by hearing children of hearing parents, or with the acquisition of sign by deaf children of deaf parents. By age 5 or 6, and despite intensive early training programs, the average profoundly deaf child has only a very reduced oral linguistic capacity (Conrad, 1979; Mayberry, 1992; K. Meadow, 1968).

The question we address is whether deaf children who are unable to learn spoken language and have not yet been exposed to sign language turn to gesture to communicate. If so, do the children use gestures in the same way that the hearing speakers who surround them do (as though they were accompanying speech), or do they refashion their gestures into a linguistic system reminiscent of the sign languages of deaf communities?

It turns out that deaf children who are orally trained often communicate using their hands (Fant, 1972; Lenneberg, 1964; Mohay, 1982; Moores, 1974; Tervoort, 1961). These hand movements even have a name—“home signs.” It may not be all that surprising that deaf children exploit the manual modality for communication—after all, it is the only modality that is accessible to them, and they are likely to see gesture used in communicative contexts when their hearing parents talk to them. What is surprising, however, is that the deaf children's gestures are structured in language-like ways (Goldin-Meadow, 2003b). Like hearing children at the earliest stages of language-learning, deaf children who have not yet been exposed to sign language use both pointing gestures and iconic gestures to communicate. The difference between deaf and hearing children is that, as they get older, the deaf children's gestures

blossom—they begin to take on the *functions* and the *forms* that are typically assumed by conventional language, spoken or signed.

Home Signs Resemble Language in Function and Form

Like hearing children learning spoken languages, the deaf children of hearing parents request objects and actions from others, but they do so using gesture. For example, one child pointed at a nail and gestured “hammer” to ask his mother to hammer the nail. Moreover, and again like hearing children, these deaf children comment on the actions and attributes of objects and people in the room. A deaf child gestured “march” and then pointed at a wind-up toy soldier to comment on the fact that the soldier was, at that very moment, marching.

Among language’s most important functions is making reference to objects and events that are not perceptible to either the speaker or the listener—displaced reference (cf. Hockett, 1960). Displacement allows us to describe a lost hat, to complain about a friend’s slight, and to ask advice on college applications. Just like hearing children learning spoken languages, the deaf children communicate about nonpresent objects and events (Butcher, Mylander, & Goldin-Meadow, 1991; Morford & Goldin-Meadow, 1997). One deaf child produced the following string of gesture sentences to indicate that the family was going to move a chair downstairs in preparation for setting up a cardboard Christmas chimney: He pointed at the chair and then gestured “move-away.” He pointed at the chair again and pointed downstairs where the chair was going to be moved. He gestured “chimney,” “move-away” (produced in the direction of the chair) “move-here” (produced in the direction of the cardboard chimney). The deaf children also use their gestures to tell stories (Phillips, Goldin-Meadow, & Miller, 2001) and can even use them to serve some of language’s more exotic functions—to talk to themselves (Goldin-Meadow, 1993) or to comment on their own and others’ gestures (Singleton, Morford, & Goldin-Meadow, 1993).

In addition to assuming the functions of language, the deaf children’s gestures assume its forms. One of the biggest differences between the deaf children’s gestures and those used by hearing children is that the deaf children often combine their gestures into strings that have many of the properties of sentences. The deaf children even combine their gestures into sentences that convey more than one proposition; they produce complex gesture sentences. A child produced the following gesture

sentence to indicate that he would clap the bubble (proposition 1) after his mother twisted open the bubble jar (proposition 2) and blew it (proposition 3): He gestured “clap,” pointed at himself, gestured “twist” then “blow,” and pointed at his mother.

Moreover, the deaf children’s gesture combinations are structured at underlying levels just like hearing children’s early sentences (Goldin-Meadow, 1985). For example, the framework underlying a gesture sentence about giving, in addition to the predicate *give*, contains three arguments—the *giver* (actor), the *given* (patient), and the *givee* (recipient). In contrast, the framework underlying a sentence about eating, in addition to the predicate *eat*, contains two arguments—the *eater* (actor) and the *eaten* (patient). These underlying frameworks influence how likely it is that a deaf child will produce a gesture for a particular argument (in fact, the likelihood with which gestures are produced provides evidence for the underlying frameworks, Goldin-Meadow, 1985).

The deaf children’s gesture combinations are also structured at surface levels, containing many of the devices to mark “who does what to whom” that are found in the early sentences of hearing children (Goldin-Meadow, Butcher, Mylander, & Dodge, 1994; Goldin-Meadow & Mylander, 1984, 1998). The deaf children indicate objects that play different thematic roles using three devices:

1. Preferentially producing (as opposed to omitting) gestures for objects playing particular roles (e.g., pointing at the drum, the patient, as opposed to the drummer, the actor).
2. Placing gestures for objects playing particular roles in set positions in a gesture sentence (e.g., producing the gesture for the patient, “drum,” before the gesture for the act, “beat”).
3. Displacing verb gestures toward objects playing particular roles (e.g., producing the “beat” gesture near the patient, drum).

The deaf children’s gesture combinations therefore adhere to rules of syntax, albeit simple ones. On this basis, the children’s gesture combinations warrant the label “sentence”—they thus resemble hearing children’s *words*, not their gestures.

The deaf children’s gestures are distinct from hearing children’s gestures in having a set of elements (gestures) that combine systematically to form novel larger units (sentences). What further distinguishes the deaf

children's gestures is that this combinatorial feature is found at yet another level—the gestures that combine to form sentences are themselves composed of parts (morphemes). Each gesture in a deaf child's repertoire is composed of a handshape component (e.g., an O-handshape representing the roundness of a penny) and a motion component (e.g., a short arc motion representing a putting-down action). The meaning of the gesture as a whole is a combination of the meanings of its parts ("round-put-down"; Goldin-Meadow, Mylander, & Butcher, 1995). In contrast, the gestures produced by hearing speakers (including hearing children and the children's own hearing parents) are composed of sloppy handshapes that do not map neatly onto categories of meanings, combined with motions that also do not map neatly onto categories of meanings (Goldin-Meadow et al., 1995; Goldin-Meadow, Mylander, & Franklin, 2005; Singleton, Goldin-Meadow, & Morford, 1993).

A final characteristic of the deaf children's gestures distinguishes them from hearing children's gestures—gestures serving nounlike functions are different in form from gestures serving verblike functions (Goldin-Meadow et al., 1994). For example, when a deaf child uses a "twist" gesture as a verb in a sentence meaning "twist-open the jar," he is likely to produce the gesture (a) without abbreviation (with several rotations rather than one), (b) with inflection (the gesture is directed toward a relevant object, in this case, the jar), and (c) *after* a point at the jar. In contrast, when the child uses the twist gesture as a noun in a sentence meaning "that's a twistable object, a jar," he is likely to produce it (a) with abbreviation (with one rotation rather than several), (b) without inflection (in neutral space rather than directed at an object), and (c) *before* the point at the jar.

The deaf children's gestures thus resemble conventional languages, both signed and spoken, in having combinatorial regularities at both the sentence and word levels, and having a noun-verb distinction. The children have invented gesture systems that contain many of the basic properties found in all natural languages. The deaf children's gesture systems, however, are not full-blown languages, and for good reason. The children are inventing their gesture systems on their own without a community of communication partners. When home-sign children are brought together into a community (as they were in Nicaragua after the first school for the deaf was opened in the late 1970s), their sign systems begin to co-

here into a recognized and shared language. That language becomes increasingly complex, particularly after a new generation of deaf children learns the system as a native language (Kegl, Senghas, & Coppola, 1999; Senghas, 1995, 2000; Senghas, Coppola, Newport, & Supalla, 1997). The manual modality can take on linguistic properties, even in the hands of a young child not yet exposed to a conventional language model. But it grows into a full-blown language only with the support of a community that can transmit the system to the next generation.

The Deaf Children's Gestures Do Not Look Like Their Hearing Parents' Gestures

The deaf children described in the preceding section had not been exposed to a conventional sign language and thus could not have fashioned their gesture systems after such a model. They were, however, exposed to the gestures that their hearing parents used when they talked to them. These parents were committed to teaching their children English and therefore talked to them as often as they could. And when they talked, they gestured. The parents' gestures might have displayed the language-like properties found in their children's gestures. It turns out, however, that they did not (Goldin-Meadow et al., 1994, 1995, 2005; Goldin-Meadow & Mylander, 1983, 1984): The parents' gestures looked just like any hearing speaker's gestures.

Why didn't the hearing parents display language-like properties in their gestures? In a sense, the deaf children's hearing parents did not have the option of displaying these properties in their gestures simply because they produced all their gestures with talk. Their gestures formed a single system with the speech they accompanied and had to fit, both temporally and semantically, with that speech—they were not free to take on language-like properties. In contrast, the deaf children had no such constraints on their gestures. They had essentially no productive speech and thus always produced gesture on its own, without talk. Moreover, because gesture was the only means of communication open to these children, it had to take on the full burden of communication. The result was language-like structure. The deaf children may (or may not) have used their hearing parents' gestures as a starting point. However, it is very clear that the children went well beyond that point. They transformed the speech-accompanying gestures they saw into a system that looks very much like language.

We are now in a position to appreciate just how versatile the manual modality is. It can take on linguistic properties when called on to do so, as in the deaf children (and, of course in conventional sign languages). But it can also assume a nonsegmented global form when it accompanies speech, as in the deaf children's hearing parents (and all other hearing speakers). This versatility is important because it tells us that the form gesture assumes is *not* entirely determined by the manual modality. Quite the contrary, it seems to be determined by the functions gesture serves, and thus has the potential to inform us about those functions. As described in the following section, speech-accompanying gestures can provide insight into how the mind works.

GESTURE IS A WINDOW ON THE MIND

The gestures that speakers produce along with their talk are symbolic acts that convey meaning. It is easy to overlook the symbolic nature of gesture simply because its encoding is iconic. A gesture often looks like what it represents (e.g., a twisting motion in the air resembles the action used to open a jar), but the gesture is no more the actual act of twisting than is the word "open." Because gesture can convey substantive information, it can provide insight into a speaker's mental representation (Kendon, 1980; McNeill, 1985, 1987, 1992).

Gesture Can Reveal Thoughts Not Found in Speech

Gesture encodes meaning differently from speech. Gesture conveys meaning globally, relying on visual and mimetic imagery. Speech conveys meaning discretely, relying on codified words and grammatical devices. Because gesture and speech employ such different forms of representation, it is difficult for the two modalities to contribute identical information to a message. Indeed, even deictic pointing gestures are not completely redundant with speech. When a child utters "chair" while pointing at the chair, the word labels and thus classifies (but doesn't locate) the object. The point, in contrast, indicates where the object is but not what it is. Word and gesture do not convey identical information, but they work together to more richly specify the same object. But, as described, there are times when word and gesture convey information that overlaps very little, if at all. A point can indicate an object that is not referred to

in speech—the child says "daddy" while pointing at the chair. Word and gesture together convey a simple proposition—"the chair is daddy's" or "daddy sat on the chair"—that neither modality conveys on its own.

Consider the children participating in the Piagetian conservation task described earlier. The child in Figure 8.1a said that the amount of water changed "'cause that's down lower than that one," while pointing at the water levels in the two containers. Here, too, word and gesture do not convey identical information; speech tells us that the water level is low, gesture tells us how low. Yet, the two modalities work together to more richly convey the child's understanding. In contrast, the child in Figure 8.1b used her gestures to introduce completely new information not found in her speech. She said the amount of water changed "'cause this one's lower than this one," but indicated the widths of the containers with her hands. In this case, word and gesture together allow the child to convey a contrast of dimensions—this one's lower but wide, that one's higher but skinny—that neither modality conveys on its own.

We can posit a continuum based on the overlap of information conveyed in gesture and speech (Goldin-Meadow, 2003a). At one end of the continuum, gesture elaborates on a topic that has already been introduced in speech. At the other end, gesture introduces new information that is not mentioned at all in speech. Although at times, it is not clear where to draw a line to divide the continuum into two categories, the ends of the continuum are obvious and relatively easy to identify. As mentioned, we have called cases in which gesture and speech convey overlapping information *gesture-speech matches* and those in which gesture and speech convey nonoverlapping information *gesture-speech mismatches*.

The term *mismatch* adequately conveys the notion that gesture and speech express different information. However, mismatch also brings with it an unintended notion of conflict. The pieces of information conveyed in gesture and in speech in a mismatch need not conflict and, in fact, rarely do. There is almost always some framework within which the information conveyed in gesture can be fitted with the information conveyed in speech. In Figure 8.1b, it may seem as though there is a conflict between the height information conveyed in the child's words ("lower") and the width information conveyed in her gestures. However, in the context of the water conservation problem, the two dimensions actually compensate for one another. Indeed, it is essential

to understand this compensation—that the water may be lower than it was in the original container, but it is also wider—to master conservation of liquid quantity.

