the time of the original experience of events, later verbal memory is more robust for events previously imitated relative to events for which imitation was deferred (Bauer, Kroupina, Schwade, Dropik, & Wewerka, 1998). If prior imitation resulted in an implicit memory, it would not be accessible to language, once acquired. In summary, both logical argument and the weight of empirical evidence suggest that the opportunity for prior imitation does not render a memory implicit, as opposed to explicit. For this reason, the results from elicited and deferred paradigms are discussed together.

Developmental Trends

Over the first 2 years of life, there are developmental changes in event memory along many dimensions. Six-month-olds, the youngest infants tested with imitation-based paradigms,¹ have fragile memories of short events that they retain for a limited period. By 24 months of age, children have robust memories for long, temporally complex sequences that they retain over extended periods. The changes indicate substantial and significant development. After outlining the normative trends of these developmental changes, I discuss what is known about the mechanisms of developmental change, and then review the literature on individual and group differences in development.

Changes in the Length of Time That Infants Remember

Perhaps the most salient change in memory over the first 2 years of life is in the length of time over which it is apparent. Because, like any complex behavior, the length of time an event is remembered is multiply determined, there is no “growth chart” function that specifies children of X age should remember for Y long. Nonetheless, evidence has emerged across numerous studies that with increasing age, infants tolerate

lengthier retention intervals. In the first published study of deferred imitation by 6-month-olds, Barr, Dowden, and Hayne (1996) found that the infants remembered an average of one action of a 3-step sequence (taking a mitten off a puppet’s hand, shaking the mitten which, at the time of demonstration, held a bell that rang, and replacing the mitten) for 24 hours. Collie and Hayne (1999) found that 6-month-olds remembered an average of one out of five possible actions over a 24-hour delay. That such young infants have recall after 24 hours is remarkable in the context of traditional conceptualizations of developments in re-presentational ability. On the other hand, such low levels of performance after 24 hours have not inspired researchers to examine retention over longer intervals.

By 9 to 11 months of age, the length of time over which memory for laboratory events is apparent has increased substantially. Nine-month-olds remember individual actions over delays from 24 hours (Meltzoff, 1988c) to 5 weeks (Carver & Bauer, 1999, 2001). By 10 to 11 months of age, infants remember over delays as long as 3 months (Carver & Bauer, 2001; Mandler & McDonough, 1995). Thirteen- to 14-month-olds remember actions over delays of 4 to 6 months (Bauer et al., 2000; Meltzoff, 1995b). By 20 months of age, children remember the actions of event sequences over as many as 12 months (Bauer et al., 2000).

Infants also recall the temporal order of actions in multistep sequences, though retaining order information presents a cognitive challenge to young infants, in particular, as evidenced by low levels of ordered recall and substantial within-age-group variability in the 1st year. Although 67% of Barr et al.’s (1996) 6-month-olds remembered some of the actions associated with the puppet sequence over 24 hours, only 25% of them remembered actions in the correct temporal order. Collie and Hayne (1999, Experiment 1) reported no ordered recall after 24 hours by 6-month-olds (the infants were exposed to three target events, two of which required two steps to complete). Among 9-month-olds, approximately 50% of infants exhibit ordered reproduction of sequences after a 5-week delay (Bauer, Wiebe, Carver, Waters, & Nelson, 2003; Bauer, Wiebe, Waters, & Bangston, 2001; Carver & Bauer, 1999). By 13 months of age, the substantial individual variability in ordered recall has resolved: 78% of 13-month-olds exhibit ordered recall after 1 month. Nevertheless, throughout the 2nd year of life, there are age-related differences in children’s recall of the order in which actions of multi-

¹Neonates have been found to imitate facial and hand gestures (e.g., Meltzoff & Moore, 1977). However, because of questions concerning the robustness of the effect (e.g., Kaitz, Meschulach-Sarfaty, Auerbach, & Eidelberg, 1988), and debates as to whether the mechanisms that support imitation by neonates and older infants are one and the same (e.g., Jacobson, 1979), the results of this line of research are not included in this review.

step sequences unfolded. The differences are especially apparent under conditions of greater cognitive demand, such as when less support for recall is provided, and after longer delays (Bauer et al., 2000).

Changes in Robustness of Memory

Over the first 2 years, there also are changes in the robustness of memory. For instance, there are changes in the number of experiences that seem to be required for infants to remember. In Barr et al. (1996), at 6 months, infants required six exposures to remember events 24 hours later. If instead, they saw the actions demonstrated only three times, they showed no memory after 24 hours (performance of infants who had experienced the puppet sequence did not differ from that of naive control infants). By 9 months of age, the number of times actions need to be demonstrated to support recall after 24 hours has reduced to three (e.g., Meltzoff, 1988c). Indeed, 9-month-olds who see sequences modeled as few as two times within a single session recall individual actions of them 1 week later (Bauer et al., 2001). Over the same delay, however, ordered recall was observed only among infants who had seen the sequences modeled a total of six times, distributed over three exposure sessions. Three exposure sessions also supports ordered recall over the longer delay of 1 month. By the time infants are 14 months of age, a single exposure session is all that is necessary to support recall of multiple different single actions over 4 months (Meltzoff, 1995b). Ordered recall of multistep sequences is apparent after as many as 6 months for infants who received a single exposure to the events at the age of 20 months (Bauer, 2004).

Another index of the robustness of memory is the extent to which it is disrupted by interference in the form of exposure to new, potentially distracting material during the retention interval, or in the form of changes in the context between encoding and retrieval. The extent to which young infants are susceptible to interference from potentially distracting material is not known. In most studies (Barr et al., 1996, being an exception), infants are exposed to multiple single actions (e.g., Meltzoff, 1988c) or to multiple multistep sequences (e.g., Carver & Bauer, 1999, 2001) within a single session. Whether levels of recall would be higher were infants exposed to fewer stimuli (or would have been lower had infants in Barr et al. been exposed to multiple stimuli) has not been examined systematically. One direct comparison suggests that exposure to potentially interfering

stimuli during a brief retention interval is not disruptive to infants by 20 months of age. In Bauer, Van Abbema, and de Haan (1999), 10-minute deferred imitation was tested under two conditions. In one, 20-month-olds were exposed to two multistep sequences and experienced an unfilled delay period prior to test: During the delay, infants were given a snack; or they engaged in play with blocks, stacking rings, or a ball. In the other condition, infants experienced a filled delay: In the 10 minutes between exposure to the sequences and test for recall of them, the infants were exposed to and received immediate recall tests on four other multistep sequences. Performance after the delay did not differ as a function of the filler activity. Nor did it differ from performance when no delay between demonstration and test was imposed. Whether distracting experiences would be more disruptive if imitation were deferred for a longer period or would produce interference in younger infants has not been examined systematically.

There are mixed reports of the extent to which infants and very young children are sensitive to contextual changes between the time of encoding and the time of test for event memory. There are some suggestions that recall is disrupted if the appearance of the test materials is changed between exposure and test. In research by Hayne, MacDonald, and Barr (1997), when 18-month-olds experienced the puppet sequence demonstrated on a cow puppet and then were tested with the same puppet, they showed robust retention over 24 hours. However, when they experienced the sequence modeled on a cow puppet and then were tested with a duck puppet, they did not show evidence of memory. At the age of 21 months, infants remembered the sequence whether tested with the same or a different puppet (see also Hayne, Boniface, & Barr, 2000; Herbert & Hayne, 2000).

There also are reports of robust generalization from encoding to test by infants across a wide age range. Infants have been shown to generalize imitative responses across changes in (a) the size, shape, color, and material composition of the objects used in demonstration versus test (e.g., Bauer & Dow, 1994; Bauer & Fivush, 1992; Lechuga, Marcos-Ruiz, & Bauer, 2001); (b) the appearance of the room at the time of demonstration of modeled actions and at the time of memory test (e.g., Barnat, Klein, & Meltzoff, 1996; Klein & Meltzoff, 1999); (c) the setting for demonstration of the modeled actions and the test of memory for them (e.g., Hanna & Meltzoff, 1993;

Klein & Meltzoff, 1999); and (d) the individual who demonstrated the actions and the individual who tested for memory of the actions (e.g., Hanna & Meltzoff, 1993). Infants are even able to use three-dimensional objects to produce events that they have only seen modeled on a television screen (Meltzoff, 1988a; although see Barr & Hayne, 1999). Evidence of flexible extension of event knowledge is seen in infants as young as 9 to 11 months of age (e.g., Baldwin, Markman, & Melartin, 1993; McDonough & Mandler, 1998). In summary, whereas there is evidence that with age, infants' memories as tested in imitation-based paradigms become more generalizable (e.g., Herbert & Hayne, 2000), there is substantial evidence that from an early age, infants' memories survive changes in context and stimuli.

Changes in Sensitivity to the Temporal Structure of Events

A robust finding is that ordered recall is facilitated by enabling relations in events. Enabling relations are said to exist when, for a given end-state or goal, one action is temporally prior to and necessary for a subsequent action. For example, to enjoy a meal of pasta with sauce, one must first cook the pasta. Because alternative temporal orders of the steps of events constrained by enabling relations either are physically impossible, logically unlikely, or both, they occur in an invariant temporal order. In contrast, actions in an event are arbitrarily ordered when there are no inherent constraints on their temporal position in the sequence. To continue the example, whether one consumes a salad before or after the pasta course is a matter of personal preference or cultural convention; there is no logical or necessary reason one course must come before the other.

Young children's ordered recall of multistep event sequences with enabling relations consistently is greater than that of arbitrarily ordered sequences. The advantage is apparent whether children are tested immediately (e.g., Bauer, 1992; Bauer & Mandler, 1992; Bauer & Thal, 1990) or after a delay (e.g., Barr & Hayne, 1996; Bauer & Dow, 1994; Bauer et al., 1995; Bauer & Hertsgaard, 1993; Bauer & Mandler, 1989; Mandler & McDonough, 1995). It also is apparent even after several experiences of arbitrarily ordered events in an invariant temporal order (Bauer & Travis, 1993; see Bauer, 1992, 1995; Bauer & Travis, 1993, for discussions of the means by which enabling relations in events may influ-

ence ordered recall). Moreover, the advantage is obvious early in development: At least by 11 months of age, children show superior ordered recall of events with enabling relations relative to events that are arbitrarily ordered (Mandler & McDonough, 1995). The advantage in ordered recall is observed even though the number of individual actions of sequences with and without enabling relations that infants recall does not differ.

Whereas from a young age, infants evidence sensitivity to enabling relations in events, development of the ability to reliably reproduce arbitrarily ordered sequences is protracted (Bauer, Hertsgaard, Dropik, & Daly, 1998; Wenner & Bauer, 1999). It is not until children are 20 months or older that they accurately reproduce arbitrarily ordered events. At that age, performance is affected by the length of the sequence. Children are reliable on shorter event sequences (3 steps in length) but not on longer ones (5 steps in length). In addition, children accurately reproduce arbitrarily ordered sequences immediately but not after a 2-week delay. In contrast, by 28 months, children recall arbitrarily ordered events even after a delay (Bauer, Hertsgaard, et al., 1998).

Changes in the Efficacy of Different Types of Reminders

In older children, cues or reminders of previously experienced events facilitate memory after a delay (e.g., Fivush, 1997; Fivush, Hudson, & Nelson, 1984; Hudson & Fivush, 1991). Verbal reminding also aids retrieval in children as young as 13 months of age (Bauer et al., 1995, 2000). Indeed, verbal reminding has the effect of reducing age-related differences in the amount of information that young children recall after a delay. In Bauer et al. (2000) for example, age-related differences in the amount remembered after various delay intervals were larger when recall was supported by event-related props alone, relative to when it was supported by event-related props and verbal reminders of to-be-remembered events. The finding that memories can be triggered by verbal reminders is particularly important to recall after long periods of time: Over significant delays, regardless of age, little that is not reminded is retrieved (e.g., Hudson & Fivush, 1991). Other reminders also are effective in aiding retrieval during the 2nd year of life. At 18 months, exposure to a videotape of another child performing activities facilitates memory for them. Still photographs of previously experienced events do not, however, serve as

effective reminders. By 24 months, even still photographs facilitate memory after a delay (Hudson, 1991, 1993; Hudson & Sheffield, 1998).

What Accounts for Developmental Changes over the First 2 Years of Life?

The last 2 decades of the twentieth century yielded a wealth of descriptive data on event memory. As is common when research is in its infancy, there was little focus on the mechanisms of age-related change. Ultimately, several sources of variance will be implicated in the explanation of developments in memory. They will range from changes in the neural processes and systems and basic mnemonic processes that permit memories to be formed, retained, and later retrieved, to the social forces that shape what children ultimately come to view as important to remember about events and even how they express their memories. In the first 2 years of life, to the extent that there has been focus on mechanisms of change, it has been primarily at the “lower” level of neural systems and basic mnemonic processes. As preparation for review of the literature, I provide a brief discussion of the neural network thought to subserve explicit event memory in the adult and the course of its development. I then examine each of the basic mnemonic processes in turn, to evaluate its contribution to age-related changes in explicit event memory.