As observers, we are often able to envision a framework that would resolve a potential conflict between the information encoded in children's talk and the information encoded in their gestures. However, the children may not be able to envision such a framework, particularly if left to their own devices. But children can profit from a framework if someone else provides it. Take the training study in conservation described earlier. When given instruction that provides a framework for understanding conservation, children who produce gesture-speech mismatches in their conservation explanations profit from that instruction and improve on the task. Children who do not yet produce mismatches and thus do not have the ingredients of a conserving explanation in their repertoires, do not profit from the instructions (Church & Goldin-Meadow, 1986; see also Perry et al., 1988; Pine et al., 2004). In sum, gesture can reflect thoughts that are quite different from the thoughts a child conveys in speech. Moreover, if such a child is offered instruction that provides a framework for those thoughts, the child is likely to learn.

Gesture Offers Unique Insight into a Child's Knowledge

The information conveyed by gesture in a gesture-speech match is obviously accessible to speech. But what about the information conveyed by gesture in a gesture-speech mismatch? The child does not express the information in speech *in that response*—otherwise we would not call it a mismatch. But perhaps the child does not express that information *anywhere* in his or her explanations of the task. Perhaps the information conveyed in the gestural component of a mismatch is truly unique to gesture.

Goldin-Meadow, Alibali, et al. (1993) examined the problem-solving strategies that a group of 9- to 10-year-old children produced in speech and gesture when solving and explaining six mathematical equivalence problems. They found that if a child produced a problem-solving strategy in the gestural component of a mismatch, that child rarely produced that strategy *anywhere* in his or her speech. Interestingly, this was not true of the problem-solving strategies found in the spoken component of the children's mismatches—these

spoken strategies could almost always be found in gesture on some other response. What this means is that whatever information the children were able to express in speech they were also able to express in gesture, not necessarily on the same problem, but at some point during the task. Thus, at least on this task, when children can articulate a notion in speech, they are also able to express that notion in gesture. But the converse is not true—when children express a notion in gesture, sometimes they are also able to express that notion in speech and sometimes they are not.

Even in judgments of others' explanations, there seems to be an asymmetrical relation between gesture and speech; when children notice a speaker's words, they also notice that speaker's gesture, but not vice versa. T. A. Graham (1999) asked very young children to "help" a puppet learn to count. Half the time, the puppet counted correctly, but the other half of the time, the puppet added an extra number (e.g., the puppet would say "one, two, three" while counting two objects). In addition, when the puppet made these counting errors, he either produced the same number of pointing gestures as number of words (three in this example), a larger or smaller number of pointing gestures (four or two pointing gestures), or no pointing gestures at all. The child's job was to tell the puppet whether his counting was correct and, if incorrect, to explain why the puppet was wrong. The interesting result from the point of view of this discussion concerns whether children made reference to the puppet's number words (speech only) or points (gesture only) or both (gesture + speech) in their explanations. The 2-year-olds did not refer to either gesture or speech; 3-year-olds referred to gesture but not speech (gesture only); and 4-year-olds referred to both gesture and speech (gesture + speech). Very few children across all three ages referred to the puppet's speech without also referring to the puppet's gesture. In other words, when they noticed the puppet's speech, they also noticed his gesture, but not necessarily vice versa.

We now know that children can express knowledge in gesture that they do not express in speech. But is there some other means by which children can tell us that they "have" this knowledge? Knowledge that is accessible to gesture but not to speech, by definition, cannot be articulated. But perhaps this knowledge can be accessed in some other less explicit way, for example, by a rating task (cf. C. Acredolo & O'Connor, 1991; Horobin & Acredolo, 1989; Siegler & Crowley, 1994). In a rating

task, all the raters need do is make a judgment about information provided by the experimenter. They do not need to express the information themselves.

Garber, Alibali, and Goldin-Meadow (1998) addressed this issue with respect to mathematical equivalence. If a child produces a problem-solving strategy uniquely in gesture, will the child later accept the answer generated by that strategy on a rating task? In Figure 8.2, for the problem $7 + 6 + 5 = \underline{\hspace{1cm}} + 5$, the child puts 18 in the blank and says “7 plus 6 is 13 plus 5 more is 18 and that’s all I did”—in other words, she gives an “add-numbers-to-equal-sign” strategy in speech. In gesture, however, she points at all four numbers (the 7, the 6, the left 5, and the right 5), thus giving an “add-all-numbers” strategy in gesture. She does not produce the add-all-numbers strategy in speech in any of her explanations. When later asked to rate the acceptability of possible answers to this problem, the child, of course, accepts 18 (the number you get when you add up

the numbers to the equal sign). However, the child is also willing to accept 23, the number you get when you add all of the numbers in the problem—that is, the answer you get when you use the problem-solving strategy that this child produced *uniquely* in gesture.

Children thus can express knowledge with their hands that they do not express *anywhere* in their speech. This knowledge is not fully explicit (it cannot be stated in words). However, it is not fully implicit either (it is evident not only in gesture but also in a rating task). Knowledge expressed uniquely in gesture thus appears to represent a middle point along a continuum of knowledge states, bounded at one end by fully implicit knowledge that is embedded in action, and at the other by fully explicit knowledge that is accessible to verbal report (cf. Dienes & Perner, 1999; Goldin-Meadow & Alibali, 1994, 1999; Karmiloff-Smith, 1986, 1992).

A growing group of researchers have come to believe that linguistic meaning is grounded in bodily action

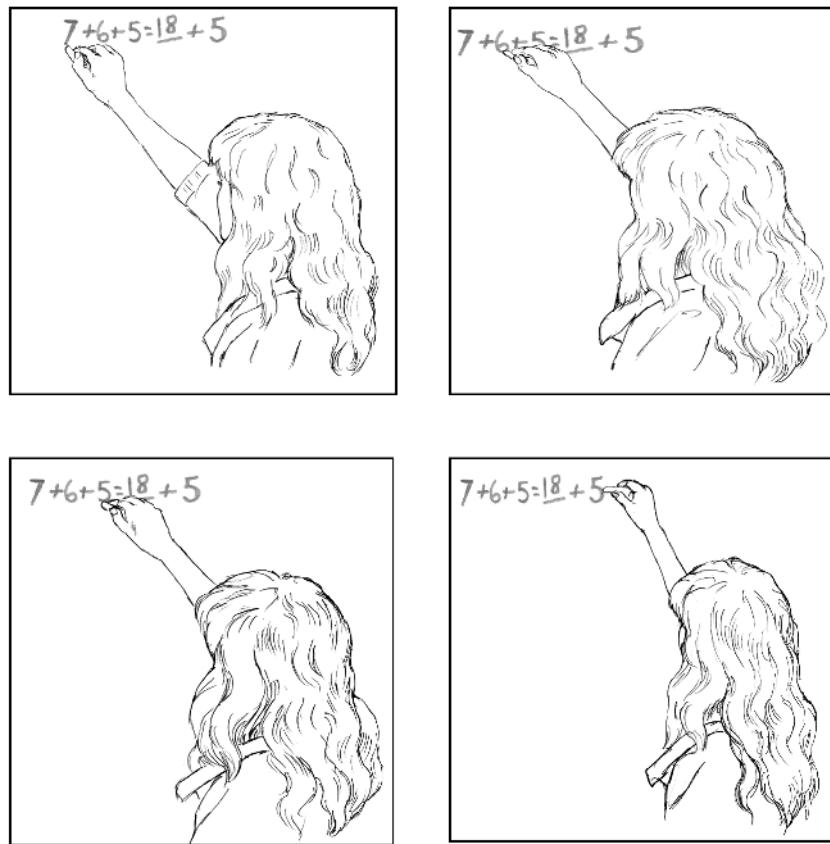

Figure 8.2 Example of a child producing a gesture-speech mismatch on a mathematical equivalence problem. The child says that she added the numbers on the left side of the equation (an add-numbers-to-equal-sign strategy). In gesture, however, she points at the last number on the right side of the equation as well as the three on the left (add-all-numbers strategy).

(Barsalou, 1999; Glenberg & Kaschak, 2002; Glenberg & Robertson, 1999)—that meaning derives from the biomechanical nature of bodies and perceptual systems and, in this sense, is embodied (Glenberg, 1997). Under this view, it is hardly surprising that gesture reflects thought. Gesture may be an overt depiction of the action meaning embodied in speech. However, gesture has the potential to do more—it could play a role in shaping those meanings. There are (at least) two ways in which gesture could play a role in creating, rather than merely reflecting, thought:

1. Gesture could play a role in shaping thought by displaying, for all to see, the learner's newest, and perhaps undigested, thoughts. Parents, teachers, and peers would then have the opportunity to react to those unspoken thoughts and provide the learner with the input necessary for future steps. Gesture, by influencing the input learners receive from others, would then be part of the process of change itself. In other words, gesture's participation in *communication* could contribute to cognitive change.

2. Gesture could play a role in shaping thought more directly by influencing the learners themselves. Gesture externalizes ideas differently and therefore may draw on different resources from speech. Conveying an idea across modalities may, in the end, require less effort than conveying the idea within speech alone. In other words, gesture may serve as a “cognitive prop,” freeing up cognitive effort that can be used on other tasks. If so, using gesture may actually ease the learner's processing burden and, in this way, function as part of the mechanism of change. In other words, gesture's participation in the process of *thinking* could contribute to cognitive change.

Gesture thus has the potential to contribute to cognitive change indirectly by influencing the learning environment (through communication) or more directly by influencing the learner (through thinking). Before considering the possible *functions* that gesture might serve, we take a moment to consider the factors or *mechanisms* responsible for gesturing.

WHAT MAKES PEOPLE GESTURE?

We begin our exploration of the mechanism underlying gesture production by focusing on communicative fac-

tors that might encourage us to gesture. We then consider cognitive factors that could lead to gesture.

Does Having a Conversation Partner Make Us Gesture?

To explore whether communicative factors play a role in the mechanism responsible for creating gesture, we need to manipulate factors relevant to communication and determine whether those factors influence gesturing. In this section, we ask whether one factor essential to communication—having a conversation partner—affects whether speakers gesture.

We Gesture More When Listeners Are Present

Our goal in this section is not to figure out whether listeners get meaning from gesture (we address this question in a later section), but to figure out whether the need to communicate information to others is the force that drives us to gesture. The easiest way to explore this question is to ask people to talk when they can see their listener and when they can't. If the need to convey information to conversation partners is what motivates us to gesture, we ought to gesture more when others can see those gestures.

A number of studies have manipulated the presence of a listener and observed the effect on gesture. In most studies, the speaker has a face-to-face conversation with a listener in one condition, and a conversation in which a barrier prevents the speaker and listener from seeing one another in the second condition. In some studies, the second condition is conducted over an intercom, and in some the first condition is conducted over a videophone. In some studies, the camera is hidden so that the speakers have no sense that they are being watched. It doesn't really seem to matter. In most studies (although not all), people gesture more when they can see their listener than when they cannot (Alibali, Heath, & Myers, 2001; Bavelas, Chovil, Lawrie, & Wade, 1992; Cohen & Harrison, 1973; Krauss, Dushay, Chen, & Rauscher, 1995; the exceptions were Lickiss & Wellens, 1978; Rimé, 1982). For example, Alibali, Heath, and Myers (2001) asked speakers to watch an animated cartoon and narrate the story to a visible versus nonvisible listener. Speakers produced more representational gestures (gestures that depict semantic content) when they could see their listener than when they could not, but not more beat gestures (simple, rhythmic gestures that do not convey se-

mantic content). Thus, speakers increase their production of at least some gestures when someone is watching.

But do speakers really intend to produce gestures for their listeners? There is no doubt that speakers change their *talk* in response to listeners. Perhaps the changes in gesture come about as a by-product of these changes in speech. Speakers could alter the form and content of their talk and those changes could automatically bring with them changes in gesture. To address this possibility, we need to examine not only changes that occur in gesture as a function of who the listener is, but also changes that occur in the accompanying speech. Alibali, Heath, et al. (2001) did just that but found no differences anywhere—speakers used the same number of words, made the same number of speech errors, and said essentially the same things no matter whether a listener was present. Thus, when the speakers in this study produced more gestures with visible than nonvisible listeners, it was not because they had changed their talk; at some level, albeit not consciously, they meant to change their gestures.

Congenitally Blind Speakers Gesture Even When Addressing Blind Listeners

Speakers gesture more when they address visible listeners than nonvisible listeners, suggesting that there is a communicative aspect to gesturing. In another sense, however, the more striking finding in each of these studies is that speakers continue to gesture even when no listener is there at all. Although statistically less likely, gesture was produced in all the experimental conditions in which there was no possibility of a communicative motive. As an example that everyone can relate to, people gesture when talking on the telephone although there is no one around to see those gestures. Why? If the need to communicate with the listener is the only force behind gesturing, why do we continue to move our hands when listeners can no longer see us?

One possibility is that we gesture out of habit. We are used to moving our hands around when we speak to others and old habits die hard. This hypothesis predicts that if someone were to spend a great deal of time talking only to unseen people, eventually that person's gestures would fade away. Another possibility is that, even when no one is around, we imagine a listener and we gesture for that listener. The only way to test these hypotheses is to observe speakers who have never spoken to a visible listener. Individuals who are blind from birth offer an excellent test case. Congenitally blind individuals have

never seen their listeners and thus cannot be in the habit of gesturing for them. Moreover, congenitally blind individuals never see speakers moving their hands as they talk and thus have no model for gesturing. Do they gesture despite their lack of a visual model?

Iverson and Goldin-Meadow (1998, 2001) asked children and adolescents blind from birth to participate in a series of conservation tasks, and compared their speech and gesture on these tasks to age- and gender-matched sighted individuals. All the blind speakers gestured as they spoke, even though they had never seen gestures or their listeners. The blind group gestured at the same rate as the sighted group, and conveyed the same information using the same range of gesture forms. Blind speakers apparently do not require experience receiving gestures before spontaneously producing gestures of their own. Congenitally blind children produce gestures at the earliest stages of language-learning just as sighted children do (Iverson et al., 2000). They even produce pointing gestures at distal objects, although those gestures are not as frequent as in sighted children and are produced with a palm hand rather than a pointing hand. Moreover, blind children produce spontaneous gestures along with their speech even when they know that their listener is blind and therefore unable to profit from whatever information gesture offers (Iverson & Goldin-Meadow, 1998, 2001).

To sum up thus far, gesture seems to be an inevitable part of speaking. We do not need others around in order to gesture (although having others around increases our gesture rate). We do not need to have ever seen anyone gesture to produce gestures of our own. Gesture thus appears to be integral to the speaking process, and the mechanism by which gesture is produced must be tied in some way to this process. Gesture frequently accompanies speech in reasoning tasks where the speaker must think through a problem. In conservation tasks, for example, participants must consider and manipulate relationships between several different spatial dimensions of the task objects simultaneously (e.g., in the liquid quantity task, the relationship between container height and width and water level). It may be easier to express aspects of these dimensions and their relationships in the imagistic medium offered by gesture than in the linear, segmented medium provided by speech (cf. McNeill, 1992). Gesture may thus provide children with a channel for expressing thoughts that are difficult to articulate in speech. As a result, children—even blind children—may produce gestures when explaining their reasoning in a

conservation task because some of their thoughts about the task lend themselves more readily to gesture than to speech. Gesture, in other words, might simply reflect a child's thoughts in a medium that happens to be relatively transparent to most listeners. We next explore whether cognitive factors play a role in the mechanism underlying gesturing.

Does Thinking Hard Make Us Gesture?

When do we gesture? One possibility is that we gesture when we think hard. If so, we would expect gesture to increase when the task is made more difficult.

Gesturing When Speaking Is Difficult

Consider first what happens when speaking is made more difficult. When we talk, we hear ourselves, and this feedback is an important part of the speaking process. If the feedback we get from our own voice is delayed, speaking becomes much more difficult. McNeill (1992) carried out a series of experiments observing what happens to gesture under delayed auditory feedback—the experience of hearing your own voice continuously echoed back. Delayed auditory feedback slowed speech down and stuttering and stammering became frequent. But it also had an effect on gesture, which increased in all speakers. (Interestingly, gesture did not lose its synchrony with speech, an outcome we might have expected given that gesture and speech form a unified system.) The most striking case was a speaker who produced absolutely no gestures at all under conditions of normal feedback, and began gesturing only during the second half of the narration, when feedback was delayed. When the act of speaking becomes difficult, speakers seem to respond by increasing their gestures.

We see a similar increase in gesturing in individuals suffering from aphasia. These individuals, typically as a result of stroke, trauma, or tumor, have greatly impaired language abilities relative to individuals without brain injury—speaking is difficult for aphasic individuals. When Feyereisen (1983) asked aphasic individuals to describe how they passed an ordinary day, they produced many more gestures than nonaphasic speakers. Again, increased gesturing seems to be associated with difficulty in speaking.

Finally, bilinguals who are not equally fluent in their two languages have more difficulty speaking their non-dominant language than their dominant language. Marcos (1979) asked Spanish-English bilinguals, some dominant

in English and others dominant in Spanish, to talk about love or friendship in their nondominant language. The less proficient a speaker was in his or her nondominant language, the more gestures that speaker produced when speaking that language (see also, Gulberg, 1998). The assumption is that speaking the nondominant language is more difficult for these individuals, and they respond by increasing their rate of gesturing.

Gesturing When the Number of Items in a Task Increases

Gesturing also increases when the focal task is itself made more difficult. For example, T. A. Graham (1999) asked 2-, 3-, and 4-year-old children to count sets of 2, 4, and 6 object arrays. Children learn to count small numbers before learning to count large numbers (Gelman & Gallistel, 1978; Wynn, 1990). If children gesture only when the counting problem is hard, we might expect them to gesture more on arrays with 4 and 6 objects than on arrays with only 2 objects. The 4-year-olds did just that (apparently, the 2- and 3-year-olds were challenged by all three arrays and gestured as much as possible on each one). When the counting task is hard, children rely on gesture (see also Saxe & Kaplan, 1981).

Gesturing has also been found to increase when speakers have options to choose among. Melinger and Kita (in press) asked native speakers of Dutch to describe map-like pictures, each depicting a path with several destinations (marked by colored dots). The speaker's task was to describe from memory the path that leads past all the destinations. Importantly, some of the maps had routes that branched in two directions, which meant that the speaker had a choice of paths (more than one item to choose among). The question is whether speakers would produce more gestures when describing the branching points on the maps than when describing points where no choices needed to be made. They did. Controlling for the amount of directional talk the speakers produced, Melinger and Kita (in press) calculated the percentage of directional terms that were accompanied by gesture at branching points versus non-branching points and found that the speakers gestured more at branching points. The presumption is that the branching points elicited more gestures because they offered the speaker more than one item to choose among and, in this sense, were conceptually challenging.

Gesturing When Describing from Memory

Describing a scene from memory ought to be more difficult than describing a scene within view. We might

therefore expect speakers to produce more gestures when asked to retrieve information from memory. De Ruiter (1998) asked Dutch-speakers to describe pictures on a computer screen so that the listener could draw them. Half of the pictures were described while they were visible on the computer screen, and half were described from memory. The speakers produced more gestures when describing the pictures from memory than when describing them in full view.

Wesp, Hesse, Keutmann, and Wheaton (2001) found the same effect in English-speakers. They asked speakers to describe still-life watercolor paintings so that the listener could later pick the painting out of a set of paintings. Half of the speakers were asked to look at the painting, form an image of it, and then describe it from memory. The other half were asked to describe the painting as it sat in front of them. Speakers who described the paintings from memory produced more gestures than those who described the paintings in full view. When the description task becomes difficult, speakers react by increasing their gesture rates.

Gesturing When Reasoning Rather Than Describing

Reasoning about a set of objects ought to be more difficult than merely describing those same objects, and thus ought to elicit more gestures. Alibali, Kita, and Young (2000) asked a group of kindergartners to participate in both a reasoning and a description task. In the reasoning task, the children were given six Piagetian conservation problems tapping their understanding of continuous quantity and mass. In the description task, they were presented with precisely the same objects, but this time they were asked to describe how the objects looked rather than to reason about their quantities. The children produced more iconic gestures (but not more deictic gestures) when *reasoning* about the objects than when *describing* the objects. In other words, they produced more gestures that conveyed substantive information when doing the harder task.

An increase in task difficulty does not always bring with it an increase in gesture (Cohen & Harrison, 1973; De Ruiter, 1998). For example, De Ruiter (1998) found no differences in the rate of gesturing for pictures that were easy versus hard to describe. Null effects are difficult to interpret. Perhaps the task was not hard enough to inspire gesture. But then, we need to specify what we mean by “hard enough.” If gesture and speech are interlinked in a specific way, then we might expect only certain types of tasks and verbal difficulties to lead to an increase in gesture. Ideally, theories

of how gesture and speech relate to one another ought to be sufficiently specified to predict the kinds of difficulties that will lead to more gesture, but we haven’t achieved the ideal yet. None of the current theories can explain these null results.

WHAT FUNCTIONS DOES GESTURE SERVE?

Thus far, we have examined studies that manipulate communicative and cognitive factors and then chart the effects of those manipulations on gesture. And we have found that the manipulations have an impact on gesturing, suggesting that both communicative and cognitive factors play a causal role in gesture production. The studies thus provide convincing evidence with respect to the *mechanisms* that underlie gesturing, the process by which gesture comes about.

The studies, however, are not conclusive with respect to the *functions* that gesture serves. Just because gesturing increases in situations where a listener is present doesn’t mean that the listener gleans information from gesture. To determine whether gesture functions to communicate information to listeners, we need to manipulate *gesture* and explore the effects of that manipulation on *listener comprehension*. Similarly, just because gesturing increases on tasks that require more thought does not mean that gesturing plays a causal role in thinking. Gesture may be reflecting the speaker’s thought processes, rather than causing them. To explore whether gesture functions to help us think, we need to manipulate *gesture* and observe the effect of the manipulation on *thinking*. We turn to studies of this sort in the next sections, focusing on the functions gestures might serve first in communication and then in thinking.

Gesture’s Role in Communication: Does Gesture Convey Information to the Listener?

A child’s gestures can signal to parents and teachers that a particular notion is already in that child’s repertoire but is not quite accessible. These listeners can then alter their behavior accordingly, perhaps giving explicit instruction in just these areas. In response to the child’s utterance, “dada” + point hat, an adult might say “yes, that’s dada’s hat,” thus translating the information the child conveyed across two modalities into the spoken modality and providing just the right target for a learner who had this notion in mind (Goldin-Meadow, Goodrich, Sauer, & Iverson, 2005). This process can

only work if adults are able to glean substantive information from a child's gesture. Although there is little disagreement in the field about whether information is displayed in gesture, there is great disagreement about whether ordinary listeners take advantage of that information. Does someone who has not taken a course in gesture-coding understand gesture? Do gestures communicate? Some researchers are completely convinced that the answer is "yes" (e.g., Kendon, 1994). Others are equally convinced that the answer is "no" (e.g., Krauss, Morrel-Samuels, & Colasante, 1991). Several approaches have been taken to this question, some more successful than others.

Looking at Gesture in the Context of Speech

We glean very little information from gesture when it is presented on its own (Feyereisen, van de Wiele, & Dubois, 1988; Krauss et al., 1991). However, we may still benefit from gesture when it is viewed as it was meant to be viewed—in the context of speech. There are hints that we get information from gesture when it accompanies speech in observations of how listeners behave in conversation. Heath (1992, cited in Kendon, 1994) describes several interchanges in which the recipient seems to grasp the meaning of an utterance before its completion, and to do so on the basis of gesture. A doctor is explaining that a particular medicine will "damp down" a symptom and makes several downward movements of his hand as he does so. The timing, however, is important. He says "they help sort of you know to dampen down the inflammation," and has already completed three downward strokes of his gesture by the time he says "you know"—he gestures before he actually produces the word "dampen." It is at this point, after the gesture but before the word dampen, that the listener looks at the doctor and begins to nod. The listener appears to have gotten the gist of the sentence well before its end, and to have gotten that gist from gesture.

Examples of this sort are suggestive but not at all definitive. We really have no idea what the listener is actually understanding when he nods his head. The listener may *think* he's gotten the point of the sentence, but he may be completely mistaken. He may even be pretending to understand. We need to know exactly what recipients are taking from gesture to be sure that they have truly grasped its meaning. To do that, we need a more experimental approach.

J. A. Graham and Argyle (1975) asked people not to gesture on half of their descriptions of drawings and

then examined how accurate listeners were in recreating those drawings when they were described with and without gesture. The listeners were significantly more accurate with gesture than without it. However, when speakers are forced not to use their hands, they may change the way they speak. In other words, the speech in the two conditions (messages with gesture versus without it) may differ, and this difference could be responsible for the accuracy effect. J. A. Graham and Heywood (1975) addressed this concern by reanalyzing the data with this issue in mind. But a more convincing approach to the problem would be to hold speech constant while exploring the beneficial effects of gesture. This manipulation can easily be accomplished with videotape.

Krauss et al. (1995) asked speakers to describe abstract graphic designs, novel synthesized sounds, or samples of tea. Listeners then saw and heard the videotape of the speakers or heard only the sound track, and were asked to select the object being described from a set of similar objects. Accuracy was straightforwardly measured by the number of times the correct object was selected. In none of the experiments was accuracy enhanced by allowing the listener to see the speaker's gestures. Thus, in certain situations, gesture can add *nothing* to the information conveyed by speech.