The Neural Substrate of Explicit Event Memory and Its Development

Although a thorough review of the neural substrate of explicit event memory and its development is beyond the scope of this chapter (see Bauer, 2006; C. A. Nelson, Thomas, & de Haan, Chapter 1, this *Handbook*, this volume), a brief review of it is essential to the goal of identifying possible mechanisms of developmental change in explicit memory in the first years of life. In adults, the formation, maintenance, and retrieval of explicit memories over the long term is thought to depend on a multi-component neural network involving temporal and cortical structures (e.g., Eichenbaum & Cohen, 2001; Markowitsch, 2000; Zola & Squire, 2000). Briefly, on experience of an event, sensory and motor inputs from multiple brain regions distributed throughout the cortex converge on parahippocampal structures within the temporal lobes (e.g., entorhinal cortex). The work of binding the elements together to create a durable, integrated

memory trace is carried out by another temporal lobe structure, the hippocampus. Cortical structures are the long-term storage sites for memories. Prefrontal structures are implicated in their retrieval after a delay. Thus, long-term recall requires multiple cortical regions, including prefrontal cortex; temporal structures; and intact connections between them.

At a general level, the time course of changes in behavior is consistent with what is known about developments in the temporal-cortical network that supports explicit memory (Bauer, 2002, 2004, 2006; C. A. Nelson, 2000; C. A. Nelson et al., Chapter 1, this *Handbook*, this volume). There are indicators that in the human, many of the medial temporal lobe components of the explicit memory system develop early. As reviewed by Seress (2001), the cells that make up most of the hippocampus are formed in the first half of gestation and virtually all are in their adult locations by the end of the prenatal period. The neurons in most of the hippocampus also begin to connect early in development—synapses are present as early as 15 weeks gestational age. The number and density of synapses both increase rapidly after birth and reach adult levels by approximately 6 postnatal months. Perhaps as a consequence, glucose utilization in the temporal cortex reaches adult levels at the same time (by about 6 months: Chugani, 1994; Chugani & Phelps, 1986). Thus, there are numerous indices of early maturity of major portions of the medial temporal components of the network.

In contrast to early maturation of most of the hippocampus, development of the dentate gyrus of the hippocampus is protracted (Seress, 2001). At birth, the dentate gyrus includes only about 70% of the adult number of cells. Thus, roughly 30% of the cells are produced postnatally. It is not until 12 to 15 postnatal months that the morphology of the structure appears adultlike. Maximum density of synaptic connections in the dentate gyrus also is delayed, relative to that in the other regions of the hippocampus. In humans, synaptic density increases dramatically (to well above adult levels) beginning at 8 to 12 postnatal months and reaches its peak at 16 to 20 months. After a period of relative stability, excess synapses are pruned until adult levels are reached at about 4 to 5 years of age (Eckenhoff & Rakic, 1991).

Although the functional significance of later development of the dentate gyrus is not clear, there is reason to speculate that it impacts behavior. As noted, on experience of an event, information from distributed regions

of cortex converges on the entorhinal cortex. From there, it makes its way into the hippocampus via either a “long route” or a “short route.” The long route involves projections from the entorhinal cortex into the hippocampus, by way of the dentate gyrus; the short route bypasses the dentate gyrus. Whereas the short route may support some forms of memory (C. A. Nelson, 1995, 1997), based on data from rodents, it seems that adult-like memory behavior depends on passage of information through the dentate gyrus (Czurkó, Czéh, Seress, Nadel, & Bures, 1997; Nadel & Willner, 1989). This implies that maturation of the dentate gyrus of the hippocampus may be a rate-limiting variable in the development of explicit memory early in life (Bauer, 2002, 2004, 2006; Bauer, Wiebe, et al., 2003; C. A. Nelson, 1995, 1997, 2000).

Like the dentate gyrus of the hippocampus, the association areas develop slowly (Bachevalier, 2001). It is not until the 7th prenatal month that all six cortical layers are apparent. The density of synapses in prefrontal cortex increases dramatically at 8 postnatal months and peaks between 15 and 24 months. Pruning to adult levels is delayed until puberty (Huttenlocher, 1979; Huttenlocher & Dabholkar, 1997; see Bourgeois, 2001, for discussion). Although the maximum density of synapses may be reached as early as 15 postnatal months, it is not until 24 months that synapses develop adult morphology (Huttenlocher, 1979). There also are changes in glucose utilization and blood flow over the second half of the 1st year and into the 2nd year; blood flow and glucose utilization increase above adult levels by 8 to 12 and 13 to 14 months of age, respectively (Chugani, Phelps, & Mazziotta, 1987). Other maturational changes in prefrontal cortex, such as myelination, continue into adolescence, and adult levels of some neurotransmitters are not seen until the 2nd and 3rd decades of life (Benes, 2001).

Because the full network that supports explicit memory in the human involves medial temporal and cortical components, it can be expected to function as an integrated whole only when each of its components, as well as the connections between them, is functionally mature. This state is reached as the number of synapses peaks; full maturity is achieved as the number of synapses is pruned to adult levels (Goldman-Rakic, 1987). Adoption of this metric leads to the prediction of emergence of explicit memory by late in the 1st year of life, with significant development over the course of the

2nd year, and continued development for years thereafter. With the exception of the dentate gyrus of the hippocampus, the medial temporal components of the network would be expected to reach maturity between the 2nd and 6th postnatal months. The cortical components, and the connections both within the medial temporal lobe (i.e., those involved in the “long route” into the hippocampus, via the dentate gyrus) and between the cortex and the medial temporal lobe, would be expected to reach functional maturity late in the 1st year and over the course of the 2nd year. The network would continue to develop, albeit less dramatically, for years thereafter. The time frame is based on increases in synaptogenesis from 8 to 20 months in the dentate gyrus (Eckenhoff & Rakic, 1991), and from 8 to 24 months in the prefrontal cortex (Huttenlocher, 1979; Huttenlocher & Dabholkar, 1997). The expectation of developmental changes for months and years thereafter stems from the schedule of protracted pruning both in the dentate gyrus (until 4 to 5 years; e.g., Eckenhoff & Rakic, 1991) and in the prefrontal cortex (throughout adolescence; e.g., Huttenlocher & Dabholkar, 1997).

What are the consequences for behavior of the slow course of development of the neural network that supports explicit event memory? At a general level, we may expect concomitant behavioral development: As the neural substrate develops, so does behavior (and vice versa). But precisely how do changes in the medial temporal and cortical structures, and their interconnections, produce changes in behavior? How do they affect memory representations? To address this question, we must consider how the brain builds a memory, and thus, how the “recipe” for a memory might be affected by changes in the underlying neural substrate. In other words, we must consider how developmental changes in the substrate for memory relate to changes in the efficacy and efficiency with which information is encoded and stabilized for long-term storage, in the reliability with which it is stored, and in the ease with which it is retrieved.

Changes in Basic Mnemonic Processes

Encoding. Association cortices are involved in the initial registration and temporary maintenance of experience. Because prefrontal cortex in particular undergoes considerable postnatal development, it is likely that neurodevelopmental changes in it are at least partially responsible for changes over the 1st year of life in the time required to encode stimuli. For example, the num-

ber of seconds required to encode a stimulus (as evidenced by the familiarization required to produce a novelty preference) decreases from roughly 30 seconds at 3 months of age to 15 seconds at 6 months (Rose, Gottfried, Melloy-Carminar, & Bridger, 1982).

In the 1st year of life, age-related differences in encoding are related to age-related differences in event memory. We have found that relative to 9-month-olds, 10-month-olds evidence more robust encoding (as indexed by event-related potentials—ERPs—to familiar and novel events immediately after exposure) and more robust recall (as indexed by deferred imitation). ERPs are scalp recorded electrical oscillations associated with excitatory and inhibitory postsynaptic potentials. Because they are time locked to a stimulus, differences in the latency and amplitude of the response to different classes of stimuli—familiar and novel, for example—can be interpreted as evidence of differential neural processing. To test recognition, we recorded infants' ERPs as they looked at photographs of props used in events to which they had been exposed interspersed with photographs of props from novel events. The amplitudes of responses to old stimuli at 10 months were larger than those of the same infants at 9 months (the study was longitudinal); there were no differences in responses to new stimuli. The differences at encoding were related to differences at recall. One month after the ERP, we tested long-term recall of the events. The infants had higher rates of recall of the events to which they had been exposed at 10 months, relative to the events to which they had been exposed at 9 months (Bauer, Wiebe, Carver, Lukowski, Haight, Waters, et al., 2006).

Age-related differences in encoding do not end at 1 year of age. Relative to 15-month-olds, 12-month-olds require more trials to learn multistep events to a criterion (learning to a criterion indicates that the material was fully encoded). In turn, 15-month-olds are slower to achieve criterion, relative to 18-month-olds (Howe & Courage, 1997b). Indeed, across development, older children learn more rapidly than younger children (Howe & Brainerd, 1989).

Whereas age-related differences in encoding (as indexed by differences in the number of learning trials required to reach a criterion) are apparent throughout the first 2 years of life, they alone do not account for the age trends in long-term explicit event memory. Even with levels of encoding controlled, older children remember more relative to younger children. In Bauer

et al. (2000), with the variance in levels of initial encoding controlled statistically, across delays ranging from 1 to 12 months, there were reliable age differences in recall of both the actions and temporal order of multistep events: Older children performed at higher levels than younger children. In samples matched for levels of encoding, younger children lost more information from memory, relative to older children (Bauer, 2005a). Similarly, Howe and Courage (1997b) found that with level of encoding controlled through a criterion learning design, after 3 months, 15-month-olds remembered more than 12-month-olds, and 18-month-olds remembered more than 15-month-olds. Findings such as these strongly suggest that changes in postencoding processes also contribute to developmental changes in event memory.

Consolidation and Storage. Although these phases are separable in the life of a memory trace, at the level of analysis available in the existing developmental data, consolidation and storage cannot be effectively separated; for this reason, I discuss them in tandem. As reviewed briefly earlier, medial temporal structures are implicated in the processes by which new memories become “fixed” for long-term storage; cortical association areas are the presumed repositories for long-term memories. In a fully mature, intact adult, the changes in synaptic connectivity associated with memory trace consolidation continue for hours, weeks, and even months, after an event. Memory traces are vulnerable throughout this time: Lesions inflicted during the period of consolidation result in deficits in memory, whereas lesions inflicted after a trace has been consolidated do not (e.g., Kim & Fanselow, 1992; Takehara, Kawahara, & Kirino, 2003). For the developing organism, the road to a consolidated memory trace may be a bumpier one than that traveled by the adult. Not only are some of the implicated neural structures relatively undeveloped (the dentate gyrus and prefrontal cortex), but the connections between them are still being sculpted and thus are less than fully effective and efficient. As a consequence, even once children have successfully encoded an event, as evidenced by achievement of a criterion level of learning, for example, they remain vulnerable to forgetting. Younger children may be more vulnerable to forgetting, relative to older children (Bauer, 2004).

To examine the role of consolidation and storage processes in long-term explicit event memory in

9-month-old infants, Bauer, Wiebe, et al. (2003) combined ERP measures of immediate recognition (as an index of encoding), ERP measures of 1-week delayed recognition (as an index of consolidation and storage), and deferred imitation measures of recall after 1 month. After the 1-month delay, 46% of the infants evidenced ordered recall of the sequences, and 54% did not. At the immediate ERP test, regardless of whether they subsequently recalled the events, the infants evidenced recognition: Their ERP responses were different to the old and new stimuli. This strongly implies that the infants had encoded the events. Nevertheless, 1 week later, at the delayed recognition test, the infants who would go on to recall the events recognized the props, whereas infants who would not evidence ordered recall did not. Thus, despite having encoded the events, a subset of 9-month-olds failed to recognize them after 1 week and subsequently failed to recall them after 1 month. Moreover, the size of the difference in delayed-recognition response predicted recall performance 1 month later. Thus, infants who had stronger memory representations after a 1-week delay exhibited higher levels of recall 1 month later. The pattern is a replication of Carver, Bauer, and Nelson (2000). These data strongly imply that at 9 months of age, consolidation and storage processes are a source of individual differences in mnemonic performance.

In the 2nd year of life, there are behavioral suggestions of between-age group differences in consolidation and storage processes, as well as a replication of the finding among 9-month-olds that intermediate-term consolidation and storage failure relate to recall over the long term. In Bauer, Cheatham, Cary, and Van Abbema (2002), 16- and 20-month-olds were exposed to multistep events and tested for recall immediately (as a measure of encoding) and after 24 hours. Over the delay, the younger children forgot a substantial amount of the information they had encoded: they produced only 65% of the target actions and only 57% of the ordered pairs of actions that they had learned just 24 hours earlier. For the older children, the amount of forgetting over the delay was not statistically reliable. It is not until 48 hours have elapsed that children 20 months of age exhibit significant forgetting (Bauer et al., 1999). These observations suggest age-related differences in the vulnerability of memory traces during the initial period of consolidation.

The vulnerability of memory traces during the initial period of consolidation is related to the robustness of recall after 1 month. This is apparent from another of the

experiments in Bauer, Cheatham, et al. (2002), this one involving 20-month-olds only. The children were exposed to multistep events and then tested for memory for some of the events immediately, some of the events after 48 hours (a delay after which, based on Bauer et al., 1999, some forgetting was expected), and some of the events after 1 month. Although the children exhibited high levels of initial encoding (as measured by immediate recall), they nevertheless exhibited significant forgetting after both 48 hours and 1 month. The robustness of memory after 48 hours predicted 25% of the variance in recall 1 month later; variability in level of encoding did not predict significant variance. This effect is a conceptual replication of that observed with 9-month-olds in Bauer, Wiebe, et al. (2003). In both cases, the amount of information lost to memory during the period of consolidation predicted the robustness of recall 1 month later.