Other researchers have found that gesture enhances the message listeners take from a communication (e.g., Berger & Popelka, 1971; Riseborough, 1981; Thompson & Massaro, 1986). For example, Riseborough (1981) gave listeners extracts from videotapes of a speaker describing an object (e.g., a fishing rod) to another person. The extracts were presented with both video and sound or with sound alone. Listeners guessed the correct object more rapidly when they could see the iconic gestures that accompanied the description than when they could not. In a subsequent experiment, Riseborough made sure that it wasn't just the hand waving that mattered. She compared responses (this time accuracy scores) to speech accompanied by vague movements versus well-defined iconic gestures, and found that accuracy was much better with the real gestures.

It is possible that listeners are not gleaning *specific* information from gesture. Gesture could be doing nothing more than heightening the listener's attention to speech which, in turn, results in more accurate and faster responses. Beattie and Shovelton (1999b) avoided this concern by examining in detail the types of information that listeners took from a message when they heard it with and without gesture. Each listener saw

clips drawn from a narration of a cartoon in the audio + video condition (sound track and picture), the audio condition (just the sound track), and the video condition (just the picture). After each clip, the listener answered a series of planned questions about the objects and actions in the clip (e.g., “What object(s) are identified here?” “What are the object(s) doing?” “What shapes are the object(s)?”).

The results were quite clear. When the listeners could see the iconic gestures as well as hear the speech, they answered the questions more accurately than when they just heard the speech. All 10 listeners showed the effect. However, gesture was more beneficial with respect to certain semantic categories than others, for example, the relative position and the size of objects. In one videoclip, the speaker said “by squeezing his nose” while opening and closing his left hand. All the listeners in both the audio + video and the audio condition accurately reported the squeezing action. However, listeners in the audio + video condition were much more likely than those in the audio condition to accurately report the size and shape of the nose, its position with respect to the squeezing hand, and whether it was moving. It is not surprising that the listeners in the audio condition did not report these pieces of information—they didn’t hear them *anywhere* in the sound track they were given. But it may be surprising (depending on your point of view) that the listeners in the audio + video condition not only noticed the extra information conveyed in gesture, but were able to integrate that information into the mental image they were developing on the basis of speech. Listeners really can glean specific information from gesture.

Looking at Gesture with Mismatching Speech

When gesture conveys precisely the same information as speech, we can never really be sure that the listener has gotten specific information from gesture. Even if a listener responds more accurately to speech accompanied by gesture than to speech alone, it could be because gesture is heightening the listener’s attention to the speech; gesture could be serving as an energizer or focuser, rather than as a supplier of information. The data from the Beattie and Shovelton (1999b) study are not plagued by this problem. We are convinced that the listeners in this study are gleaning specific information from gesture simply because that information does not appear *anywhere* in speech. It must be coming from gesture—it has no place else to come from. In general, the best place

to look for effects of gesture on listeners is in gesture-speech mismatches—instances where gesture conveys information that is not found in speech.

McNeill, Cassell, and McCullough (1994) asked listeners to watch and listen to a videotape of someone recounting a “Tweety Bird” cartoon. The listener never sees the cartoon, only the narration. Unbeknownst to the listener, the narrator is performing a carefully choreographed program of mismatching gestures along with a number of normally matching gestures. The listener’s task is to retell the story to yet another person, and that narration is videotaped. The question is whether we will see in the listener’s own narration traces of the information conveyed by gesture in the mismatched combinations planted in the video narrative. And we do. Consider an example. The narrator on the videotape says, “he comes out the bottom of the pipe,” while bouncing his hand up and down—a verbal statement that contains no mention of how the act was done (no verbal mention of the bouncing manner), accompanied by a gesture that does convey bouncing. The listener resolves the mismatch by inventing a staircase. In her retelling, the listener talks about going “downstairs,” thus incorporating the bouncing information found *only* in the narrator’s gestures into her own speech. The listener must have stored the bouncing manner in some form general enough to serve as the basis for her *linguistic* invention (“stairs”). The information conveyed in gesture is often noticed by listeners, but it is not necessarily tagged as having come from gesture (see also Bavelas, 1994).

We find the same effects when adult listeners are asked to react to gesture-speech mismatches that children spontaneously produce on either a mathematical equivalence task (Alibali, Flevares, & Goldin-Meadow, 1997) or a conservation task (Goldin-Meadow, Wein, & Chang, 1992). Half of the videotapes that the adults saw were gesture-speech matches (e.g., Figure 8.1a) and half were gesture-speech mismatches (e.g., Figure 8.1b and Figure 8.2). The adults, half of whom were teachers and half undergraduate students, were simply asked to describe the child’s reasoning. Recall that a mismatch contains two messages, one in speech and one in gesture. A match contains only one. If adults are gleaning information from child gesture, we might therefore expect them to say more when they assess a child who produces a mismatch than when they assess a child who produces a match. And they did. In both studies, the adults produced many more “additions”—that is, they mentioned information that could not be found anywhere in the

speech of the child they were assessing—when evaluating children who produced mismatches than when evaluating children who produced matches. Moreover, over half of these additions could be traced back to the gestures that the children produced in their mismatches. Consider this example. In the conservation task, one child said that the rows contained different numbers of checkers after the top row had been spread out “because you moved ‘em.” However, in his accompanying gesture, the child indicated that the checkers in one row could be matched in a one-to-one fashion with the checkers in the other row (he pointed to a checker in one row and then to the corresponding checker in the other row, and repeated this gesture with another pair of checkers). An adult described this child as saying “‘you moved ‘em’ but then he pointed . . . he was matching them even though he wasn’t verbalizing it,” while producing a one-to-one correspondence gesture of her own. Thus, the adult had attributed to the child reasoning that was explicitly mentioned in the child’s speech (reasoning based on the fact that the checkers had been moved), along with reasoning that appeared only in the child’s gesture (reasoning based on one-to-one correspondence).

In this example, the adult explicitly referred to the child’s gestures. Some of the adults were very aware of the children’s gestures and remarked on them in their assessments. However, these adults were no better at gleaning substantive information from the children’s gestures than were the adults who failed to mention gesture. Thus, being explicitly aware of gesture (at least enough to talk about it) is not a prerequisite for decoding gesture. Moreover, teachers were no better at gleaning information from the children’s gestures than were the undergraduates. At first glance, this finding seems surprising given that teachers have both more experience with children and more knowledge about learning processes than undergraduates. However, from another perspective, the lack of difference suggests that integrating knowledge from both modalities is, in fact, a basic feature of the human communication system, as McNeill (1992) would predict. Everyone can read gesture, with or without training.

Looking at Adult Reactions to Children Gesturing “Live”

When the best examples of gesture-speech mismatches are pulled out and shown to adults twice on a videotape so they can hardly help but notice the gesture, untrained adults are able to glean substantive meaning from ges-

ture. But this experimental gesture-reading situation is a bit removed from the real world. At the least, it would be nice to study adults reacting to real-live children producing whatever gestures they please.

Goldin-Meadow and Sandhofer (1999) asked adults to watch children responding to Piagetian conservation tasks “live.” After each task, the adult’s job was to check off on a list all the explanations that the child expressed on that task. After all the data had been collected, the explanations that the children produced were coded and analyzed. The children produced gesture-speech mismatches in a third of their explanations; that is, they conveyed information found *only* in gesture a third of the time. And the adults were able to decode these gestures. They checked explanations that children expressed in the gesture half of a gesture-speech mismatch, and did so significantly more often than they checked those explanations when they were not produced in either gesture or speech. The adults were thus able to glean substantive information from a child’s gestures, information that did not appear anywhere in that child’s speech, and could do so in a relatively naturalistic context. Listeners can get meaning from gesture even when it is unedited and fleeting.

However, this situation hardly approaches conditions in the real world. The listeners were not really listeners at all; they were “overhearers,” observing gesturers but not participating in a conversation with them. Goldin-Meadow and Singer (2003) videotaped eight teachers who had been asked to individually instruct a series of children in mathematical equivalence. They found that all the teachers were able to glean substantive information from the children’s gestures. The teachers paraphrased or reiterated explanations that the children produced in the gestural component of a mismatch. Moreover, when they reiterated these explanations, the teachers often translated the information conveyed uniquely in child gesture into their own speech, making it clear that they had truly understood the information conveyed in the child’s gestures.

Gesture’s Role in Communication: Does Gesturing Influence How Listeners React to a Speaker?

One of gesture’s most salient features is that it is “out there,” a concrete manifestation of ideas for all the world to see. Gesture could be a signal to parents and teachers that a particular notion is already in a child’s repertoire, although not quite accessible. These listeners

could then alter their behavior accordingly, perhaps offering instruction in just these areas. If so, children would be able to shape their own learning environments just by moving their hands.

Children's Gestures Shape Their Learning Environment

Several facts need to be established to support the hypothesis that gesturing shapes learning through its communicative effects.

- Ordinary listeners must be able to process the gestures children produce and glean substantive information from them, not just in laboratory situations but in real live interactions with children.
- Those listeners must change their behavior in response to the children's gestures, treating children differently simply because of the gestures the children produce.
- Those changed behaviors must have an effect on the child, preferably a beneficial effect.

We have reviewed evidence for the first of these points. Adults (teachers and nonteachers alike) can read the gestures that children produce in naturalistic situations. Moreover, there is good evidence for the second point. When asked to instruct children, teachers provide different instruction as a function of the children's gestures. Before instructing each child, the teachers in the Goldin-Meadow and Singer (2003) study watched that child explain how he or she solved six math problems to the experimenter. Some children produced mismatches during this pretest. The teachers seemed to notice and adjust their instruction accordingly; they gave more variable instruction to the children who produced mismatches than to those who did not produce mismatches: (a) They exposed the mismatchers to more types of problem-solving strategies; (b) they gave the mismatchers more explanations in which the strategy that they expressed in gesture did not match the strategy that they expressed in speech; in other words, the teachers produced more of their own mismatches. Thus, the gestures that children produce can influence the instruction they get from their teachers.

The final point to address in terms of gesture's role in bringing about cognitive change is whether the instruction that teachers spontaneously offer children in response to their gestures is helpful for learning (the

third point). But first we consider why teachers might produce gesture-speech mismatches of their own.

Why Do Teachers Produce Gesture-Speech Mismatches?

It is easy to understand why a teacher might produce a variety of different problem-solving strategies when instructing a child. But why would a teacher present one strategy in one modality and a different strategy in the other modality? In other words, why would a *teacher* produce a gesture-speech mismatch?

Children who produce mismatches are in a state of cognitive uncertainty, possessing knowledge about the task that they cannot quite organize into a coherent whole. Teachers generally are not uncertain about how to solve the math problems they teach. However, they may be uncertain about how best to *teach* children to solve the problems, particularly mismatching children who are producing many inconsistent strategies. It is this uncertainty that may then be reflected in a teacher's mismatches. In general, a mismatch reflects the fact that the speaker is holding two ideas in mind—two ideas that the speaker has not yet integrated into a single unit (see Garber & Goldin-Meadow, 2002; Goldin-Meadow, Nusbaum, Garber, & Church, 1993)—in the teacher's case, a single instructional unit. This way of describing mismatch is, at least plausibly, as applicable to adults when teaching as it is to children when explaining.

However, teachers' mismatches do differ from the children's (Goldin-Meadow & Singer, 2003), and these differences may be important. Not surprisingly, teacher's mismatches for the most part contain correct problem-solving strategies, often two correct strategies that complement one another. For example, on the problem $7 + 6 + 5 = \underline{\hspace{2cm}} + 5$, one teacher expressed an equalizer strategy in speech ("we need to make this side equal to this side") while expressing a grouping strategy in gesture (point at the 7 and the 6, the two numbers which, if added, give the answer that goes in the blank). Both strategies lead to correct solutions yet do so via different routes. In contrast, children's mismatches contain as many incorrect strategies as correct ones.

Even more important, teachers' mismatches do not contain unique information, but children's mismatches do. Recall that children often convey information in the gestural component of their mismatches that cannot be found *anywhere* else in their repertoires. The children's mismatches thus convey their newest ideas. Although these ideas are not always correct, the experimentation

displayed in these mismatches may be essential in promoting cognitive change. The children's mismatches thus display the kind of variability that could be good for learning (cf. Siegler, 1994; Thelen, 1989). In contrast, teachers do not convey unique information in their mismatches (Goldin-Meadow & Singer, 2003). All the strategies that the teachers express in the gestural component of a mismatch can be found, on some other problem, in their speech. The teachers' mismatches do not contain new and undigested thoughts and, consequently, do not reflect the kind of variability that leads to cognitive change. Indeed, teachers' mismatches can best be characterized in terms of the kind of variability that comes with expertise—the back-and-forth around a set point that typifies expert (as opposed to novice) performance on a task (cf. Bertenthal, 1999). Both experts and novices exhibit variability. However, the variability that experts display is in the service of adjusting to small (and perhaps unexpected) variations in the task. In contrast, the variability that novices display reflects experimentation with new ways of solving the task and, in this way, has the potential to lead to cognitive change.

It is important to point out that mismatch *can* reflect experimentation in adults. When adults are uncertain about how to solve a problem, they too produce mismatches (e.g., Perry & Elder, 1997), and it is likely that those mismatches will exhibit the properties found in child mismatches rather than those found in teacher mismatches, that is, information that cannot be found anywhere else in the speaker's repertoire. In other words, when adults are learning a task, their mismatches are likely to exhibit the kind of variability that can lead to cognitive change.

Do Teachers Spontaneously Give Children What They Need?

Teachers instinctively expose children who produce mismatches to instruction containing a variety of problem-solving strategies and many mismatches (Goldin-Meadow & Singer, 2003). Is this instruction good for learning? Mismatching children do indeed profit from the instruction, but they, of course, are ready to learn this task. To find out whether this particular type of instruction promotes learning, we need to move to a more experimental procedure.

Singer and Goldin-Meadow (2005) gave 9- and 10-year-old children instruction that contained either one or two problem-solving strategies in speech. In addition,

they varied the relation between that speech and gesture. Some children received no gesture at all, some received gesture that matched its accompanying speech, and some received gesture that mismatched its accompanying speech. The results were clear and surprising. One strategy in speech was much more effective than two strategies in speech. Thus, it does not seem to be such a good idea for teachers to offer their students a variety of spoken strategies. However, regardless of whether children received one or two strategies in speech, mismatching gesture was more effective than either matching gesture or no gesture at all. Offering children gesture-speech mismatches appears to be an effective instructional strategy.

Why might mismatching gestures be so effective in promoting learning? The children in Singer and Goldin-Meadow's (2005) study were able to profit from a second strategy in instruction, but only when that second strategy was presented in gesture in a mismatch. Mismatching gesture provides the learner with additional information, and presents that information in a format that may be particularly accessible to a child on the cusp of learning. The visuospatial format found in gesture not only captures global images easily, but also allows a second (gestured) strategy to be presented *at the same time as* the spoken strategy. By placing two different strategies side by side within a single utterance (one in speech and one in gesture), mismatches can highlight the contrast between the two strategies. This contrast may, in turn, highlight the fact that different approaches to the problem are possible—an important concept for children grappling with a new idea.

Can Gesture Be Put to Better Use?

Teachers spontaneously use gesture to promote learning. But they don't always use it as effectively as possible. Can gesture be put to better use? There are at least two ways in which gesture can be harnessed to promote cognitive change. We can teach adults to be better gesture-readers, and we can teach adults to be better gesture-producers.

Kelly, Singer, Hicks, and Goldin-Meadow (2002) taught adults to read the gestures that children produce on either conservation or mathematical equivalence tasks. Adults were given a pretest, instruction in gesture-reading, and then a posttest. Instruction varied from just giving a hint ("pay close attention not only to what the children on the videotape say with their words,

but also to what they express with their hands"), to giving general instruction in the parameters that experts use when describing gesture (handshape, motion, placement), to giving specific instruction in the kinds of gestures children produce on that particular task. The adults improved with instruction, more so when given explicit instruction but even when given a hint. Moreover, the adults were able to generalize the instruction they received to new gestures they had not seen during training. Importantly, improvement in reading gesture did *not* affect the adults' ability to glean information from the children's speech on the conservation task; they identified the child's spoken explanations perfectly before and after instruction. There was, however, a slight decrement in the number of spoken explanations the adults reported after instruction on the math task, although this decrement was offset by an increase in the number of gestured explanations the adults reported after instruction. The challenge for us in the future is to figure out ways to encourage teachers and other adults to glean information from children's gestures while at the same time not losing their words.

Children are more likely to profit from instruction when it is accompanied by gesture than when that same instruction is not accompanied by gesture (Church, Ayman-Nolley, & Mahootian, 2004; Perry, Berch, & Singleton, 1995; Valenzano, Alibali, & Klatzky, 2003). But the gestures that teachers spontaneously use with their children are not *always* helpful. The following interchange occurred when a teacher was asked to teach a child mathematical equivalence. The teacher had asked the child to solve the problem $7 + 6 + 5 = \underline{\hspace{2cm}} + 5$ and the child put 18 in the blank, using an incorrect "add-numbers-to-equal-sign" strategy to solve the problem. In her speech, the teacher made it clear to the child that he had used this strategy: She said, "so you got this answer by adding these three numbers." In her gestures, however, she produced an "add-all-numbers" strategy: She pointed at the 7, the 6, the 5 on the left side of the equation *and* the 5 on the right side of the equation (see Figure 8.3 and compare it with Figure 8.2). After these gestures, the teacher went on to try to explain how to solve the problem correctly but, before she could finish, the child offered a new solution—23, precisely the number you get if you add up all of the numbers in this problem. The teacher was genuinely surprised at her student's answer and was completely unaware that she herself might have given him the idea to add up all the

numbers in the problem. A teacher's gestures can lead the child astray. The larger point, however, is that the gestures teachers produce have an impact on what children take from their lessons and therefore may affect learning. If so, teachers (and other adults) need to be encouraged to pay more attention to the gestures that they themselves produce.

Gesture may require our attention not only in teaching situations but also in legal interviews that involve children. Given the prevalence of gesture, it is not hard to imagine that children will gesture when responding to questions in a forensic interview and that those gestures will, at times, convey information that is not found in their speech. If so, the interesting question—both theoretically and practically—is whether adult interviewers pick up on the information that children convey uniquely in gesture and, if not, whether they can be trained to do so. The flip side of the question is also of great importance: Do adult interviewers convey information in their gestures that they do not consciously intend to convey, and if so, does that information influence how children respond to their queries? In other words, is a sub rosa conversation taking place in gesture that does not make it onto the transcripts that become the legal documents for forensic interviews (see Broaders, 2003; Broaders & Goldin-Meadow, 2005, for evidence that gesture can play this type of role in an interview situation)? Because the details children recall of an event can often be influenced by the way in which the interviewer poses the question (e.g., Ceci, 1995), this issue becomes a timely one and one in which attention to gesture might make a difference.

Gesture's Role in Thinking: Does Gesturing Influence the Speaker's Cognition?

We have seen that gesture can convey information to listeners. The question we address in this section is whether gesture serves a function for speakers as well as listeners. The fact that we persist in gesturing even when there are no obvious communicative gains (e.g., when talking on the phone) propels us to seek a within-speaker function.

Gesturing Can Lighten the Speaker's Cognitive Load

There is indeed evidence that gesturing is a boon to the gesturer. In some circumstances, speakers find speaking

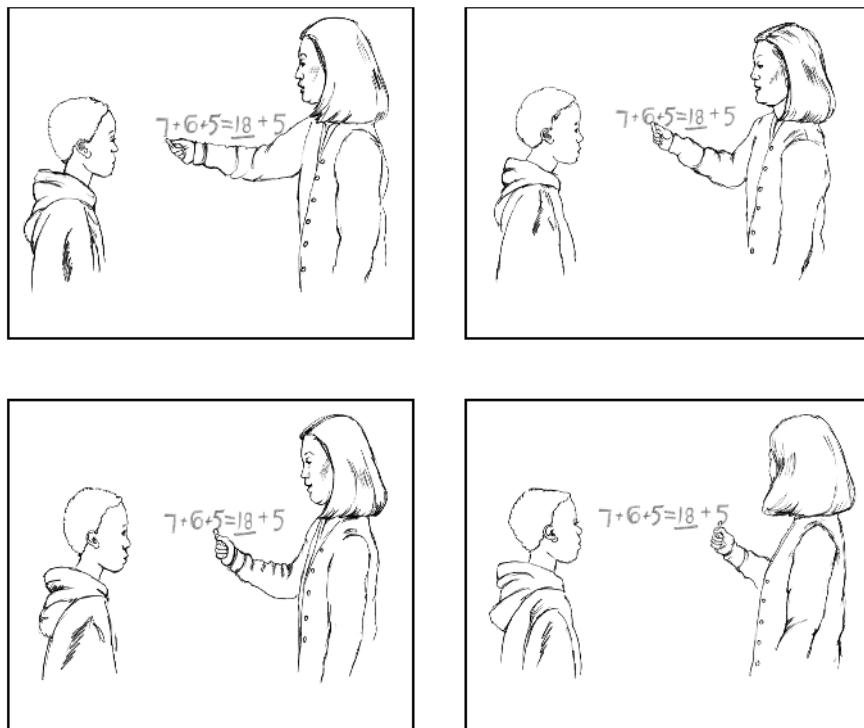

Figure 8.3 The gestures teachers produce can have an impact on the student. In her speech, the teacher points out to the child that he added the first three numbers to get his incorrect answer of 18. However, in her gesture, she points at all the numbers in the problem, including the last number on the right side of the equation (an add-all-numbers strategy; see Figure 8.2 for an example of a child-produced add-all-numbers strategy). The child's response was to add up all the numbers in the problem and give 23 as his answer. He had paid attention to his teacher's gestures.

cognitively less effortful when they gesture than when they do not gesture. Goldin-Meadow, Nusbaum, Kelly, and Wagner (2001) asked children and adults to solve math problems (addition problems for the children, factoring problems for the adults). Immediately after solving a problem, the child or adult was given a list of items to remember (words for the children, letters for the adults). The participants were then asked to explain how they solved the math problem and, after their explanation, to recall the list of items. Note that the participants produced their explanations while keeping the list in memory; the two tasks thus made demands on the same cognitive resources. On half of the problems, the participants were given no instructions about their hands. On the other half, they were told to keep their hands still during their explanations of the problems. The participants gave the same types of explanations for the math problems when they gestured and when they did not gesture. However, the number of items they remembered was not the same. Both children and adults remembered significantly more items when they gestured than when

they did not gesture, suggesting that a spoken explanation accompanied by gesture takes less cognitive effort than a spoken explanation without gesture.

There is one potential problem with these findings. Perhaps asking people not to move their hands may add a cognitive load to the task. If so, the recall pattern might not reflect the beneficial effects of gesturing but rather the demands of this extra cognitive load. Data from a subset of the participants address this concern. These participants gestured on only some of the problems on which they were allowed to move their hands; as a result, on some problems they did not gesture *by choice*. The number of items that these participants remembered when they gestured was significantly higher than the number they remembered when they did not gesture either *by choice* or *by instruction*. Indeed, the number of items remembered did not differ when the participants did not gesture *by choice* or *by instruction*. Thus, the instructions not to gesture did not add to cognitive load and the beneficial effects on recall appear to be attributable to gesture.

Why might gesture lighten a speaker's cognitive load? Perhaps gesture lightens cognitive load by raising the overall activation level of the system so that words reach a firing level more quickly (Butterworth & Hadar, 1989). If so, the act of moving one's hands ought to affect recall, not what those hand movements mean. However, the meaning of the gestures does have an impact on recall (Wagner, Nusbaum, & Goldin-Meadow, 2004): Speakers remember fewer words when their gestures convey a different message from their speech, that is, when they convey two messages (one in speech and one in gesture), rather than one (the same message in speech and gesture).

Instead of merely adding activation to the system, gesture might help speakers retrieve just the right word in their explanations (which would, in turn, save them cognitive effort so that they could perform better on the memory task). Gesture, particularly iconic gestures, might assist word finding by exploiting another route to the phonological lexicon, a route mediated by visual coding (Butterworth & Hadar, 1989). Some evidence, in fact, suggests that gesture can facilitate lexical recall (Rauscher et al., 1996; but see Alibali et al., 2000; Beattie & Coughlan, 1998, 1999).

Lexical access does not account for all the beneficial effects of gesture. Gesture may also help link or "index" words and phrases to real-world objects. Glenberg and Robertson (1999) argue that indexing is essential for comprehension; once a word is indexed to an object, the listener's knowledge of that particular object can guide his or her interpretation of the language. Making these links might be important, not only for listeners but also for speakers. Alibali and DiRusso (1999) explored the benefits of gestural indexing for preschoolers performing a counting task. Sometimes the children were allowed to gesture, in particular, to tick off the items, while they counted and sometimes they were not. The children counted more accurately when they gestured than when they did not gesture. Thus, using gesture to hook word to world can improve performance on a task.

Finally, gesturing could help speakers organize information for the act of speaking and in this way ease the speaker's cognitive burden. Kita (2000) has argued that gesture helps speakers "package" spatial information into units appropriate for verbalization. If this hypothesis is correct, speakers should find it easier to convey spatial information when they gesture than when they do not gesture. Rimé, Schiaratura, Hupet, and Ghyselinckx (1984) prevented speakers from gesturing and

found that these speakers produced less visual imagery in their talk when they did not gesture than when they did. Alibali, Kita, Bigelow, Wolfman, and Klein (2001) performed the same manipulation and found that their child speakers produced fewer perceptual-based explanations when they did not gesture than when they did.