The data just reviewed suggest that even once children have successfully encoded an event, they remain vulnerable to forgetting. *Within an age group*, differences in vulnerability to intermediate-term forgetting (over 48 hours and 1 week in Bauer, Cheatham, et al., 2002; and Bauer, Wiebe, et al., 2003; respectively) account for significant variance in long-term recall. *Between age groups*, younger children are more vulnerable to intermediate-term forgetting relative to older children. In the case of the ERP data, the source of intermediate-term forgetting can with relative confidence be attributed to consolidation or storage failure: (a) The immediate recognition data indicated that the events had been encoded; and (b) the suggestion of consolidation or storage failure after 1 week was apparent on a recognition measure, a task that makes low demands on retrieval processes, effectively eliminating them as a potential source of variance. The behavioral data are more ambiguous. It is possible that age-related differences in performance should be attributed to retrieval processes instead of to differences in consolidation or storage processes. Older children may appear to remember more because the available retrieval cues are more effective for them, relative to the younger children. This issue is considered next.

Retrieval. Retrieval of memories from long-term storage sites is thought to depend on the prefrontal cortex. The prefrontal cortex undergoes a long period of postnatal development, making it a likely candidate source of age-related differences in long-term recall.

Liston and Kagan (2002) implicated changes in retrieval processes associated with developments in the prefrontal cortex as the explanation for their finding that infants exposed to laboratory events at the ages of 17 and 24 months recalled them 4 months later, whereas infants 9 months at the time they experienced the events did not.

Although retrieval processes are a compelling candidate source of developmental differences in long-term recall, there are few data with which to evaluate their contribution. A major reason is that most studies do not allow for assignment of relative roles of encoding, consolidation and storage, and retrieval processes. As discussed in the section on encoding, older children learn more rapidly than younger children. Yet age-related differences in encoding effectiveness rarely are taken into account. (Liston & Kagan, 2002, provided no information on encoding.) In studies that rely exclusively on deferred imitation (e.g., Hayne et al., 2000), it is impossible to evaluate the potential role of encoding differences because no measures of encoding are obtained. In addition, with standard testing procedures, it is difficult to know whether a memory representation has lost its integrity and become unavailable (consolidation or storage failure) or whether the memory trace remains intact but has become inaccessible with the cues provided (retrieval failure). Implication of retrieval processes as a source of developmental change requires that encoding be controlled and that memory be tested under conditions of high support for retrieval. One study in which these conditions were met was Bauer, Wiebe, et al. (2003; that is, ERPs indicated that the events had been encoded; the suggestion of consolidation or storage failure was apparent on a recognition memory task). The results, described in the preceding section, clearly implicated consolidation and storage, as opposed to retrieval.

Another study that permits assessment of the contributions of consolidation and storage relative to retrieval processes is Bauer et al. (2000). In addition to providing data on children of multiple ages (13, 16, and 20 months) tested over a range of delays (1 to 12 months), the study has three other features that make it an attractive source of data relevant to the question of interest. First, because immediate recall of half of the events was tested, measures of encoding are available. Second, the children were given what amounted to multiple test trials, without intervening study trials, thereby providing multiple opportunities for retrieval. As discussed by Howe and his colleagues (e.g., Howe & Brainerd, 1989; Howe & O'Sullivan, 1997), the first test trial could be expected to initiate

a retrieval attempt. If a memory trace remained and was at a reasonably high level of accessibility, the event would be recalled. If, on the other hand, a memory trace remained but was relatively inaccessible, the retrieval would strengthen the trace and route to retrieval of it, increasing accessibility on the second test trial. Conversely, lack of improvement across test trials would imply that the trace was no longer available (although see Howe & O'Sullivan, 1997, for multiple nuances of this argument). Third, immediately after the recall tests, relearning was tested. After the second test trial, the experimenter demonstrated each event once, and allowed the children to imitate. Since Ebbinghaus (1885/1913), relearning has been used to distinguish between an intact but inaccessible memory trace and a trace that has disintegrated. If the number of trials required to relearn a stimulus was smaller than the number required to learn it initially, savings in relearning were said to have occurred. Savings presumably accrue because the products of relearning are integrated with an existing (though not necessarily accessible) memory trace. Conversely, the absence of savings is attributed to storage failure: There is no residual trace on which to build. In developmental studies, age-related differences in relearning would suggest that the residual memory traces available to children of different ages are differentially intact.

To eliminate encoding processes as a potential source of developmental differences in long-term recall, in a reanalysis of the data from Bauer et al. (2000) subsets of 13- and 16-month-olds and subsets of 16- and 20-month-olds were matched for levels of encoding (as measured by immediate recall; Bauer, 2005a). The amount of information the children forgot over the delays was then examined. For both comparisons, even though they were matched for levels of encoding, younger children exhibited more forgetting relative to older children. The age effect was apparent on both test trials. Moreover, in both cases, for older children, levels of performance after the single relearning trial were as high as those at initial learning. In contrast, for younger children, performance after the relearning trial was lower than at initial learning (Bauer, 2005a). Together, the findings of age-related differential loss of information over time and of age effects in relearning strongly implicate storage processes, as opposed to retrieval processes, as the major source of age-related differences in delayed recall.

Summary. Ultimately, a number of factors will be found to explain age-related variance in event memory

in the first years of life. At present, one of the few sources of change to be evaluated is that associated with developments in the basic mnemonic processes of encoding, consolidation and storage, and retrieval. Evaluation of their relative contributions implicates consolidation and storage as a major source of developmental change. That is, age-related differences in long-term recall remain even when differences in encoding are eliminated. Moreover, age-related differences in long-term recall are apparent even after multiple retrieval attempts; even after relearning, younger children do not perform as well as older children. This conclusion is consistent with the loci of developments in the neural substrate of explicit memory. Late in the 1st year and throughout the 2nd year of life, there are pronounced changes in the temporal lobe structures implicated in integration and consolidation of memory traces. A likely consequence is changes in the efficiency and efficacy with which information is stabilized for storage, with resulting significant behavioral changes in resistance to forgetting.

Group and Individual Differences in Event Memory in Infancy

Whereas there are regular developments in event memory in the first years of life, there is not a growth-chart-type function for the length of time over which we expect infants and children of specific ages to remember. A limitation on such a function is that many task differences influence performance. Infants and children who receive multiple exposures to events, the orders of which are constrained by enabling relations, and who are provided with effective reminders at the time of retrieval, will, on average, recall them over weeks and even months. In contrast, infants and children who receive a single exposure to events that lack enabling relations, and who at the time of retrieval, have little support for recall, will, on average, recall little of their experiences. Even with task parameters controlled, there are individual differences in children's performance throughout the period of transition from infancy to early childhood. For example, whereas some 20-month-old children recall all possible actions of multi-step events, others recall as few as one action (Bauer et al., 2000).

Consideration of the mechanisms of age-related change in event memory suggests some likely candidate sources of group and individual variability. One possi-

ble source is differences in the rate of maturation that may affect brain development and thus, the efficacy and efficiency with which memories are encoded, consolidated and stored, and later retrieved. At a group level, this suggestion has been explored by examining possible gender differences in early event memory. Differences in event memory also may result from individual variability in factors that could be expected to affect the operation of the basic mnemonic processes, including the speed with which information is processed (e.g., Rose, Feldman, & Jankowski, 2003) and the success with which attentional resources are regulated (e.g., Colombo, Richman, Shaddy, Greenhout, & Maikranz, 2001). Whereas these specific sources of variance have not as yet been examined for their effects on event memory as measured in imitation-based tasks, another potential source of variance—language—has received attention. Individual differences in language comprehension, language production, or both, could be expected to facilitate encoding and to enhance the efficacy of verbal retrieval cues in particular. Conversely, systematic variability in event memory could be expected to result from early experiences that may negatively impact the development of neural structures implicated in consolidation and storage, for example. Each of these possibilities is explored.

Children's Gender

Attention to children's gender as a possible source of group differences in early event memory has been prompted by suggestions that girls mature more rapidly than boys (e.g., Hutt, 1978; although see Reinisch, Rosenblum, Rubin, & Schulsinger, 1991). Consistent with this possibility, some studies have reported gender-related differences in performance at what might be viewed as "transitional" points in the development of event memory. First, at 9 months of age—an age marked by substantial variability in long-term ordered recall—gender differences have been detected in three experiments. In one case, the effect of gender favored girls (Carver & Bauer, 1999). However, in the other two cases, the effect favored boys (Bauer et al., 2001; Experiments 1 and 2). Second, at 28 months of age—an age at which children make great strides in recall of arbitrarily ordered events—girls have been found to perform at higher levels, relative to boys (Bauer, Hertsgaard, et al., 1998). With these exceptions, tests for possible gender effects either have not been carried out or have been found to be nonsignificant.

As discussed in Bauer, Burch, and Kleinknecht (2002), a possible reason for the lack of significant gender effects is that most studies of early event memory feature small samples (ranging from 8 to 32 participants per cell of a research design with a modal sample size of 12 participants). This was not the case in Bauer, et al. (2000), in which 360 13- to 20-month-olds (185 of whom were girls) were tested. On the first test trial, when the children were prompted only by the event-related props, some isolated gender differences emerged. For example, 16- and 20-month-old girls tested for recall after 9 months had lower levels of performance than same-age boys. There were no reliable gender effects in any of the other four delay conditions (1, 3, 6, and 12 months). Notably, on the second test trial (which featured verbal reminders in addition to event-related props), even the isolated gender-related effects disappeared (Bauer, Burch, et al., 2002). Although we cannot prove the null hypothesis, the lack of meaningful effects in a large-scale study, coupled with isolated and sometimes contradictory findings in smaller-scale studies, implies that gender is not a major source of systematic variability in early event memory.

Children's Language

Although imitation-based tasks are nonverbal, individual variability in language comprehension, language production, or both, could contribute variance in event memory. In many studies, demonstration of to-be-remembered events is accompanied by verbal narration (e.g., Bauer et al., 2000). Better comprehension of the narration would support more elaborative encoding. Children who comprehend more of the language associated with an event also would be expected to derive greater benefit from language-based retrieval cues. Even when narration is not provided (e.g., Meltzoff, 1985, 1988a, 1988b, 1995b), language development is a possible source of variability because children with greater language skills potentially could verbally encode the events that they observe, thus providing themselves with additional retrieval cues. As discussed later in the section "Continuities and Discontinuities . . .," the ability to "augment" nonverbal representations with language plays a role in the later verbal accessibility of memories likely encoded without the benefit of language (Bauer, Kroupina, et al., 1998; Bauer, Wenner, et al., 2002; Bauer & Wewerka, 1995, 1997; Cheatham & Bauer, 2005).

Although language skills are a potential source of systematic variability in early event memory, their effects have rarely been examined. One such test was undertaken by Bauer, Burch, et al. (2002), based on the sample of 360 13- to 20-month-olds tested in Bauer et al. (2000). In the sample, MacArthur-Bates Communicative Development Inventories for Toddlers (20-month-olds) and for Infants (13- and 16-month-olds; Fenson et al., 1994) were available on 336 of the 360 children. The MacArthur-Bates Communicative Development Inventories are well normed, valid, parent-report instruments for assessing children's early communicative development. Based on the inventories, children's reported productive vocabulary scores ranged from 0 to 651 words (across the 13- to 20-month age range); their reported receptive vocabulary scores ranged from 11 to 393 words (across the 13- to 16-month age range). The sample thus featured ample power and variability to permit detection of systematic relations between children's language and children's recall memory performance. Nevertheless, none of the correlations was statistically significant. Thus, as measured in this large sample of children, neither reported productive nor receptive vocabulary was reliably related to event memory (Bauer, Burch, et al., 2002).

Children from Special Populations

Between the time an event is encoded and the time the resulting representation of it is stored and retrieved, memory traces undergo consolidation processes subserved by hippocampal structures. As discussed, the protracted development of portions of the hippocampal formation is a source of age-related variability in event memory. Individual differences also are apparent. Many potential sources of individual variability—such as the speed with which information is processed—have not as yet been investigated. In contrast, possible effects of pre- and postnatal insults to the hippocampus and surrounding structures have been examined in three special populations: infants raised for the first months of life in international orphanages and then adopted into homes in the United States, infants born to mothers with diabetes, and infants born prior to term but otherwise healthy. The results suggest that consolidation processes are subject to perturbation. They might be taken to suggest that similar yet less extreme circumstances may account for variability in the general population.

For each of the target special populations, there were *a priori* reasons to expect variability in event memory.

In the case of infants adopted from international orphanages, the stress and deprivation (both social and cognitive) associated with institutional care would be expected to negatively impact brain development in general and the hippocampus in particular (the hippocampus is especially vulnerable to effects of stress and deprivation; see Gunnar, 2001, for a review). Work with animal models has shown that infants of mothers with diabetes are exposed prenatally to chronic metabolic insults, including iron deficiency. For reasons that are not clear at this time, the hippocampus is a region of the brain that is at particular risk for reductions in iron uptake (Erikson, Pinero, Connor, & Beard, 1997). Finally, there is an extensive literature documenting poor cognitive outcomes for preterm infants with medical risk factors (e.g., infants who had very low birth weight or experienced intraventricular hemorrhages). Relatively less is known about the later developmental status of infants who survive prematurity sustaining no measurable neurological damage and with few to no social risk factors. In light of mounting evidence that experience plays a crucial role in shaping normative brain development, it is reasonable to expect that later- and more slowly developing memory systems may be vulnerable to variations in postnatal experience.

The data from each of the three special populations were collected in different studies. Nevertheless, in each study, using imitation-based techniques, the infants were tested for immediate and 10-minute delayed recall of multistep events. The measure of immediate recall afforded a means of controlling for possible differences in encoding. The measure of 10-minute deferred imitation was expected to be diagnostic of memory function: (a) adults suffering from medial temporal lobe amnesia exhibit deficits in performance on tasks with delays as brief as 5 to 10 minutes (e.g., Reed & Squire, 1998); (b) medial temporal lesions inflicted on nonhuman primates produce deficits after delays of 10 minutes (e.g., Zola-Morgan, Squire, Rempel, Clower, & Amaral, 1992); and (c) in normally developing human infants, recall after a 10-minute delay is correlated with recall after a 48-hour delay (Bauer et al., 1999). These observations suggest that performance after a 10-minute delay provides information as to the integrity of medial temporal function.

In Kroupina, Bauer, Gunnar, and Johnson (2004), children who as infants had been adopted from international orphanages showed deficits on the 10-minute de-

ferred imitation task, relative to matched home-reared infants. The deficits were apparent even after controlling for differences in encoding. Consistent with suggestions that prenatal iron deficiency may compromise hippocampal function, at 12 months of age, infants born to mothers with diabetes showed deficits in memory after a 10-minute delay (DeBoer, Wewerka, Bauer, Georgieff, & Nelson, *in press*). The groups did not differ on immediate imitation. Finally, among infants who were otherwise healthy at the time of their preterm birth, performance after a 10-minute delay was correlated with gestational age at birth (infants born prematurely performed poorly on the task, relative to full-term infants; de Haan, Bauer, Georgieff, & Nelson, 2000). Preterm birth was associated with higher levels of immediate imitation, relative to term birth. In each of these cases, 10-minute deferred imitation proved to be especially sensitive to subtle differences in cognitive function associated with atypical prenatal environments, postnatal environments, or both. Whereas these effects were observed in targeted special populations, they suggest possible sources of individual variability in the larger population. That is, chronic stress and relative cognitive and perhaps social deprivation are associated with poverty; many maternal health conditions could be expected to have a negative impact on fetal nutritional status; and even in developed nations, there are high rates of preterm birth.

DEVELOPMENTS IN AND AFTER THE PRESCHOOL YEARS

To study event memory in the first 2 years of life, researchers rely on nonverbal measures. Beginning in the 3rd year, verbal means of assessment become a viable alternative. This opens up new possibilities: Children can be tested for memory not only of controlled laboratory events but of events from their lives outside the laboratory as well. This combination of approaches has yielded a wealth of data about children's memories for the routine events that make up their everyday lives, such as making cookies, going to school, and going to the grocery store, and about their memories for unique events, such as the time the stove caught on fire while making cookies, the 1st day of school, and the flat tire on the way to the store. Some of the events are personally sig-

nificant and contribute to an emerging autobiography or personal past. Major findings from each of these categories are reviewed.

Children's Memories for Routine Events

As noted in the section "Traditional Accounts . . .," earlier in this chapter, early studies of young children's memories for the events of their own lives focused on their scriptlike representations of everyday, routine events. The research revealed "minimalist," yet nevertheless accurate, reports of "what happens" in the context of everyday activities by children as young as 3 years of age. The children's reports included actions common to the activities and almost invariably, the actions were mentioned in the temporal order in which they typically occurred. Representative of the findings was the answer provided by a 3-year-old child to the question "What happens when you have a birthday party?": "You cook a cake and eat it" (K. Nelson & Gruendel, 1986, p. 27).

The early studies of young children's memories for everyday events and routines contained other important findings (summarized in K. Nelson, 1986, 1997). For example, they showed that children were both veridical and consistent in their sequencing of the actions in events. These qualities were especially apparent for events that tend to unfold in the same order time and again, such as those characterized by causal and enabling relations (discussed earlier in this chapter). In addition, the studies revealed a great deal of both interchild commonality and intrachild consistency in the elements of events that children apparently found worthy of mention in their reports. Almost invariably, the actions were those most central or important to the event (e.g., a cake at a birthday party), suggesting that children appreciated the goals of many of the events of their everyday lives. The studies also hinted at the power of scriptlike representations for young children. Because the memory representations were general rather than specific (they described what *usually* or *generally* happens, as opposed to *what happened* at a particular time), they served as a basis from which to predict what would happen in the future. They also provided a basis for generating possible alternative actions or outcomes. That is, because the form was general (e.g., "you eat"), many alternatives could be conceived to fill any given role in the event, thereby providing a foundation from which to construct not only knowledge about how

events unfold, but the parts that different actors and objects play in them as well.

The early research on children's event memories revealed evidence of significant mnemonic competence. It also indicated developmental differences. First, older children's reports of everyday events included more information, relative to younger children. Whereas a 3-year-old told of cooking a cake and then eating it, 6- and 8-year-old children told of putting up balloons, receiving and then opening presents from party guests, eating birthday cake, and playing games. Second, relative to younger children, older children more frequently mentioned alternative actions: "and then you have lunch *or whatever you have*." Third, with age, children include in their reports more optional activities, such as "*Sometimes* then they have three games . . . then *sometimes* they open up the other presents." Finally, with increasing age, children mentioned more conditional activities, such as "*If you're like at Foote Park or something, then it's time to go home.*" (K. Nelson & Gruendel, 1986, p. 27).

Some of the differences in younger and older children's reports might reflect the greater number of experiences of events such as birthday parties that older children have, relative to younger children. It would only be with experience that one would come to learn that the number of games played at a party or the precise timing of opening of presents varies from party to party, for example. Indeed, many of the age-related changes noted in this research also were seen to take place as children accrued experience with events (Fivush & Slackman, 1986). Yet, experience alone does not account for the developmental differences. In laboratory research in which children of different ages are given the same amount of experience with a novel event, older children produce more elaborate reports relative to younger children (e.g., Fivush, Kuebli, & Clubb, 1992; Price & Goodman, 1990).

Children's Memories for Unique Events

Research on children's memories for the routine events of their lives literally changed the way that researchers viewed young mnemonists: Rather than as a "floor effect" comparison group for children who were older and more competent, children as young as 3 were viewed as reliable informants about past events. The research had another impact as well: it opened the door for the study of children's memories for unique events. Researchers

noted that whereas young children seem to form generalized memories of the events of their lives, they also distinguish between “what happens” (in general) and “what happened” (in particular). When children were asked a general question such as “What happens when you have snack at camp?” they responded in the timeless present tense (e.g., “We *have* cookies”). In contrast, when they were asked a specific question such as “What happened when you had snack at camp yesterday?” children responded in the past tense (e.g., “We *had* grape juice”; K. Nelson & Gruendel, 1986). Children’s specific responses to questions about unique episodes strongly suggested that memory for unique events coexisted with generalized event memories. This suggestion was timely, given that within the adult literature on autobiographical or personal memory, the phenomenon of infantile or childhood amnesia was being “re-discovered” (Pillemer & White, 1989; White & Pillemer, 1979). Labeled by Sigmund Freud (1905/1953), the “remarkable amnesia of childhood,” infantile or childhood amnesia is the relative paucity among adults of memories for unique events from the first 3 to 4 years of life. Adults report a steadily increasing number of memories of events that took place from the age of 3 years to 7 years, yet the number of memories from this period is smaller than the number expected based on adult rates of forgetting alone. Virtually universally, theories to explain the amnesia suggested that adults had few memories from early in life because as children they had not formed them (for a review, see Bauer, 2006). Research on children’s recall of unique events promised to provide an empirical test of this tenacious assumption.

An early and influential study of young children’s recall of specific past events was conducted by Fivush, Gray, and Fromhoff (1987). They interviewed 2- to 3-year-old children about events that had occurred within the past 3 months and about events that had occurred more than 3 months ago. A striking finding was that all 10 children in the sample recalled at least one event that had happened 6 or more months in the past. Indeed, the children reported the same amount of information about events that had taken place more than 3 months ago as they did about events that had taken place within 3 months. This study thus convincingly demonstrated that children quite young at the time of experience of specific, unique events are able to remember them over long periods. This conclusion was further supported by a study of 3- and 4-year-old children’s recall of a trip to DisneyWorld (Hamond & Fivush, 1991). Whether the

children had experienced the event 6 months previously or 18 months previously, the amount recalled did not differ. Moreover, the older and younger children did not differ in the number of information units they provided. The number of elements of the experience reported by children who were only 3 years of age when they visited DisneyWorld was not different from the number reported by children who were a full year older. The age groups did differ, however, in how elaborate their reports were. Whereas the younger children tended to provide the minimum required response to a question, the older children tended to provide more elaborate responses. For example, when asked “What did you see at DisneyWorld,” younger children tended to reply “Dumbos,” whereas older children tended to embellish their response by reporting, for example, the size of the Dumbos: “big Dumbos.”

Age-Related Changes in Preschoolers’ Recall of Past Events

Studies such as those conducted by Fivush et al. (1987) and Hamond and Fivush (1991) made clear that even over long delays, 2- to 3-year-old children remember specific events. Although the ability is in evidence at an early age, it nevertheless undergoes changes with development. The changes could be expected to affect both the sheer number of events remembered from the preschool years, and the robustness of the memories formed. After outlining the developmental changes, I discuss an important consequence of the changes—development of a autobiographical or personal past. I then discuss possible mechanisms of the changes, followed by patterns of individual and group differences in the normative trends.

Age-Related Changes in How Long Children Remember

Taking our cues from the literature on memory development in the first 2 years of life, we might expect to see increases in the length of time over which preschool-age children remember. In actuality, the available data are mixed. On the one hand, there are studies such as Hamond and Fivush (1991) suggesting no difference after an 18-month delay in the number of units of information reported by children who had been 3 versus 4 years of age at the time of the event of a trip to DisneyWorld. Similarly, Sheingold and Tenney (1982) reported the re-

sults of a study in which they asked older children and adults specific questions about the birth of a younger sibling. For births that occurred when the participant was older than age 3 years (range 3 to 17 years), high levels of recall were observed. For adult participants who had been at least 3 years of age at the time of their siblings' births, it did not matter whether the birth had taken place when the participant was 3 years of age or 17 years of age: The number of questions that they were able to answer about the birth did not differ.

Whereas some studies suggest that the amount of time over which children remember is relatively unaffected by their age at the time of the experience, others suggest that the memories of older children are more robust, relative to those of younger children. For example, Quas and her colleagues assessed children 3 to 13 years of age for their memories for a painful medical procedure that they had experienced between the age of 2 and 6 years (Quas et al., 1999). Children who were older at the time of the procedure provided clearer evidence of recall of it. In contrast to the older children's detailed reports, the reports of the younger children were vague or the children evidenced no recall of the event. In fact, none of the children who had been 2 years of age at the time of the procedure demonstrated clear memory for it later, whereas most of the children who had been at least 4 years old at the time of the procedure remembered it (Quas et al., 1999). Similar patterns were observed by Peterson and Whalen (2001), who interviewed children 7 to 18 years of age about injuries incurred 5 years previously, when they were 2 to 13 years of age, and Pillemer, Picariello, and Pruett (1994), who interviewed 9- and 10-year-old children about an unexpected fire alarm that they had experienced 6 years previously, when they were 3 or 4 years of age. In both cases, the older the child at the time of the experience the more robust the memory years later.

It is worthy to note that the studies that suggest no effect of age are of positive events: a trip to DisneyWorld and birth of a sibling. In contrast, the studies that suggest effects of age are of negative events: medical procedures that were painful, stressful, or both, and an unexpected fire alarm. The reasons for this apparent difference are unclear. It is possible that positive events may be better remembered because they more readily lend themselves to discussion and interpretation after the fact, resulting in a stronger memory representation. Alternatively, the difference may be due to children's differential comprehension of events of different types.

The positive events that have been studied may have been better understood by younger children, relative to the negative events that have been studied. The importance of children's understanding of the causal and temporal structure of events for later recall is suggested by the work of Pillemer, Picariello, and Pruett. When they were interviewed 2 weeks after the unexpected fire alarm, most of the 3- and 4-year-old children were able to provide at least some information about the event. The younger children made more errors in their reports though; the larger number of errors may have been related to their poorer understanding of the event. For instance, only 33% of the younger children, in contrast to 75% of the older children, described a sense of urgency in leaving the building. In addition, 44% of the older children, but only 8% of the younger children, mentioned the cause of the alarm spontaneously. When the children were interviewed 6 years later, when they were 9 and 10 years of age, there were striking age differences in recall. Of the children who had been 4 at the time of the experience, 57% were able to provide either a full or at least a fragmentary narrative about the event, whereas only 18% of the children who had been 3 at the time of the experience were able to do so (Pillemer et al., 1994). The authors concluded that for the children who showed higher levels of recall after the long delay "causal reasoning at time 1 may have served as an organizing principle for thinking about the event, for imposing temporal order on the sequence of events, and for constructing a story-like narrative memory" (p. 103). Although the suggestion is compelling, additional research is necessary to determine whether the forgetting functions for more and less positive events differ from one another (see additional discussion later in this chapter).