So what have we learned about gesture's effect on the gesturer? We know that speakers tend to gesture more when the task becomes difficult. They appear to do so, not merely as a reflection of the cognitive effort they are expending, but as a way to *reduce* that effort. Giving an explanation while gesturing actually takes *less* cognitive effort than giving an explanation without gesturing. However, we do not yet understand the mechanism by which gesturing lightens the speaker's load.

Gesture's Direct Impact on the Learner: Can Gesturing Create Ideas?

We have seen that gesturing can aid thinking by reducing cognitive effort. That effort can then be used on some other task, one which would have been performed less well had the speaker not gestured on the first task. Gesturing thus allows speakers to do more with what they have and, in this way, can promote cognitive change. But gesturing has the potential to contribute to cognitive change in other ways as well—it could affect the *direction* that the change takes.

Gesture offers a route, and a unique one, through which new information can be brought into the system. Because the representational formats underlying gesture are mimetic and analog rather than discrete, gesture permits speakers to represent ideas that lend themselves to formats (e.g., shapes, sizes, spatial relationships)—ideas that, for whatever reason, may not be easily encoded in speech. Take, for example, a child who expresses one-to-one correspondence in gesture but not in speech. This child may find it relatively easy to focus on aligning the two rows of checkers in the visuospatial format that gesture offers—and at a time when he does not have sufficient grasp of the idea to express it in words. Gesture provides a format that makes it easy for the child to discover one-to-one correspondence and thus allows this novel idea to be brought into his repertoire earlier than it would have been without gesture. Once brought in, the new idea can then serve as a catalyst for change.

The suggestion here is that gesture does not just *reflect* the incipient ideas that a learner has, but it actually helps the learner formulate and therefore *develop* these

new ideas. One implication of this hypothesis is that thought would have been different had the speaker not gestured. To test the hypothesis, we need a technique for assessing thought that is independent of gesture and speech; we need a way to figure out whether thought has been altered that does *not* involve looking at either gesture or speech. At the moment, no studies have been designed with this particular goal in mind. We do, however, have examples of studies that explore gesture's effect on *talk*, studies in which gesture is manipulated (either discouraged or encouraged) and the effect of the manipulation on talk is then examined.

Alibali, Kita, and colleagues (2001) *discouraged* children from gesturing by asking them to explain their answers to a series of conservation tasks when they could move their hands freely and when their hands were placed in a muff and therefore restrained. As expected under the view that gesture helps speakers organize spatial information, the children produced more perceptual-based explanations when they were allowed to move their hands freely than when they were not. The idea is that the act of gesturing promotes thinking, in particular, spatial thinking—and not gesturing inhibits it (see also Rimé et al., 1984).

But note that we can also *encourage* speakers to move their hands while they talk. If children are asked to move their hands when they explain their solutions to a math problem, they begin to produce problem-solving strategies that they have never produced before, some correct and some incorrect (Broaders & Goldin-Meadow, 2002). For the most part, these new strategies can be found only in the children's gestures. The interesting question is what would happen if these children were given instruction in mathematical equivalence. Having enlarged their store of implicit problem-solving strategies after being encouraged to gesture, would the children now be particularly likely to profit from instruction? If so, children may be able to improve their ability to learn just by moving their hands.

Wolff and Gutstein (1972) not only asked speakers to gesture but they dictated which movements the speakers produced. The experimenters could therefore make specific predictions about the kinds of ideas that ought to infiltrate the stories accompanied by gesture. They taught speakers either a circular or linear movement. Some of the speakers were asked to generate short stories while performing the assigned gesture with their eyes closed. Others generated their stories while watching an experimenter perform the assigned gesture.

Raters were asked to judge whether the stories had linear or circular content. Speakers who produced linear gestures created stories that were judged more linear than the stories created by speakers who produced circular gestures. And speakers who watched linear gestures also created stories that were judged more linear than the stories created by speakers who watched circular gestures. A third control group was taught either the linear or circular gesture but did not use or see the gesture when producing stories. There were no differences in the ratings of the stories generated by these speakers. These results suggest that waving your hands about in prescribed ways can affect what you are going to say. Moreover, the impact of gesture is not restricted to producing gesture. Its impact was felt even by those speakers who merely witnessed others' hand movements, a finding that confirms the conclusion we came to earlier—gesture does have an impact on listeners.

An elegant aspect of the Wolff and Gutstein (1972) study is that the speakers who produced gestures did so with their eyes closed. Thus, they felt their gestures but did not see them. It is consequently very clear that there can be separable effects on the content of talk of *seeing* and *feeling* hand movements. The effects could be additive—had the speakers been allowed to both see and feel their own gestures (which is, after all, what typically happens when speakers talk), the content of their stories might have been that much more skewed. Alternatively, feeling one's own gestures may be such a powerful stimulus that little is added by watching them. Moreover, the perspective we have on our own gestures is distinctly different from the perspective we have on others' gestures. We may get something out of watching other speakers' gestures, but little out of watching our own. This is an area where many questions remain.

The Wolff and Gutstein (1972) findings are striking because the gestures were completely unrelated to the storytelling task. However, from an educational (or even a conversational) point of view, it would be worth exploring the effects on thinking of movements that are more directly related to the task. For example, what would happen if we asked a child who did not know how to solve the problem $4 + 5 + 3 = \underline{\hspace{1cm}} + 3$ to produce a V-hand under the 4 and the 5 and a point at the blank while explaining the problem? This gesture represents the "grouping" strategy—group 4 and 5 together, add them, and put the sum in the blank. If the actions that the children are forced to produce do, in fact, influence their thinking, we might expect them to produce more

correct solutions on these problems than children who are not required to make these movements—or even more telling, more correct solutions than children who are required to make other less targeted movements. In this way, gesturing could shape thinking.

CONCLUSION

Why do we gesture? Perhaps gesturing is a vestige of the evolutionary process that gave us speech. It could be a hanger-on that accompanies the act of speaking but plays no active role in how we speak or think. If so, gesture would be of interest for what it can reveal to us about the process of speaking or thinking, but it would have no influence on the process itself. This is the least we can say about gesture. But evidence is mounting in favor of the view that gesture does more than just reflect thought—it shapes it as well. If we find that gesture is causally involved in change, its effect is likely to be widespread. Gesture is pervasive, appearing in all sorts of situations and over all ages and cultures. Gesture is ever-present, and we notice it even though we typically do not know we are noticing it. The time seems ripe to include gesture as a full-fledged part of the conversation.

It may come as a surprise that the current volume of the venerable *Handbook of Child Psychology* is the first to contain a chapter on "event memory." With some notable exceptions (e.g., Bartlett, 1932), it was not until the mid-1970s that research on entities termed "events" became

I gratefully acknowledge the support of the NICHD for the work from my laboratory cited in this review (HD-28425, HD-42483). I also extend my heartfelt appreciation to my colleagues Robyn Fivush, Jean Mandler, and Katherine Nelson, for their comments on a draft version of this review; for their foundational and ongoing contributions to the field I have had the privilege to represent; and for the many spirited conversations in which we have engaged that have served to sharpen and otherwise further my perspective on developmental changes in event memory. Thank you.

common in the adult cognitive literature, with research on stories (e.g., Rumelhart, 1975), scripts (e.g., Schank & Abelson, 1977), and schemas (e.g., Kintsch, 1974). Whereas developmental scientists were not far behind in the effort (Mandler & Johnson, 1977; K. Nelson, 1978; Stein & Glenn, 1979), at the time of preparation of the 1983 (fourth) edition of the *Handbook*, a review of the data on children's memories for the events of their lives nevertheless consumed only 4 pages of Jean Mandler's (1983) 57-page (excluding References) chapter, "Representation" (with additional space devoted to representation of stories). By the time the fifth edition was published in 1998, there was a wealth of new information about children's memories for events, but the body of data was not yet recognized as constituting a coherent

domain. Instead, the themes that are brought together in this chapter were distributed across several chapters, most prominently “Infant Cognition” (Haith & Benson, 1998), “Representation” (once again by Mandler, 1998), and “Memory” (Schneider & Bjorklund, 1998).

WHAT IS EVENT MEMORY AND WHY IS IT IMPORTANT?

What kind of memory is event memory? At its most basic, an event can be almost anything: a leaf fluttering in the breeze, ice forming on a pond, or ink running on a piece of paper. For a coherent body of work to be summarized under the heading “Event Memory,” the term *event* needs to be defined in a meaningful way. Borrowing from Katherine Nelson (1986), for purposes of this chapter, I define events as “involv(ing) people in purposeful activities, and acting on objects and interacting with each other to achieve some result” (p. 11). Purposeful activity unfolds over time: It has a beginning, a middle, and an end. Moreover, because the actions in events are oriented toward a goal or result (even if not all the participants in or observers of the event are privy to it), there frequently are constraints on the order in which they unfold: Actions preparatory to an outcome must occur before it in time. This definition eliminates from consideration simple physical transformations such as fluttering, freezing, and smearing, which do not involve actors engaged in purposeful activity. In contrast, the definition effectively includes the activities in which individuals engage as they move through a typical day (such as eating breakfast, going to school, and having dinner at a restaurant) as well as the unique experiences that ultimately define us as individuals. It is memory for these episodes with which this chapter is concerned. The definition also specifies what there is to be remembered about events—actors, actions, objects, and the orders in which the elements combine to achieve specific goals.

Defining events as purposeful activities in which individuals engage highlights why the ability to remember events is important and, thus, why the study of the development of event memory is important. First, memories of past events guide present behavior and are a basis on which we plan future behavior. Although we think about memory as being about the past, most of the uses to which we put memory concern the present and the fu-

ture. For example, we use our experience of prior trips to the grocery store to guide our behavior on the current trip (e.g., we look for our favorite cookies in Aisle 1, based on our memory of finding them there in the past), as well as to plan for future trips (e.g., we reorder next week’s shopping list because we remember that the store moved the cookies from Aisle 1 to Aisle 6).

Second, events and stories about them are major instructional tools, both informally and formally. It is through participating in events that we learn that cookies and fruit both make good snacks; that it feels better to win the game than to lose it; and that when you are running late, the bus leaves on time (without you!). In formal academic settings, it is through listening to and reading stories and enacting events from the past that we learn about the forces that shaped history and the political lessons that could, were we to heed them, prevent us from repeating it. The episodes of our own and others’ lives are major sources of semantic content and knowledge.

Third, memories of the events in which we participated are self-defining: Who we are is who we were and what we did. Memories of personally relevant experiences and events (termed *autobiographical memories*) are the ones that we share when we are getting to know new people or reconnecting with old acquaintances. We use our past experiences to explain our present behavior and to motivate choices for the future. For these reasons and more, the ability to remember past events is important to the mature as well as the developing human.

THE SCOPE OF THIS CHAPTER

From the partial list of the functions of event memory just presented, it is possible to discern at least some of the topics of this chapter. It includes reviews of the literature on children’s developing ability to remember the experiences of their lives—both routine and unique. Focus is on children’s abilities to recall the actors, actions, and objects of events, the order in which the activities unfold, and the goals of activities. There are discussions of age-related changes in the basic processes of memory (encoding, consolidation, storage, and retrieval) that permit children to remember more, more accurately, over longer periods. There also are discussions of some factors that affect event memory, as well as the factors that shape narrative skills for its expres-

sion. Both normative developmental trends and individual variability are featured. Possible sources of individual differences and mechanisms responsible for developmental trends are suggested.

There also are some topics that are not covered in this chapter even though they are relevant to how past events are remembered. First, as already noted, events have temporal extent: They unfold over time. Events also have spatial extent: They occur in a particular place. Whereas being able to locate an event in space is important to memory for it, memory for spatial location is covered in another chapter of the *Handbook* (Newcombe & Huttenlocher, Chapter 17, this *Handbook*, this volume), and thus is not a focus of specific discussion here. Second, there are times when individuals are called on to report on specific episodes in legal contexts. Most typically, the events on which they are required to report are at least unpleasant and possibly traumatic. Some of the literature on children's recall of negative, stressful, or traumatic events is reviewed in the course of comparison with their memories for positive or neutral experiences (see section "Is Memory for Stressful . . .," later in this chapter). The forensic and social policy issues surrounding children as eyewitnesses are not, however, a focus here.

Third, much of what is remembered about events was not intentionally or deliberately encoded for later retrieval. With the obvious exceptions of major transitional events such as weddings and births, we do not go about our daily activities deliberately attempting to remember them. As such, we do not necessarily engage in specific activities designed to preserve the events in memory, such as rehearsal. This is not to say that we do not make deliberate efforts to learn from our experiences. Everyday and unique events are full of "life lessons" that we may intentionally attempt to extract. For example, we may deliberately make a note to remember that a new red sweater should not be included in a laundry load of whites. The object of our intention is the lesson, though, not the event or episode that gave rise to the lesson: We hope to remember to separate by color, not the time and place that we learned the necessity of doing so. Because we do not typically make deliberate or strategic attempts to remember most of the episodes of our lives, whether and how children employ deliberate strategies for remembering events has not been a major focus in the event memory literature. Developments in strategic memory are reviewed elsewhere in the

Handbook (Pressley & Hilden, Chapter 12, this *Handbook*, this volume).