Age-Related Changes in the Productivity of External Cues to Recall

Whereas even young children remember events over the long term, there are suggestions that their recall is more dependent on external cues and reminders, relative to that of older children. For example, in Hamond and Fivush's (1991) study of children's reports of trips to Disney-World, only 22% of the children's recall was spontaneous. The balance of the information was elicited in response to direct questions. Although the effect was not substantial, the younger children produced less information spontaneously (19%) relative to the older children (25%). Thus, whereas an older child's response to a question like "What did you do at DisneyWorld?" might be

"We rode fun rides," a younger child might simply respond "rides." If the interviewer wanted more information about the rides, such as whether they were fun, she would need to ask: "Was it fun?" in response to which the younger child likely would respond "Yes." The net effect was that younger children required more cues to retrieve the same amount of information.

A potential consequence of younger children's greater reliance on external prompts and cues, relative to older children, is a lower level of consistency in the information retrieved about an event. As discussed by Fivush and Hamond (1990), if each time a child is asked to retrieve an event memory the same cues are provided, then the same elements will be retrieved each time. If the cues are different on each retrieval attempt, then different elements will be retrieved on each trial. The result would be a low level of consistency in recall from trial to trial. Fivush and Hamond provided data consistent with this suggestion. They asked mothers of 2-year-olds to talk with their children about novel events from the past (e.g., the first airplane trip, going to the beach). Six weeks later, a different interviewer asked the children about the same events. A striking finding was that 76% of the information that the children reported at the second interview was new and different relative to that provided at the first interview. Nevertheless, the information was judged by the children's mothers' to be accurate. The inconsistency in young children's recall contrasts with consistency in adults (e.g., McCloskey, Wible, & Cohen, 1988). Critically, over time, it may contribute to instability of the memory trace: Children may preserve a small core of features that is called up each time they talk about an event; the less stable "fringe" around the core may eventually become inaccessible. Younger children may be more susceptible to this source of instability, relative to older children.

Age-Related Changes in What Children Report

With age, children report different types of information. Older children and adults focus on what is unique or distinctive about an experience, whereas younger children seem to comment on what is common across experiences or what is routine. Indications of this tendency were apparent in some of the earliest work on young children's recall of past events. For example, Todd and Perlmutter (1980) reported that roughly 50% of the past events mentioned in the context of conversations between adult experimenters and children were initiated by the children. Of the child-nominated events, 66% concerned

routine, as opposed to novel, experiences (see also K. Nelson, 1989).

The tendency to focus on routine or common features continues into the early preschool years. Fivush and Hamond (1990) report that, in response to the interviewer's invitation to talk about going camping, a 2-year-old child, after providing the interviewer with the distinctive information that the family had slept in a tent, went on to mention the more typical features of the camping experience:

Interviewer: You slept in a tent? Wow, that sounds like a lot of fun.

Child: And then we waked up and eat dinner. First we eat dinner, then go to bed, and then wake up and eat breakfast.

Interviewer: What else did you do when you went camping? What did you do when you got up, after you ate breakfast?

Child: Umm, in the night, and went to sleep. (p. 231)

In the study from which this excerpt was taken, 48% of the information that the children reported was judged to be distinctive, implying that 52% of it was not. Given that many of the events that young children experience are "firsts" (e.g., first camping trip, first airplane ride, first visit to the dentist), in order to understand them, children may focus on what the novel experience has in common with previous experiences. This pattern changes over time. By 4 years of age, children report about three times more distinctive information than typical information (Fivush & Hamond, 1990).

What are the potential consequences of focus on the features that different events have in common, as opposed to what makes them unique? A suggestion comes from research on children's memories for repeated experiences of the same or a highly similar event. The work has revealed that with repeated experience, event memories become generalized and schematized. For instance, in research in which kindergartners were asked to tell "what happens" at school multiple times over the first weeks of experience, the children omitted details of their experiences and substituted generic information (Fivush, 1984; Fivush & Slackman, 1986). On the 2nd day of kindergarten, a child noted that on arrival at school: "We play with blocks over there, and the puppet thing over there, and we could paint." By the 10th week of school, the same prompt yielded a response such as "We can play." As the typical features of the event are

abstracted, the episodic quality of the memory for each individual experience is lost. The end result is a highly stable, but generic, representation of what typically happens, as opposed to “what happened one time” (Hudson, 1986). By extension, an expected consequence of focus on what is common across experience is that a unique event such as camping gets “fused” into the daily routine of eating and sleeping. In the process, the features that distinguish events from one another may fade into the background and be lost. The result would be fewer memories of episodes that are truly unique. Conversely, with increasing age, children seem to focus on the more distinctive features of events, with a resulting increase in the number of memories that are truly unique.

Age-Related Changes in How Much Children Report

With age, not only do children include different types of information in their narratives, but they include more information, both spontaneously and in response to prompts and cues. In research by Fivush and Haden (1997), children during the period from 3 to 6 years of age increased the number of prepositions in their average narrative more than twofold, from 10 to 23. Young children’s narratives include basic information about what actions occurred in the event; they feature intensifiers, qualifiers, and internal evaluations; and the actions in the narrative are joined by simple temporal and causal connections (e.g., *then*, *before*, *after*; and *because*, *so*, *in order to*, respectively). What accounts for the increase in narrative length over this age period are age-related increases in orienting devices, conditional actions, and descriptive details. With age, as children recount events, they provide (a) more information about who was involved and when and where the event occurred, (b) more information about optional or variable actions (e.g., “*When it turned red light, we stopped*”; Fivush & Haden, 1997, p. 186), and (c) more elaborations (Fivush & Haden, 1997). As a result, relative to younger children’s, older children’s stories are more complete, easier to follow, and more engaging.

The dramatic increases with age in the amount of information that children *report* tempts the conclusion that there also are age-related increases in the amount of information that children *remember* about events. This is not a safe conclusion, however. It is relatively clear that perhaps especially for younger children, verbal reports underestimate the richness of memories. First, as noted, children often report new and different information each time they are interviewed about an event. This

strongly implies that in any given interview, children are providing only a portion of what they remember. Second, as children get older, they have been shown to provide *more* information about an event, relative to the amount provided when they were younger. Children interviewed at the age of 9 to 10 years provided twice as much information about Hurricane Andrew (a Class IV hurricane that hit southern Florida in 1992) than they had shortly after the storm, which occurred when they were 3 to 4 years of age (117 and 57 propositions, respectively; Fivush, Sales, Goldberg, Bahrick, & Parker, 2004). This trend is precisely the opposite of the typical decline in recall over time. The trend could not be attributed to acquisition of more general knowledge about hurricanes or other storms in the time between interviews; overwhelmingly, the new information provided specific details about the experiences of the children’s families, as opposed to general information about storms. Because we have no reason to believe that the children’s actual memories improved with time, the pattern implies that the younger children remembered more than they reported. Children report more with age, but because of the inevitable confounding between increases in age and increases in narrative skills, it is not clear whether they also remember more.

Emergence of Autobiographical or Personal Memory

Changes in how long unique experiences or events are remembered, in the productivity of external cues to recall, in the uniqueness of events remembered, and in how much is reported about past events are critical ingredients in the development of a particular type of memory for specific events that emerges during the preschool years—*autobiographical* or *personal* memory. Autobiographical or personal memories are the memories of events and experiences that make up one’s life story or personal past. They are the stories that we tell about ourselves that reveal who we are and how our experiences have shaped our characters. As implied by this description, autobiographical memories differ from “run-of-the-mill” event memories in that autobiographical memories are infused with a sense of personal involvement or ownership in the event. They are memories of events that happened to one’s self; in which one participated; and about which one had emotions, thoughts, reactions, and reflections. It is this feature that puts the “auto” in *autobiographical*.

In addition to the defining feature that autobiographical memories are about one's self, there are characteristic features that mark memories as autobiographical, one of which is that autobiographical memories tend to be of unique events that happened at a specific place, at a specific time. In other words, they are memories of particular episodes or experiences. Autobiographical memories also entail a sense of conscious awareness that one is reexperiencing an event that happened at some point in one's own past. This specific type of awareness, termed *autonoetic* or self-knowing (Tulving, 1983), has been associated with memory from the time of William James (1890). Indeed, for James, "Memory requires more than the mere dating of a fact in the past. It must be dated in *my* past. . . . I must think that I directly experienced its occurrence" (p. 612).

Evidence that, over the course of the preschool years, event memories take on more and more autobiographical features is readily apparent in children's narratives. From a very young age, children include references to themselves in their narratives: "I fell down." With age, they increasingly pepper their narratives with the subjective perspective that indicates the significance of the event for the child (Fivush, 2001). For example, they go beyond comment on the objective reality of "falling down" to convey how they felt about the fall: "I fell down and *was so embarrassed* because everybody was watching!" It is this subjective perspective that provides the explanation for why events are funny, or sad, for instance, and thus of significance to one's self.

There also are changes in the marking of events as having taken place at a specific place and time. Children increasingly include specific references to time, such as "on my birthday," "at Halloween," or "last winter" (K. Nelson & Fivush, 2004). Markings such as these not only establish that an event happened at a time different from the present, but they begin to establish a time line along which an organized historical record of when events occurred can be constructed. Children also include in their narratives more orienting information, including where events took place and who participated in them (e.g., Fivush & Haden, 1997). These changes serve to distinguish events from one another, thereby making them more distinctive.

Finally, with age, children include in their narratives an increasing number of elements that suggest rich detail that would contribute to the sense of reliving the experience. They include more intensifiers ("Cause she was *very* naughty"), qualifiers ("I *didn't like* her videotape"),

elements of suspense ("And *you know what?*"); examples from Fivush & Haden, 1997), and even repetition of the dialogue spoken in the event ("I said, 'I hope my Nintendo my Super Nintendo is still here'"); from Ackil, Van Abbema, & Bauer, 2003). The amount of descriptive detail that children provide in their narratives increases dramatically over the preschool years. In Fivush and Haden (1997), for example, children went from using approximately 4 descriptive terms per event at age 3 years to using 12 such terms per event at 6 years. The result is a much more elaborate narrative that brings both the storyteller and the listener to the brink of reliving the experience. It is tempting to conclude that these changes account for the finding among adults of a steadily increasing number of memories of events that took place from the age of 3 years to 7 years (Bauer, 2006).

What Develops in Preschoolers' Recall of Past Events?

Over the preschool years, there are changes in children's recall of specific past events, including events considered autobiographical. A likely source of the developmental changes is improvement in the efficiency of the basic mnemonic processes of encoding, consolidation, storage, and retrieval. These changes affect the strength and integrity of the memory representation, as well as accessibility of it. Extramnemonic factors are implicated as well. For instance, increases in memories that are personally relevant and located in a particular place and time likely are associated with developments in self-concept and temporal concepts, respectively. Changes in children's abilities to report what they remember also are likely contributors to observed developmental changes. Each of these sources of age-related change is discussed in turn.

Developmental Changes in Basic Mnemonic Processes

A prominent source of age-related changes in basic mnemonic processes is brain development. Whereas the temporal-cortical network that supports explicit memory develops late in the 1st year and throughout the 2nd year of life, neural events continue for years beyond infancy. Neurogenesis in the dentate gyrus of the hippocampus continues throughout childhood and adulthood (Tanapat, Hastings, & Gould, 2001). Whereas maximum synaptic density in the dentate

gyrus is reached by 16 to 20 postnatal months, pruning to adult levels continues until at least 4 to 5 years of age (Eckenhoff & Rakic, 1991). It is only then that we would expect mature levels of function to be achieved (Goldman-Rakic, 1987). In the prefrontal cortex, synaptic density peaks between 15 and 24 months and pruning of synapses to adult levels begins near puberty (Bourgeois, 2001). In the years between, in some cortical layers there are changes in the sizes of cells and the lengths and branching of dendrites (Benes, 2001). Throughout the prefrontal cortex, myelination continues during this time, and neurotransmitters such as acetylcholine increase to adult levels (Benes, 2001). In short, well beyond infancy there is continued development in the neural substrate supporting long-term explicit memory. Whereas these later neurodevelopmental changes may not be associated with functional changes as dramatic as those in the first 2 years of life, they nevertheless can be expected to have consequences throughout the preschool years.

Encoding

Developmental changes in prefrontal cortex in particular can be expected to contribute to age-related changes in the efficiency with which preschool-age children encode information. For example, there are changes in short-term memory span, as measured by tests such as memory for digits or words. Whereas children 2 years of age are able to hold only about 2 units of information in mind, by the ages of 5 and 7, they can remember 4 and 5 units, respectively. Over the preschool years, children become more effective at keeping task-irrelevant thoughts out of short-term memory, thereby reducing the potentially interfering material that otherwise would limit capacity. Although the most pronounced changes in memory strategies are apparent in the school years, even in the preschool years there are developmental increases in the use of rehearsal to maintain the accessibility of to-be-remembered material over time (see Pressley & Hilden, Chapter 12, this *Handbook*, this volume). The net result of these changes is that children become increasingly adept not only at maintaining information in temporary registration, but in initiating the type of organizational processing that promotes consolidation of it.

Although there is sound rationale for expecting that developmental changes in encoding over the preschool years might contribute to age-related changes in event memory over the same period, few studies can be

brought to bear to evaluate the hypothesized relation. One reason for the paucity of relevant data is that researchers interested in long-term memory frequently either have not measured initial encoding (memory is tested only well after the event), or levels of encoding have not been controlled (immediate memory may be tested, but the impact of age-related differences in initial learning is not controlled).

Whereas there are not studies in which the variance associated with differential encoding has been evaluated for its potential impact on recall over spans of months to years, there are some experimental studies in which encoding has been controlled by bringing children of different ages to a criterion level of learning. Most such studies have been conducted with school-age children (7- to 11-year-olds; e.g., Brainerd & Reyna, 1995), or with very young children (12- to 18-month-olds; Howe & Courage, 1997b, reviewed earlier), as opposed to preschoolers. As outlined earlier, with levels of learning controlled in this way, age-related differences in infants' and very young children's long-term memory still obtain (Howe & Courage, 1997b; see also Bauer, 2005a; Bauer et al., 2000, for the same result when children are matched for levels of encoding and when variance is controlled statistically, respectively). The same result is obtained with school-age children and, using a much smaller database, with preschool-age children as well (Howe & O'Sullivan, 1997). These studies suggest that developmental differences in encoding alone do not account for age-related variance in long-term memory.

Consolidation and Storage

Changes in the processes by which memory representations are consolidated and stored can be expected throughout the preschool years, in association with neurodevelopmental changes within the medial temporal and prefrontal structures, as well as in the connections between them. Neuroimaging techniques such as ERPs could be brought to bear on the question, as they are in the infancy period (Bauer et al., 2006; Bauer, Wiebe, et al., 2003; Carver et al., 2000). However, such studies have not been conducted with preschool-age children. Neither is there a plethora of behavioral studies to address the question. Interpretation of most existing behavioral data is complicated by an inability to separate the contributions of the basic mnemonic processes. On the basis of a single test, it is difficult, if not impossible, to know whether a memory representation remains intact but is inaccessible given the cues provided (retrieval

failure) or whether the trace has lost its integrity (consolidation/storage failure; Tulving, 1983). Moreover, as noted, an additional complication in developmental research is the likelihood of uncontrolled and even unmeasured age-related differences in encoding. The result is that few research traditions yield data that can productively be applied to the question of whether hypothesized age-related differences in consolidation and storage processes contribute to age-related differences in the robustness of long-term recall.

Researchers working in the context of the trace-integrity framework (Brainerd, Reyna, Howe, & Kingma, 1990) and conceptually related fuzzy-trace theory (Brainerd & Reyna 1990) have produced a series of studies designed to evaluate the relative contributions of storage versus retrieval processes. To eliminate encoding differences as a source of age-related effects, participants are brought to a criterion level of learning prior to imposition of a delay. In addition, to permit evaluation of the contributions of storage processes versus retrieval processes, participants are provided multiple test trials, without intervening study trials (see earlier discussion of the logic of this experimental approach). In one such study, 4- and 6-year-old children learned and then recalled 8-item picture lists (Howe, 1995). In this study, as in virtually every other study conducted within this tradition (reviewed in Howe & O'Sullivan, 1997), the largest proportion of age-related variance in children's recall was accounted for by memory failure at the level of consolidation and storage, as opposed to retrieval. The observation that consolidation and storage failure rates decline throughout childhood implies that these processes are a source of developmental change.

Retrieval

Retrieval of memories from long-term storage is thought to depend on prefrontal cortex, a neural structure that undergoes an extremely protracted course of postnatal development. Because they would be expected to change slowly as a consequence, retrieval processes seem to provide a ready answer to the question: "What develops in memory during the preschool years." The results of research from the trace-integrity framework and fuzzy-trace theory traditions stand in apparent contradiction of this expectation, however: Whereas consolidation and storage failure rates decline throughout childhood, retrieval failure rates remain at relatively constant levels (Howe & O'Sullivan, 1997). The apparent lack of change in retrieval failure rates

throughout childhood undermines the suggestion that retrieval processes are a major source of developmental change during this period.

If changes in retrieval processes are not a major source of age-related changes in long-term recall in childhood, then why do younger children seem to be more dependent on external retrieval cues, relative to older children? The answer to this question may lie in recognition that the presence or absence of retrieval cues makes an enormous difference *regardless of age*. Even at our peak of mnemonic competence, we are dependent on cues to retrieval. Indeed, all recall is cued, be it by an external prompt or an internal association (Spear, 1978). Thus, the developmental phenomenon is not that, with increasing age, children gain independence from cueing—but that, with increasing age, children provide more information per cue. The change in rate of return from external prompts and probes may imply that cues "spread" further for older children relative to younger children. That is, it is possible that in older children, a given cue activates more associated elements, relative to the number activated in a younger child. An alternative possibility is that the "spread per cue" does not change with age, but that older children simply report more of the coactivated elements, relative to younger children.

Another possibility is that with age, children are able to benefit from a wider and wider array of cues. Such changes are apparent in the infancy literature. At 18 months of age, exposure to a videotape of another child performing laboratory events facilitates children's memories, but exposure to still photographs of the same activity does not. At 24 months, exposure to still photographs of activities facilitates memory, but simply hearing the activity described does not. By the age of 3 years, a verbal description is sufficient to activate event memory (Hudson, 1991, 1993; Hudson & Sheffield, 1998). In a similar vein, whether they encountered them in the laboratory in which they had been used or at home, the props used to produce event sequences facilitate 3-year-old children's verbal memories for events experienced at the age of 20 months. In contrast, still photographs of the props do not (Bauer et al., 2004). These specific examples are of apparent changes in the sensitivity to different types of external representations (props, videotapes, and still photographs) as cues by children during the transition from infancy to early childhood. Across the preschool period, analogous changes may occur in children's responses to different

verbal cues to recall. If this is the case (no research has explicitly tested the possibility), then more cues may be necessary to obtain the same amount of information from younger relative to older children because for the younger children, some of the cues simply were not effective aids to retrieval.

Does the fact that regardless of age recall is dependent on cueing imply that developmental changes in prefrontal cortex have nothing to do with memory development in childhood? Although possible, it is highly unlikely. It is more likely that the role played by developmental changes in prefrontal cortex differs from that previously assumed (Bauer, 2006). Rather than on retrieval processes, a major effect of developments in prefrontal structures may be on consolidation and storage processes. Consolidation is an interactive process between medial temporal and cortical structures. As such, changes in cortical structures may be as important to developments in consolidation processes as are changes in medial temporal structures. Moreover, the ultimate storage sites for long-term memories are the association cortices. Prefrontal cortex is thought to play an especially significant role in storage of information about the *where* and *when* of events and experiences, the very features that distinguish experiences from one another and contribute to their autobiographical quality. Thus, developmental changes in prefrontal cortex may play their primary role in supporting more efficient consolidation and more effective storage; their role in improving retrieval processes may be secondary.

Conceptual Developments

Changes in basic mnemonic processes associated with brain development are not the only source of developmental change in the preschool years. There is reason to expect that developments in conceptual domains also contribute to age-related changes in memories of specific past events in general and autobiographical memories in particular. Because they are features that define and characterize autobiographical memories, developments in three conceptual domains are especially relevant: self-concept, spatial and temporal concepts, and autonoetic awareness.

Self-Concept

Throughout the preschool years, there are changes in the self-concept that could be expected to contribute to an increasingly autobiographical perspective in children's

reports of past events. There are two senses of self that comprise one's self-concept: a subjective sense of "I" as an entity with thoughts and feelings, and an objective sense of "me" as an entity with features and characteristics that make one different and separate from others. Some scholars suggest that by the second half of the 2nd year of life the "I" and the "me" have coalesced into a self system sufficient to serve as an organizer for experiences that are relevant to the self (e.g., Howe & Courage, 1993, 1997a). This development is signaled by children's abilities to identify themselves in pictures and to recognize themselves in mirrors. One suggestion that achievement of this very basic sense of self is related to autobiographical memory development comes from a longitudinal study conducted by Harley and Reese (1999). They found that children who were earlier to recognize themselves in a mirror (assessed at 19 months) made faster progress in independent autobiographical memory reports (assessed at 25 and 32 months), relative to children who were later to evidence mirror self-recognition.

There are additional developments in the self-concept that take place over the preschool years, each of which could be expected to contribute to increased "personalization" of memories for specific past events. Between 2 and 4 years of age, children seem to develop a sense of the *self in time* (K. Nelson, 1989) or *temporally extended self* (Povinelli, 1995)—a self that extends backward and forward in time. Recognition of continuity of self over time makes possible establishment of a history of experience of significance to the self. It makes experiences from the past relevant to the present in a way that an ahistorical self-concept simply cannot. Consistent with the suggestion that development in this aspect of the self-concept may have relevance for developments in autobiographical memory is the finding that 3-year-old children who are able to identify themselves in a time-delayed video make more contributions to autobiographical memory conversations with their mothers, relative to 3-year-olds who do not show evidence of appreciation of themselves as existing over time (Welch-Ross, 2001).

Another aspect of the self that is later to develop (relative to recognition of one's physical features) is an *evaluative* or *subjective perspective* that specifies how an event made the experiencer think or feel. Throughout the preschool years, there are steady increases in children's references to emotional and cognitive states in reports about past events (e.g., Kuebli, Butler, & Fivush,

1995). Variability in the evaluative or subjective stance is predictive of 36-month-old children's contributions to autobiographical memory conversations with their mothers (Welch-Ross, 2001). The finding is consistent with the suggestion that an increasingly subjective perspective on experience facilitates inclusion of events in an autobiographical record: Experiences are not just objective events that played out, but are events that influenced the self in one way or another.

Placing Events in a Specific Time and Place

Autobiographical memories are of events that took place at a particular place and time. Logically then, developments in the ability to locate events in time and place should be related to age-related changes in autobiographical memory (K. Nelson & Fivush, 2004). By 9 months of age, a large subset of infants remember the temporal order in which event sequences unfold. By 20 months of age, this ability is both reliable and robust. These findings make clear that infants know that *within an event*, Action 1 happened before Action 2. They do not, however, provide evidence that such young children have an appreciation of *when the entire event occurred*, relative to when another entire event occurred.

The ability to place events on a time line develops over the preschool years. For example, Friedman (1990, 1993) has shown developmental changes in preschool-age children's understanding of the order of familiar, daily activities, as well as their understanding of the sequence, duration, and distance of events, relative to one another. In addition, there are developmental changes in children's use of linguistic markers that place events in relation to one another on a time line (e.g., "my birthday" comes after "Halloween"), consistent use of which is not apparent until children are 4 to 5 years of age. Although children's understanding of temporal relations develops over the preschool years, and there is a logical argument that such developments might relate to age-related changes in autobiographical memory (K. Nelson & Fivush, 2004), there is not a body of data relating the two domains. Also missing from the literature are studies examining children's ability to locate memories in a particular place as well as how this ability relates to autobiographical memory. The literature on children's memories for the source of information (e.g., whether they learned a fact from a puppet or an experimenter) is relevant in this regard (Drummey & Newcombe, 2002). However, how memory for source relates to autobiographical memory development has not been explored systematically.

Developments in Autonoetic Awareness

A characteristic feature of autobiographical memories is that retrieval of them is accompanied by autonoetic awareness: a sense that the event recollected is one that happened in the past (Tulving, 1983). This type of awareness depends on the more general ability to identify the source or origin of one's knowledge. There are age-related changes in this ability throughout the preschool years. For instance, it is not until 4 to 6 years of age that children (a) seem to know what sense organ to use to find out the properties of an object (e.g., that one uses one's eyes, not one's hands, to determine color: O'Neill, Astington, & Flavell, 1992); (b) accurately identify the source of learning of newly acquired words versus words that they have known for a long time (e.g., Taylor, Esbensen, & Bennett, 1994); and (c) distinguish true knowledge from a lucky guess (Sodian & Wimmer, 1987). Consistent with the suggestion that development of these abilities is related to improvements in recall is the finding that 3- and 5-year-old children who successfully distinguished a lucky guess from true knowledge showed higher levels of free recall of items on a list, relative to same-age peers who failed to make the distinction (Perner & Ruffman, 1995). In addition, children who understand what senses can be used to gain what types of information show an advantage in recall for pictures directly experienced relative to pictures seen only on video, whereas children who fail to evidence such knowledge do not (Perner, 2001). It remains to be seen whether relations between these concepts and reports of autobiographical memories also would obtain.

Developmental Changes in and the Socialization of Narrative Production

One of the most salient sources of developmental change during the preschool years is in the expression of memory: Older children report more about events from the past, relative to younger children. As noted, whether that means that older children also remember more, relative to younger children, is an open question. Yet, it is a basic fact of mnemonic life that more elaborated memory representations are better remembered, relative to less elaborated ones. Thus, even if the differences in narrative competence do not originate from differences

in memory, *per se*, they may contribute to them, over time. Sources of change in narrative competence include the medium of expression—the basic elements of language—and socialization of the narrative form of storytelling.

Basic Elements of Language

Because developments in the basic elements of language are discussed elsewhere in the *Handbook* (see Tomasello, Chapter 6; Waxman & Lidz, Chapter 7, this *Handbook*, this volume), my treatment of them is brief. Over the first 4 years of life, most normally developing children go from being strictly nonverbal to using most of the adult forms of grammar. Although there are individual differences, children typically utter their first words sometime between 9 and 15 months of age. By roughly 18 months, on average, they have 50 words in their vocabularies. From this age until first grade, children are estimated to learn 5.5 words per day; by the fifth grade, they understand approximately 40,000 words (Anglin, 1993). Often coincident with the milestone of 50 words, children begin producing simple multiword forms, such as “more juice.” The first elements of grammar (e.g., morphological markings) are apparent by 30 months of age. By age 4 years, all but the more intricate grammatical forms (e.g., passive constructions) are apparent (in English, that is; there is considerable cross-linguistic variability in grammatical development). Acquiring the structures of complex sentences and forms continues well into the school years. With developments in the basic elements of language, children are able to convey the contents of their memories more effectively and efficiently.