Finally, to say that much of what we remember about everyday and unique events is not deliberately encoded into memory is not to say that our memories for events are unconscious or outside awareness. There is a major distinction in the broader domain of memory between conscious, declarative, or explicit memory and unconscious, nondeclarative, procedural, or implicit memory. Although it is not universally accepted (see, e.g., Roediger, Rajaram, & Srinivas, 1990; Rovee-Collier, 1997), by both developmental and adult cognitive scientists, it is widely recognized that the different types of memory constitute different systems or processes that serve distinct functions and are characterized by fundamentally different rules of operation (e.g., Schacter, Wagner, & Buckner, 2000; Squire, Knowlton, & Musen, 1993). *Explicit* memory involves the capacity for conscious recognition or recall of the *who*, *what*, *where*, *when*, *why*, and *how* of experience. It is devoted to recollection of such things as names, dates, places, facts, and events, as well as descriptive details about them. These are entities that we think of as being encoded symbolically and that thus can be described with language. Explicit memory is characterized as fast (e.g., supporting one-trial learning), fallible (e.g., memory traces degrade, retrieval failures occur), and flexible (not tied to a specific modality or context). In contrast, the type of memory termed *implicit* represents nonconscious abilities, including the capacity for learning skills and procedures, priming, and some forms of conditioning. The knowledge tied up in skills and procedures is not of names, dates, facts, and events, but of finely tuned motor patterns and perceptual skills. It is not encoded symbolically and thus is not accessible to language. Implicit memory is characterized as slow (with the exception of priming, it results from gradual or incremental learning), reliable, and inflexible.

Under ordinary circumstances, explicit and implicit memory operate in parallel. That is, in most cases, one derives both explicit and implicit knowledge from the same experience. Learning to drive is a good example. Student drivers consciously learn components of the skill. From their instructors and instruction manuals they learn that to stop the car they should depress the brake; if the car is moving fast, they should allow more time for braking. Drivers can verbally express these elements of their knowledge: They are quite explicit. Yet

few drivers—even highly skilled ones—can state the amount of time or the number of pounds of pressure on the brake pedal required to bring to a stop a slow-moving versus a fast-moving vehicle. This knowledge is not conveyed to the novice driver through spoken or written language. Nor is it acquired by observation of other drivers' actions. Rather, it is acquired through practice, practice, and more practice executing the motor movements of braking. The resulting knowledge is tied up in the driver's muscles and joints (the new driver "gets the feel for it") and is not accessible to conscious reflection. How do we know when something is accessible to conscious reflection? Köhler and Moscovitch (1997) suggest that "one is conscious or aware of [a memory] when a verbal or nonverbal description can be provided of [it] or a voluntary response can be made that comments on it" (p. 306).

Another important point is that, in most cases, explicit knowledge and implicit knowledge not only are acquired in parallel but continue to coexist, even after execution of the behavior no longer seems to require conscious awareness. Whereas the skill of driving starts out very demanding of attentional resources, it eventually can be performed almost automatically (without conscious attention paid to it). Such changes tempt the conclusion that once these skills no longer require conscious attention to execute, they have become implicit (or procedural). A moment's reflection reveals the flaw in this logic: If explicit knowledge were to become implicit, it would mean that it was no longer explicit. The fact that I can tell you that to stop the car you apply pressure to the brake proves that my knowledge remains accessible to consciousness. I still have the explicit knowledge, even though I do not depend on that knowledge to execute the behavior. Although the explicit and implicit memory systems operate in parallel, in the domain of event memory, research has been concerned almost exclusively with the explicit aspects of experience. In keeping with this tradition, the literature reviewed in this chapter is on explicit memory. Moreover, the primary focus is developments in recall as opposed to recognition.

TRADITIONAL ACCOUNTS OF THE DEVELOPMENT OF EVENT MEMORY

As in so many areas of cognitive developmental science, the study of memory development got "off the ground"

with Piaget (1952). Before his writings were translated into English and made widely available to an English-speaking audience, the study of child development focused primarily on motor and physical development and on children's affective development (see Hartup, Johnson, & Weinberg, 2001, for a review). Much of the early work on cognition concerned the development of general intellectual ability and reasoning and problem-solving skills as opposed to specific cognitive developments such as memory (a notable exception was Foster, 1928, who conducted one of the earliest studies of memory for prose material by preschool-age children). In contrast, Piaget made clear and strong predictions about many specific cognitive capacities, including memory. He suggested that for the first 18 to 24 months of life infants lacked symbolic capacity, and thus, the ability to mentally represent objects and events. Instead, they were thought to live in a "here-and-now" world that included physically present entities with no past and no future. In other words, infants were described as living an "out-of-sight, out-of-mind" existence.

Compelling illustrations of the out-of-sight, out-of-mind attitude were provided in Piaget's (1952, 1962) extensive observations of his own children. An example from his daughter, Lucienne, makes the point. At 8 months of age, Lucienne was playing with a toy stork. Piaget took the toy and in full view of Lucienne, hid it under a cover. As long as Piaget hid only a portion of the stork, Lucienne removed the cover and retrieved it. However, when Piaget hid the entire stork under the cover, Lucienne simply stared at Piaget, or began playing with another toy. The change in attitude toward the stork was not for lack of interest in it, for if Piaget then revealed the stork, Lucienne smiled and tried to grasp it. Nor was the problem the need to remove the cover: As long as a portion of the stork was visible, Lucienne easily moved the cover out of the way to get the toy. Piaget interpreted this collection of behaviors as evidence that when the toy was out of sight, it no longer existed for the child. He suggested that the reason for this rather bizarre behavior was that infants lacked the symbolic means to represent information not available to the senses (to mentally *re-present* it).

Piaget hypothesized that by 18 to 24 months of age, children had constructed the capacity for mental representation. Even then, they were thought to be without the necessary cognitive structures to organize events along coherent dimensions that would make the events memorable. Consistent with this suggestion, in retelling

fairy tales, children as old as 7 years made errors in temporal sequencing (Piaget, 1926, 1969). Piaget attributed their poor performance to the lack of reversible thought. Without it, children could not organize information temporally and thus could not tell a story from beginning, to middle, to end.

With the rise of information-processing theories in the 1960s and 1970s, researchers began to think about changes in memory as due not to developments in reversible thought, but to hypothesized changes in the efficiency of encoding, storage, and retrieval processes. The major interest was in how properties of the to-be-remembered materials, study conditions, activities during the retention interval, and so forth, influenced memory. A prototypical memory experiment from the 1960s and 1970s was to give children of different ages lists of words or pictures to study and remember. In a classic study, John Flavell and his colleagues gave picture lists to children 5, 7, and 10 years of age. They found that whereas the youngest children did little to help themselves remember (they did not employ memory strategies) and in fact remembered few pictures, the oldest children verbally rehearsed the materials and presumably as a consequence, remembered more (Flavell, Beach, & Chinsky, 1966; see Pressley & Hilden, Chapter 12, this *Handbook*, this volume, for a review of the literature on deliberate and strategic remembering). Indeed, the way to ensure that your experiment “worked” was to include younger and older children, thereby assuring a nice pattern of developmental change.

Changing the Course of Research on Developments in Event Memory

Three “events” happened in the late 1970s and early 1980s that changed the direction of research on children’s memory. One of the events was recognition of the importance to memory of the organization or structure within to-be-remembered materials. A second, and related, event was recognition of the importance to memory of familiarity with the event or domain of the to-be-remembered material. The third event was development of a means of assessing event memory in pre- and early verbal children.

The Importance of Organization or Structure

Recognition that not all to-be-remembered material is created equal contributed to change in the landscape of developmental research on memory. As just noted, re-

search on children’s memory undertaken in the 1960s and 1970s frequently used lists of words or pictures for stimuli. In some cases, the lists included related items (e.g., several pictures of animals interspersed with several pictures of clothing items), but in many experiments, following the tradition established in the adult literature (as early as Ebbinghaus, 1885/1913), the materials were virtually devoid of meaning or structure. This allowed researchers to examine the properties of memory (e.g., speed of acquisition, decay rate) without the potentially confounding factor of familiarity (and in the developmental literature, potentially *differential* familiarity, as a function of age and experience). Yet, many of the things that individuals experience and remember are highly structured. The stories that we hear and read are not made up of randomly ordered bits but of antecedent actions followed by consequences. Early work by Piaget (1926, 1969) implied that appreciation of this structure was a relatively late developmental achievement. Contrary to this expectation, in an influential series of studies, Jean Mandler and her colleagues (e.g., Mandler & DeForest, 1979; Mandler & Johnson, 1977) demonstrated not only that children are sensitive to the structure inherent in story materials, but that their memory for them is qualitatively similar to that of adults.

The work was based on the recognition that stories and other types of narratives follow a common hierarchical organization. They begin with an introduction of the protagonist of the story and establishment of the time and place of the events (“Once upon a time, in a land far away, there lived a beautiful princess . . .”). This setting information is followed by an episode in which the protagonist carries out some action or sequence of actions designed to fulfill a goal. After one or more attempts to achieve the goal, the story wraps up with an outcome of the actions (the goal is either achieved or thwarted) and an ending (“And they lived happily ever after”). The work of Mandler and her colleagues (e.g., Mandler & DeForest, 1979; Mandler & Johnson, 1977; see also Stein & Glenn, 1979) indicated that even young children are sensitive to this structure. For example, children have higher levels of recall of stories that follow the canonical form, relative to stories that violate it. In addition, children tend to “correct” poorly organized stories, to conform to the hierarchical structure (see Mandler, 1984, for a review). Findings such as these made two things abundantly clear: First, event memory is affected by the organization or structure of to-be-remembered events; and second, when

to-be-remembered events are well organized, even young children can be expected to recall them.

The Importance of Familiarity

A second formative experience for the study of developments in event memory was recognition of the importance of familiarity with a domain or event for memory performance. An illustrative example is Micheline Chi's (1978) research on expertise in the domain of chess. Chi asked children and adults to participate in two tests: one in which participants had to remember chess positions and another in which they had to remember random strings of digits. What made the study unique was that the children in the study (who had a mean age of 10 years), were more knowledgeable about chess relative to the adults. Chi found that in the domain of strings of digits, as was expected, the adults outperformed the children. However, in the domain of chess, the children outperformed the adults. Based on these and similar results from other studies, Chi concluded that knowledge of a domain was an important determinant of memory performance.

The importance of knowledge of a domain also was apparent in research on event memory. Indeed, by asking children for reports in domains that they knew well, Katherine Nelson and her colleagues discovered mnemonic competence in children as young as 3 years of age. Rather than asking children to recall lists of words or pictures, or even stories of a protagonist's experiences, they asked, "What happens when you make cookies?" and "What happens when you go to McDonald's" (K. Nelson, 1978; K. Nelson & Gruendel, 1981; see also Todd & Perlmuter, 1980). In this work, Nelson and her colleagues were guided by the script model advanced by Schank and Abelson (1977). Schank and Abelson posited cognitive structures termed *scripts* that guide adults' actions in familiar situations. For example, most adults have a script for "what happens" at a fast-food restaurant. When we enter a restaurant and find a counter, behind which is mounted a menu board, we know that we should approach the counter to order. We "know" that we should behave in this way, even if we have never visited the particular restaurant location before, and even if we have never frequented that particular restaurant chain before. We know not only the elements of the activity, but the order in which the actions should be carried out (e.g., we will be asked to pay for our order before we receive it). Scripts also tell us what *not* to expect: It is our fast-

food restaurant script that would cause us to be surprised if, on driving up to a fast-food restaurant, a tuxedo-clad valet offered to park our car.

To determine whether young children also seem to be guided by scripts for what to do Nelson and her colleagues adopted a straightforward research design:

Our research design was simple: We asked 3- and 4-year-old children to tell us what happened when they engaged in some everyday routines. Following Abelson and Schank's lead that adults have prototypical restaurant scripts, one of our first script questions was "what happens when you go to MacDonald's." . . . Even the 3-year-olds turned out to be extraordinarily good at this, and produced the first systematic evidence that 3- and 4-year-olds could reliably order an extended sequence of actions according to its temporal and causal relations. (K. Nelson, 1997, p. 3)

On average, the children mentioned 11 different acts in the McDonald's event, and they agreed on 82% of them. K. Nelson and Gruendel (1986) interpreted the fact that all the children mentioned the act of eating as evidence that they appreciated the central goal of the event. In addition, the children's temporal ordering of the acts was virtually flawless. Moreover, children did not require multiple experiences of events to evidence formation of scriptlike representations. Fivush interviewed kindergarten children after only a single day of school. Although the children had experienced the school-day routine just once, they nevertheless appeared to have general representations of it, as evidenced by this response from one of the participants to the question, "What happens when you go to school?":

Play. Say hello to the teacher and then you do reading or something. You can do anything you want to . . . clean up and then you play some more and then clean up and then play some more and then clean up. And then you go to the gym or playground. And then you go home. Have your lunch and go home. You go out the school and you ride on the bus or train and go home. (Fivush & Slackman, 1986, p. 78)

Assessing Event Memory Nonverbally

The third major "event" that changed the direction of research on young children's memory was development of an experimental means of testing assumptions about limitations on explicit memory in infants younger than 18 to 24 months. In the first of a series of papers, Andrew Meltzoff (1985) reported that 24-month-old in-

fants were able to defer imitation for 24 hours. Piaget (1952) had identified deferred imitation as one of the hallmarks of the development of symbolic thought: He used his daughter Jacqueline's deferred imitation of a cousin's temper tantrum as an illustration of her developing representational capacity. What Meltzoff did was to bring deferred imitation under experimental control by presenting to infants, not temper tantrums, but another novel action, namely, pulling apart a dumbbell-shaped toy. He found that 80% of the 24-month-olds imitated the action immediately after seeing it modeled. Among the children required to defer imitation for 24 hours, 70% produced the behavior. In contrast, 20% of children who had seen the toy but had not seen the specific action performed on it (naive control children) produced the behavior immediately and 25% produced it after the delay.

Whereas the finding that 24-month-olds were able to defer imitation was in keeping with the estimates set forth by Piaget, another of Meltzoff's findings (1985) was not. Specifically, he reported that 14-month-olds also were able to defer imitation over 24 hours: 45% of the infants who had seen the action modeled performed it 24 hours later (compared with 7.5% of naive controls). Shortly thereafter, Bauer and Shore (1987) published findings that over a 6-week delay, infants 17 to 23 months of age remembered not only individual actions but temporally ordered sequences of action. Even after 6 weeks, they were able to reproduce in the correct temporal order the steps of putting a ball into a cup, covering it with another cup, and shaking the cups to make a rattle. Most striking of all was the finding that 9-month-olds were able to defer imitation of single actions over 24 hours (Meltzoff, 1988c). Indeed, the capacity for deferred imitation appeared quite robust: The same levels of performance were observed when 9-month-olds were required to defer imitation as when they were permitted to imitate immediately. These findings initiated concerted efforts to map the development of explicit memory in the first years of life.

It is important to note that evidence of imitation after a delay was not the first indication of memory in children younger than 18 to 24 months of age. As early as 1956, Fantz had introduced the visual paired comparison task as a measure of infant memory. In visual paired comparison, two identical stimuli are placed side by side for a period of time after which one of the stimuli is replaced by a novel stimulus. Longer looking at the novel

stimulus is taken as evidence of memory for the familiarization stimulus. In addition, in the 1960s, Rovee-Collier began publishing results from her conjugate reinforcement paradigm (see Rovee-Collier, 1997, for a review). In this task, a mobile is suspended above an infant's crib or sling seat. After a brief baseline period during which researchers measure the rate at which infants kick, they tether the infant's leg to the mobile with a ribbon such that, as the infant kicks, the mobile moves. Infants readily learn the contingency between their own kicking and the movement of the mobile. Once the conditioned response is acquired, a delay is imposed, after which the mobile again is suspended above the infant. This time, however, the infant's leg is not attached to the mobile. If the posttraining rate of kicking is greater than the rate of kicking in the procedurally identical baseline (before the infant experienced the contingency), then memory is inferred (e.g., Rovee-Collier & Gerhardstein, 1997).

What was different about the imitation procedures used by Meltzoff (1985, 1988c) and Bauer and Shore (1987; see also Bauer & Mandler, 1989) relative to the other infant memory paradigms was that the imitation procedures provided tests of a capacity that Piaget himself had identified as indicative of representational ability. In contrast, the behaviors evidenced in the visual paired comparison and mobile conjugate reinforcement paradigms appeared sensorimotor in nature. Visual paired comparison (and other attentional preference techniques) provided experimental demonstrations of the sorts of recognition behaviors that Piaget had described in his own infants (and for which he saw no need to invoke representational ability). The patterns of generalization, extinction, and reinstatement exhibited by infants in the conjugate reinforcement paradigm were typical of those in operant conditioning paradigms used with a range of animal species (e.g., Campbell, 1984). As a consequence, although these other techniques had been used for many years, they did not serve as an impetus for research on explicit memory in the first years of life to the same extent as the findings from imitation-based tasks.

Whereas originally the argument that imitation-based paradigms provide a means of testing explicit memory was based in Piaget's (1952) observations, some characteristics support the claim. Because the argument has been developed in detail elsewhere (e.g., Bauer, 2005b, 2006; Carver & Bauer, 2001), I present

only two components of it. First, as reviewed in the section “Continuities and Discontinuities . . . ,” later in this chapter, once children acquire the requisite language, they talk about events that they experienced as preverbal infants, in the context of imitation tasks (e.g., Bauer, Wenner, & Kroupina, 2002). This is strong evidence that the format in which the memories are encoded is explicit, as opposed to implicit or procedural (formats inaccessible to language). Second, the paradigm passes the “amnesia test.” Whereas intact adults accurately imitate sequences after a delay, patients with amnesia due to hippocampal lesions perform no better than naive controls (McDonough, Mandler, McKee, & Squire, 1995). Adolescents and young adults who sustained hippocampal damage early in life also exhibit deficits in performance on the task (Adlam, Vargha-Khadem, Mishkin, & de Haan, 2005). This suggests that the paradigm taps the type of memory that gives rise to recall. For these reasons, the task has come to be widely accepted as a nonverbal analogue to verbal report (e.g., Bauer, 2002; Mandler, 1990b; Meltzoff, 1990; K. Nelson & Fivush, 2000; Rovee-Collier & Hayne, 2000; Schneider & Bjorklund, 1998; Squire et al., 1993).

Event Memory in Infancy and Early Childhood

The events just described (research on children’s recall of stories, preschoolers’ scripts, and development of a nonverbal means of assessing explicit memory in infancy) proved that even young children have substantial mnemonic competence. These events did more than that though. In a very real sense, they gave birth to the domain of this chapter—research on the development of children’s event memory for ordinary experiences in their everyday lives, as well as novel, one-time experiences that they encounter either in the laboratory or in the world outside it. The developments also motivated research on event memory in infancy and very early childhood. If by 3 years of age, children already have well-organized event representations, then the capacity to form them must have developed earlier. Imitation-based tasks provided the means to test this critical assumption.

In the following sections, I outline what we have learned about event memory over roughly 2 decades of research. Although it has the unfortunate by-product of perpetuating the traditional sense of discontinuity between infancy and childhood, the literatures on these major developmental periods are discussed separately.

Separate treatment is almost demanded by the dramatic differences in the research methodologies. Whereas in infancy, nonverbal, imitation-based tasks are used to assess event memory, the literature on childhood is based almost exclusively on verbal reports.

EVENT MEMORY IN THE FIRST 2 YEARS OF LIFE

Contrary to the traditional conceptualization of the first 2 years of life as a period devoid of the capacity to recall the past, event memory develops rapidly and substantially during this time. For a number of reasons, the literature reviewed to substantiate this conclusion is restricted to the nonverbal imitation-based paradigms of elicited and deferred imitation. First, why the task must be nonverbal is obvious—infants (from the Latin *infantia* meaning “inability to speak”) cannot talk. Second, as noted, whereas there are a number of nonverbal paradigms for assessing memory in infancy (e.g., visual paired comparison, mobile conjugate reinforcement), imitation-based tasks are the most widely accepted analogue to the prototypical measure of recall memory, verbal report. Third, imitation-based tasks permit tests of infants using materials that are similar to the events commonly tested with older children. That is, infants are presented with actions or sequences of actions performed by actors on objects in order to reach a clear goal (though it is not discussed, there is evidence that infants perceive the actions and event sequences as goal based: e.g., Carpenter, Akhtar, & Tomasello, 1998; Meltzoff, 1995a; Travis, 1997). This feature of the paradigm affords a point of contact with the literature from older children. In addition, reproduction of sequences in the correct temporal order provides especially compelling evidence that infants’ and children’s behavior is guided by recall: Once the model is complete, there is no perceptual support for the order in which the actions should be produced. Fourth, the other nonverbal paradigms are used almost exclusively with infants in the 1st year of life (although see Hartshorn et al., 1998, for an exception). In contrast, imitation-based tasks have been used with infants as young as 6 months and as old as 36 months, thereby, again, permitting assessment of continuity. Finally, since the other nonverbal paradigms are used almost exclusively in the 1st year of life, re-

sults from them are reviewed elsewhere in the *Handbook* (see Cohen & Cashon, Chapter 5, this *Handbook*, this volume).

Assessing Event Memory Using Elicited and Deferred Imitation

In imitation-based tasks of event memory, an adult uses props to produce an action or sequence of actions that the infant or child then is permitted to imitate. An example sequence is “making a rattle” by putting a ball or block into a nesting cup, covering it with a second cup, and shaking the cups to make a rattling sound. In *deferred imitation* the opportunity to imitate comes only after a delay of minutes to months. By contrast, *elicited imitation* is a more generic term describing techniques in which imitation may be permitted prior to imposition of a delay. Imitation-based tasks are well suited for use with human infants because they do not require either verbal instructions or a verbal response. Instead, they capitalize on the natural tendency to copy interesting actions. Although the task does not depend on verbalization, in some laboratories, testers narrate their actions as they produce them (“Let’s make a rattle. Put the ball in the cup. Cover it up. Shake it”) and may even provide verbal “reminders” of the sequences at the time of test (“You can use this stuff to make a rattle”; Bauer, Hertsgaard, & Wewerka, 1995). In other cases, testers present the target actions in silence and response periods are signaled only by presentation of the props to the infant (e.g., Meltzoff, 1988c).

There are other procedural variants on the task. For example, in some cases, single object-specific actions (e.g., pulling apart a dumbbell-shaped object) are demonstrated as many as three times, followed by a time-limited response period (e.g., Meltzoff, 1988a). In other cases, sequences varying in length from 2 to 9 steps are demonstrated two times, followed by a child-controlled response period (e.g., Bauer et al., 1995). This is not the place for a review of the implications of task differences, many of which are unknown. However, one task difference, whether infants are permitted to imitate prior to imposition of a delay, merits discussion. Some researchers have pointed out the desirability of permitting imitation prior to imposition of a delay, in order to obtain a measure of initial learning (e.g., Bauer, 2005a; Howe & Courage, 1997b). However, because Piaget’s (1952) original argument regarding the signifi-

cance of imitation of a novel behavior concerned deferred imitation, it has been suggested that valid use of imitation-based tasks as tests of recall requires that imitation be deferred (e.g., Hayne, Barr, & Herbert, 2003; Meltzoff, 1990). The concern is that if infants are permitted to imitate prior to final test they might form an implicit or procedural memory of the action(s) or sequence, thereby complicating interpretation of later imitation as an index of explicit memory. The concern has proven to be unfounded. First, as noted, implicit or procedural memory is characterized by gradual acquisition. Even in healthy adults, implicit learning of sequences of motor movements, such as acquired in serial reaction time tasks, requires multiple interactive trials to establish (e.g., Knopman & Nissen, 1987). There is little cause for concern then that a single behavioral reproduction would be a sufficient basis for implicit learning in an infant.

Second, it is not clear that prior opportunity to imitate affects later performance. Whereas some studies have indicated that the opportunity for immediate imitation enhances memory (e.g., Bauer et al., 1995; Meltzoff, 1990), other studies have found no effects (e.g., Barr & Hayne, 1996; Bauer, Wenner, Dropik, & Wewerka, 2000). Moreover, when enhancing effects are found, they are consistent with those associated with more elaborative encoding, as opposed to qualitatively different memory representations. For example, whereas electrophysiological (event-related potentials, ERPs—discussed in a later section) responses to photographs of previously experienced events are faster and more robust for infants permitted the opportunity to imitate, relative to infants who only watched events modeled, the scalp distribution and morphology of the responses are the same in the two groups (Lukowski et al., 2005). Quantitative differences in the face of qualitative similarities in electrophysiological responses to events enacted and observed also are apparent in adult participants (e.g., Senkfor, Van Petten, & Kutas, 2002).

Third, the suggestion that the opportunity for prior imitation results in an implicit memory is contraindicated by the finding that, once they develop the language skills necessary to do so, children talk about events they experienced as preverbal infants in the context of imitation-based tasks. Importantly, they talk about events for which imitation was deferred and also about events that they were permitted to imitate (e.g., Bauer, Wenner, et al., 2002). In fact, for children who were younger at