Socialization of Narrative Production

As soon as children begin acquiring the basic elements of language, they recruit them in their efforts to communicate. Much (though certainly not all) of early language use is instrumental: Children are trying to accomplish something when they utter “more juice.” Whereas children refer to events in the *here-and-now* as soon as they have words, there is a longer course of development for using language to refer to the *there-and-then*. There is strong evidence that children’s competence in reporting on past events is influenced by the narrative environment in which they are raised. The evidence comes primarily from investigations of children’s developing autobiographical memory abilities.

Children first begin using language to talk about the past by the middle of the 2nd year. At this young age, past-tense forms typically are used to refer to events from the very recent past or for everyday events (see K. Nelson & Fivush, 2000, 2004, for reviews). Children participate in conversations about past events primarily by answering questions posed by adult partners. The adult might say, “We had ice cream, didn’t we?” and the child participates by responding, “Yes!” By the age of 2 years, children begin to provide mnemonic content. At this age, when parents ask their children, “What did we have?” they can expect an answer: “Ice cream!” Children do not, however, go on to elaborate their responses. Around 3 years of age, children become fuller participants in memory conversations. Whereas at this age, most memory conversations still are initiated by the parents, children bring up past events as potential topics of conversations. Some children are able to tell complete, albeit brief, stories about past events. More commonly, they participate by providing content-filled responses to inquiries from their parents, as well as some elaborations. As noted, over the preschool years, children assume more of the conversational burden by producing longer, more detailed narratives and by providing more information in response to questions from their conversational partners.

Children do not construct event memory narratives in a vacuum. It is in the context of dialogues, often with parents, that they learn both the skills for narrative construction and the social purposes of narrative. Since the middle 1980s, it has been apparent that parents differ in the way they support or scaffold their children’s developing narrative skills. Moreover, it is increasingly obvious that variability among parents is systematically related to individual differences in children’s developing autobiographical narrative skills.

Parental Styles of Conversation. Although several labels have been used to capture the differences, there is consensus that parents exhibit two styles that vary in terms of the parents’ contributions to conversations (K. Nelson, 1993; K. Nelson & Fivush, 2000, 2004). Parents who frequently engage in conversations about the past, provide rich descriptive information about previous experiences, and invite their children to “join in” on the construction of stories about the past, are said to use a *high elaborative* style. In contrast, parents who provide fewer details about past experiences

and instead pose specific questions to their children, are said to use a *low elaborative* or *repetitive* style. Two examples from conversations recorded in my laboratory help illustrate the difference, as well as why the low elaborative style also is described as “repetitive.” In both cases, the conversations are between mothers and their 3-year-old children.

High Elaborative Style

Mother: Say, J . . . , what was at Lauren’s house a long time ago at her birthday party?

Child: (no response)

Mother: What did you hold—they were so tiny—at Lauren’s house? Remember?

Child: A baby.

Mother: A baby kitty.

Child: Yeah, a baby kitty.

Mother: That’s right. Oh and it was so soft. How many kitties did she have?

Child: Um, five.

Mother: Uh-huh. That’s right.

Child: And they got away.

Mother: And they got away from you. Yeah.

Low Elaborative or Repetitive Style

Mother: E . . . , do you remember going to Sandy’s house and playing at her house?

Child: (nods in agreement)

Mother: Did they have some kids at her house?

Child: Yeah.

Mother: What kinds of kids were at her house?

Child: David.

Mother: David. Was he the only child that was at her house?

Child: (nods in agreement)

Mother: What other kids were at her house?

Stylistic differences are robust and extend beyond the context of mother-child conversations about past events. For example, although much of the research on stylistic differences in early autobiographic contexts has been with mothers, the limited research done with fathers indicates that they, too, exhibit stylistic differences (Haden, Haine, & Fivush, 1997). Whereas both mothers and fathers become more elaborative as their children get older and more skilled in autobiography, levels of elaboration nevertheless are correlated over time (Reese, Haden, & Fivush, 1993). In addition, mothers, at least, show similar patterns with multiple chil-

dren in the family (Haden, 1998; K. D. Lewis, 1999; the relevant studies with fathers have not yet been done). Finally, stylistic differences are apparent not only when parents are eliciting memory reports from their children, but also as events are being experienced and thus, encoded (Bauer & Burch, 2004; Haden, Ornstein, Eckerman, & Didow, 2001; Tessler & Nelson, 1994).

Relations between Parental Style and Children’s Event Memory Narratives.

Parental stylistic differences have implications for children’s autobiographical memory reports. Specifically, both concurrently and over time, children of parents using a more elaborative style report more about past events than children of parents using a less elaborative style (e.g., Bauer & Burch, 2004; Fivush, 1991; Fivush & Fromhoff, 1988; Peterson & McCabe, 1994). Both of these patterns are nicely illustrated in a longitudinal study conducted by Reese et al. (1993). The researchers examined conversations between 19 mother-child pairs, over four time points: 40, 46, 58, and 70 months. Concurrent correlations between maternal elaborations and children’s memory responses were observed at all four time points. The correlations ranged in strength from .59 to .85. Thus, at each session, the more elaborations mothers provided, the more memory contributions their children made. Concurrent correlations between maternal elaborations and children’s participation in memory interviews have been observed in samples of children as young as 19 months (Farrant & Reese, 2000) and 24 to 30 months (Hudson, 1990) of age. There also are concurrent correlations between maternal verbal elaborations and 24-month-old children’s performance in an imitation-based task (Bauer & Burch, 2004). Thus, relations with maternal elaboration extend beyond verbal paradigms to non-verbal measures of children’s memory performance in a controlled laboratory task.

Also apparent in the data from Reese et al. (1993) are cross-lagged relations between maternal verbal behavior and children’s memory contributions. Mothers who used more elaborations when their children were 40 months of age had children who at 58 and 70 months made more memory contributions. Maternal elaborations at the 58-month time point were related to children’s memory contributions at the 70-month time point. Largely absent were relations within children, across time (e.g., children’s memory responses at 40 months were not related to their memory responses at 46 months); and between children’s behavior at earlier time points and mothers’

behavior at later time points (e.g., children's memory responses at 40 months were not related to mother elaborations at 46 months). In both cases, the only such relations were observed between 58 and 70 months. The entire pattern is consistent with suggestions that the process of event memory narrative development is one of social construction, with more experienced partners scaffolding the performance of their younger collaborators. Harley and Reese (1999) extended the pattern of findings to mother-child dyads enrolled at 19 months of age and followed longitudinally until 32 months of age. These results imply that scaffolding begins well before children are making independent contributions to memory conversations.

If, through conversations about past events, children internalize the canonical narrative form for organizing and expressing their memories, we should see evidence that their skills extend beyond the context of mother-child conversations. Several studies have demonstrated that children whose mothers use a more elaborative style exhibit greater narrative competence not only in conversations with their mothers, but in independent narratives as well (e.g., Bauer & Burch, 2004; Boland, Haden, & Ornstein, 2003; Fivush, 1991; Peterson & McCabe, 1992; although see Harley & Reese, 1999, for negative evidence in younger children).

Summary and Conclusions

As is the case for event memory in the first 2 years of life, changes in basic mnemonic processes are a source of developmental change in event memory in the preschool years. The changes presumably are related to developments in the neural substrate that supports explicit event memory. Much additional work is necessary both to examine the relative contributions of each of the basic mnemonic processes and to test the relations. For autobiographical memory in particular, there is reason to believe that developments in self-concept, in understanding of temporal and spatial concepts, and of the origins of the contents of mind, are additional sources of developmental change. The relatively small number of empirical tests of relations between autobiographical memory and these concepts that have been conducted are largely consistent with these suggestions.

A larger body of work has addressed a third source of developmental change in the preschool years, socialization of event memory narratives. There is strong evidence that variability in the narrative environment in which children craft their narrative skills is related to

the proficiency that children gain. Working in collaboration with a parent who uses a more elaborative style, over time, children come to produce longer memory reports, to include more sophisticated narrative devices, and to include more evaluative comments. Each of these features contributes to a more "colorful" narrative. However, a more detailed narrative account is not the same as a more detailed memory representation (e.g., Bauer, 1993; Mandler, 1990a). Individuals who produce shorter, less dramatic accounts of their experiences may have memory representations every bit as detailed, integrated, and coherent as individuals who produce more dramatic ones: The difference may be in the public story, rather than in the private memory representation. This consideration does not make the study of social influences on narrative development any less important. But it is desirable to keep this possibility in mind as we consider the mechanisms of event memory development.

Group and Individual Differences in Event and Autobiographical Memory in the Preschool Years

Given the sources of developmental change identified, what would we expect to see in terms of group and individual differences in event and autobiographical memory in the preschool years? As was the case in infancy, we might expect to see group differences in basic mnemonic processes as a function of maturation, and individual differences as a function of language and information-processing variables such as speed of processing and attention. Moreover, as children are called on to report on events from their everyday lives, we might expect to see variability as a function of background knowledge or expertise. We might also expect to see differences in mastery of theoretically relevant concepts as a function of children's experience with the domains. Consideration of possible sources of variance in narrative socialization suggests that we might expect to see effects of variables that affect parent-child interaction and thus socialization, including children's temperament and the dyadic variable of attachment status. Finally, there is the possibility of culture group differences. Each is discussed in turn.

Group and Individual Differences in Basic Mnemonic Processes

In keeping with the cognitive tradition of focus on group trends, relatively little attention has been paid to how

group differences or individual characteristics of the child might relate to variability in basic mnemonic processes. They have received the most attention in the context of research on the factors affecting children's eyewitness testimony and suggestibility. Even within this literature, however, the corpus of research is relatively meager.

Gender. In infancy, the expectation of possible gender differences stems from consideration of overall maturational changes favoring girls. In the preschool years, it stems from the observation that most often memory is tested verbally, and in general, girls are more verbal than boys (Maccoby & Jacklin, 1974). The possibility of better performance on verbal memory tasks by girls relative to boys has been examined in the literature on deliberate remembering and strategy use (with mixed results: see Pressley & Hilden, Chapter 12, this *Handbook*, this volume). Gender-related differences also have been a focus in the literature on narrative socialization (and are discussed in a subsequent section). They have not, however, been a focus in examinations of the basic processes of encoding, consolidation, storage, and retrieval.

Language. As discussed, there is potential for language to influence basic mnemonic processes. In the preschool years, there is additional reason to expect effects of language on memory, given that in most studies, memory is measured verbally. Yet, as in the early years of life, in the preschool period, language variables have not been found to be a reliable or robust source of individual differences in event memory. Whereas there are some reports of relations between children's language development and their mnemonic performance (e.g., Bauer & Wewerka, 1995; Walkenfeld, 2000; Welch-Ross, 1997), there also are reports of failure to find relations within the same age periods (Greenhoot, Ornstein, Gordon, & Baker-Ward, 1999; Reese & Brown, 2000; Reese & Fivush, 1993). At this point, the relations between language and basic mnemonic processes of event memory in the preschool years are unclear.

Information Processing Variables. There is a tradition of research on information-processing variables as a source of individual differences in children's memory. Most of this research has focused on deliberate or strategic remembering, as opposed to event memory. In

addition, rather than information-processing variables per se, the predictor variable usually is intelligence or aptitude. The general finding is that more gifted children (children with higher IQ and aptitude scores) perform at higher levels on tests of memory, relative to less gifted children (e.g., Schneider & Bjorklund, 1998). Given that, as measured by elementary cognitive tasks, gifted children are faster processors, it is likely that faster information processing and more attentional control results in more effective and more efficient encoding and consolidation, as well as deployment and use of strategies.

Background Knowledge. As noted, one of the forces that led to research on children's event memory was the finding that background knowledge or expertise affected children's memory (e.g., Chi, 1978). The relation between memory performance and background knowledge is firmly established in the event memory literature. For example, Goodman, Quas, Batterman-Faunce, Riddlesberger, and Kuhn (1994) found relations between children's knowledge of a painful medical procedure and their subsequent reports of it. Children who knew more about the procedure in advance of it subsequently reported less inaccurate information and were more resistant to suggestive questions than children who were less knowledgeable. Knowledge also can have deleterious effects on performance. In situations in which aspects of a single experience deviate from knowledge of "what usually happens," general knowledge may actually interfere with recall of the specific features of an episode (e.g., Ornstein, Merritt, Baker-Ward, Furtado, Gordon, & Principe, 1998). Even this example makes clear that background knowledge is a source of individual difference in event memory. In most cases, it has a facilitating effect on memory performance.

Group and Individual Differences in Conceptual Developments

Consideration of possible group and individual differences in conceptual domains that theoretically bear relations with event memory in general and autobiographical memory in particular originated from a somewhat unlikely source: the search for universals in cognitive development. To help determine whether basic cognitive achievements, such as a sense of self, are universally acquired, environmental influences, such as those associated with different family constellations and different socialization practices, were assessed. The

relevant literature is small; possible variability in children's understanding of temporal and spatial marking of specific events has not been systematically explored, and for this reason, the concept is not discussed.

Family Constellation Variables. Although there is variability in early self-recognition, it is not related to demographic variables such as maternal education, socioeconomic status, birth order, and number of siblings (M. Lewis & Brooks-Gunn, 1979). Whether such variables affect the later-developing aspects of the self-concept has not been systematically explored. Perhaps most relevant to the question of whether there are group or individual differences in children's understanding of the sources of knowledge is research by Dunn and her colleagues. They found that the quality of sibling interactions before age 3 years predicted false-belief task performance at age 4 years (Dunn, Brown, Slomkiwski, Tesla, & Youngblade, 1991). Research by Lewis and his colleagues suggested that it is not simply a sibling effect but an *older* sibling effect. The number of older siblings 3- to 5-year-old children have is related to their success on false-belief tasks: Firstborn children, who thus have no older siblings, have the lowest rate of success (C. Lewis, Freeman, Kyriakidou, Maridaki-Kassotaki, & Berridge, 1996).

Different Socialization Practices. Another possible source of variability in young children's conceptual development is socialization practices. Consistent with this suggestion, there is evidence that parental narrative style relates to the development of an evaluative or subjective self. Children whose mothers used a number of evaluative terms in autobiographical memory conversations when the children were 3 years of age used a number of such terms when they were 6 years of age (Fivush, 2001). Moreover, there are culture group differences for this practice. When Chinese mothers and their children talk about the past, they make fewer mentions of the child, relative to mothers from the United States. Perhaps not coincidentally, in conversations about the past, children from Asian cultures refer to themselves less frequently and provide fewer personal evaluations (Han, Leichtman, & Wang, 1998; Wang, Leichtman, & Davies, 2000). Finally, there is some evidence that parental narrative style relates to children's understanding of the sources of knowledge. Welch-Ross (1997) found that maternal elaborations were positively related to and ma-

ternal repetitions were negatively related to 3- to 4-year-old children's scores on tasks designed to assess their understanding of mind.

Group and Individual Differences in Narrative Socialization

In contrast to the limited literature on group and individual differences in basic mnemonic processes and on conceptual developments, research on group and individual differences in narrative socialization has been especially active and productive. Several sources of systematic variability have been identified.

Gender. In the context of the literature on the socialization of event and autobiographical memory narratives, gender was considered a potential source of variance in part because of gender differences in adult women's and adult men's autobiographical narratives and the possibility that they are a consequence of early socialization. Relative to men, when women talk about past events, they tend to produce narratives that are longer, more detailed, and more vivid. One of the most salient differences in the narratives of women and men is the way they represent emotion. Women report talking about emotions more frequently than do men (Allen & Hamsher, 1974); their memory narratives are more saturated with emotion language, relative to those of men (Bauer, Stennes, & Haight, 2003); and memories about emotional experiences seem to be more readily accessible to women than to men (Davis, 1999).

There is evidence that girls and boys are differentially socialized in the context of conversations about past events. First, there is a consistent finding that parents are more elaborative in conversations about past events with their daughters than with their sons (e.g., Fivush, Berlin, Sales, Mennuti-Washburn, & Cassidy, 2003; see Fivush, 1998, for a review). Parents also more frequently confirm the participation of their daughters in conversations, relative to their sons. These findings suggest that relative to boys, girls receive more reinforcement for participating in conversations about past events and participate in more detailed and elaborate narratives.

Second, differences associated with the gender of the child also are apparent in the emotional content of conversations about past events. Adams, Kuebli, Boyle, and Fivush (1995) reported that across the 40- to 70-month time period, parents used both a greater number and a

greater variety of emotion words with daughters than with sons. In a separate sample of 32- to 35-month-olds and their mothers, however, this trend was not apparent and, in fact, was even reversed (Fivush & Kuebli, 1997). Whether the different patterns are the result of the different ages considered or differences in the samples themselves cannot be determined from the existing data. Mothers also tend to talk about different emotions with their 3-year-old daughters and sons. Mothers have more frequent and longer conversations about sadness with daughters than with sons; mothers have more frequent and longer conversations about anger with sons than with daughters (e.g., Fivush & Kuebli, 1997; although see Fivush, Berlin, et al., 2003 for an exception). The findings about sadness persist over time and are still apparent at 6 years. Mothers do not differ in the amount of time they spend talking with their daughters and sons about events in which their children were scared or happy. Together, these findings suggest that both mothers and fathers discuss emotional aspects of past events differently with daughters and with sons.

The “lessons” about narrative in general and emotion language in particular offered by their parents are not lost on preschool-age children. Buckner and Fivush (1998) found that 7-year-old girls tend to produce longer, more coherent, and more detailed narratives than same-age boys. In addition, relative to boys’, more girls’ narratives are social in their theme. Girls and boys also differ in use of emotion language in their narratives. As discussed by Kuebli et al. (1995), in the longitudinal sample that was the source of much of the data described in this section (Reese et al., 1993), across the 40-, 58-, and 70-month time points, both the number and variety of emotion words used by girls increased. For boys, neither metric increased. As a consequence, whereas girls and boys did not differ in the number or variety of emotion words used at 3 years of age, by the time the children were 6 years of age, girls were producing both a greater number and a larger variety of emotion words, relative to boys. Over the preschool years then, girls come to pepper their event memory narratives with emotion, whereas boys do not increase their emotional expressiveness. This pattern is reflected in adults’ autobiographical narratives about events from their childhoods (Bauer, Stennes, et al., 2003).

Language. There has been relatively little work on the question of whether differences in children’s language abilities affect socialization of event memory nar-

rative production. Farrant and Reese (2000) found that both children’s expressive language abilities and their receptive language abilities were correlated with maternal reminiscing style concurrently as well as over 19 to 40 months. Bauer and Burch (2004) reported that in the context of an elicited-imitation task in which mothers demonstrated multistep sequences and tested their 24-month-old children’s memories for them, mothers who reported that their children had larger productive vocabularies produced more elaborations as they modeled shorter (but not longer) sequences. These two studies of relations between young children’s language abilities and maternal verbal behavior are suggestive. They should serve to motivate additional research with children early in the socialization process, as well as with children throughout the preschool years.

Temperament. Temperament or behavioral style refers to patterns of responding to environmental stimuli (e.g., Rothbart & Bates, 1998). It has emerged as a potential source of individual differences in children’s event memory and narrative socialization because of speculation that variability in emotionality and its regulation might relate to children’s responses to parental socialization attempts, to their abilities to talk about emotional states, or both. For example, K. D. Lewis (1999) argued that highly sociable children may elicit more social interaction from their parents and thus might also encourage a more elaborative style of conversation. In contrast, children who have difficulty regulating their attention or level of activity might elicit a higher level of regulatory speech, perhaps manifested in more repetitions.

Consistent with these suggestions, in samples of 3- and 5-year-old children and their parents, with children’s ages and memory talk controlled statistically, children rated by their parents as more sociable and active received fewer repetitions and evaluations, and proportionally more elaborations (K. D. Lewis, 1999). Lewis interpreted these effects to suggest that mothers who perceive their children to be less active may feel the need to engage them in the task, by using evaluations and repetitions of their utterances. Conversely, children perceived to be more sociable may be viewed as good conversational partners. In the preschool years, readiness to participate in conversation likely is a major component of what gets termed “sociability.” Precisely this relation has been found between 24-month-old children and their mothers. Mothers who rated their children

high on the Interest and Persistence subscale of the Toddler Behavior Assessment Questionnaire (TBAQ) were especially verbally engaged with their children, as measured by higher rates of production of elaborations, repetitions, affirmations, and total category tokens (Bauer & Burch, 2004). Thus, children who were perceived as typically showing interest and persistence received more verbal scaffolding in the elicited-imitation context. In contrast to K. D. Lewis's (1999) observations with older children, maternal verbal behavior was unrelated to scores on the Activity Level subscale of the TBAQ. Again, although far from definitive, these two studies of relations between children's temperament characteristics and maternal behavior in conversations about past events are suggestive and should motivate additional research.

The Attachment History of the Dyad. Rather than being a characteristic of the child, attachment history is a feature of the parent-child dyad. Fivush and Va-sudeva (2002) developed the argument that given the social purpose of reminiscing, aspects of the socioemotional relationship between the adult and child might be related to their style of coconstruction of the events of their lives. This expectation is derived in part from the observation that mothers seem to have different goals as they reminisce with their children. Mothers who are less elaborative appear to have a pragmatic purpose: to get their children to remember specific pieces of information. Mothers who are more elaborative appear to engage their children in conversation for the sake of sharing. The goals of engagement and sharing of experience not only are facilitated by a strong interpersonal relationship, but actually emerge from it. That is, it is the strong socioemotional connection that motivates one to share to begin with.

The concept of mother-child attachment has a long and distinguished history that I do not undertake to review in this chapter. For present purposes, it is sufficient to note that parents and their children differ in the "quality" of their attachment relationship. Most mothers are sensitive to their children's needs and respond to their infants' signals in a timely and appropriate manner. Their infants are likely to develop a secure attachment that keeps them in proximity to the mother yet permits them to move beyond her to explore the world and gain a measure of independence from the caregiver, apparently confident in the knowledge that on return, mother not only will be there, but will be welcoming.

Other mothers exhibit less sensitivity to their infants' signals and needs. They might respond less contingently, or not at all, presumably engendering in their infants a sense that the caregiver cannot be counted on. Their infants are likely to develop an insecure attachment that is less successful in promoting developmentally appropriate levels of dependence and independence. The fruits of early attachment relationships are preserved well beyond infancy, as evidenced by relations with adult romantic relationships (Roisman, Madsen, Henninghausen, Sroufe, & Collins, 2001; although see M. Lewis, Feiring, & Rosenthal, 2000).

A body of research within the attachment tradition suggests that the mother-child attachment relationship might be related to the style of reminiscing in the dyad. Dyads with a secure attachment relationship have been described as engaging in more open communication, relative to dyads with less secure relationships (e.g., Bretherton, 1990). In addition, children who are classified as securely attached evidence more sophisticated narrative skills in tasks in which they are asked to complete a story with a socioemotional theme (e.g., Waters, Rodriguez, & Ridgeway, 1998). Discussions of emotional and evaluative aspects of events may be especially affected by the attachment relationship, given that they involve a measure of interpretation of the internal states of others.

Although there is compelling motivation and rationale for investigating possible relations between the attachment relationship and maternal style of reminiscing, there have been few empirical studies. Fivush and Va-sudeva (2002) examined the possibility of a relation in a sample of mothers and their 4-year-old children. There was a significant relation between maternal rating of attachment and maternal elaboration: Mothers who indicated a more secure attachment relationship with their children were more elaborative in the memory conversation context. The relation was apparent for both mother-daughter and mother-son dyads. In addition, mothers who used a high proportion of emotion terms had girls who produced a large number of memory elaborations; the relation was not observed among mother-son dyads. As argued by the authors, the pattern as a whole suggests that children in securely attached dyads are more likely to engage in elaborative parent-child reminiscing that, in turn, promotes development of skills for autobiographical narrative production.

Newcombe and Reese (2003) conducted a longitudinal investigation of possible relations between maternal

reminiscing style and children's narrative development as a function of the security of the attachment relationship. The families were enrolled in the study when the children were 19 months of age and followed longitudinally with observations at 25, 32, 40, and 51 months. Attachment status was assessed at the last session. Mothers in dyads that were assessed as securely attached increased their use of evaluations over the course of the study, whereas mothers in dyads that were insecurely attached did not. Across time points, children in securely attached dyads produced more evaluations than did children in insecurely attached dyads. In addition, for securely attached dyads, beginning when children were 25 months of age, there were both concurrent and cross-lagged correlations between mothers' and children's use of evaluations in the context of conversations about past events. These results suggest that the development of aspects of a child's narrative competence are influenced by the quality of the socioemotional relationship between the mother and her child. Together with the findings of Fivush and Vasudeva (2002), they compel additional research.

Culture Group Differences. The final source of variability in narrative socialization to be considered is that associated with cultural group. In the adult literature, there are striking differences in the age of earliest reportable autobiographical memory for European Americans compared with Asian Americans and Koreans living in America (e.g., MacDonald, Uesiliana, & Hayne, 2000; Mullen, 1994; Wang, 2001). The age of earliest memory for European Americans is several months earlier than that of Asian Americans or Koreans. The difference may be associated with variability in cultural perspectives on the value and goals of reminiscing (K. Nelson, 1988). As described by Mullen (1994):

The difference between Asians and Caucasians may reflect two very different sets of socialization goals: one in which conformity to norms of social behavior is highly valued and dwelling on one's own subjective experiences is maladaptive, and one in which adults actively encourage children to elaboratively narrativize their personal experiences as part of a process of developing a sense of individuality and self-expression that is valued in the culture. (pp. 76–77)

If it is the case that differences in adults' autobiographical memories from early childhood are influenced by differences in socialization, then those differences ought to be apparent in early parent-child interaction. To

begin to test this hypothesis, Mullen and Yi (1995) analyzed naturally occurring conversations between American and Korean mothers and their 40-month-old children. They found that Korean dyads engaged in talk about the past less frequently than American dyads. In addition, the conversations of the Korean dyads included fewer details than those of American dyads (see also Choi, 1992, for comparison of Korean and Canadian mothers). These differences in the base rate of talk about the past are reminiscent of differences in mothers who exhibit an elaborative compared with a low-elaborative style: Dyads in which the mother exhibits an elaborative style tend to have longer conversations that include more narrative content.

To determine whether mother-child conversations about the past also differ in other features that distinguish the elaborative from the low-elaborative maternal style, Wang et al. (2000) collected memory narratives from American mothers and their 3- to 4-year-old children and from Chinese mothers and their 3- to 4-year-old children. The samples included comparable numbers of girls and boys, and the children were well matched for their levels of language development, as measured by mean length of utterance. The dyads were observed in their homes in the United States and China, respectively, by an experimenter from the same native country as the dyad. American mothers produced fewer repetitions and more evaluations when talking with their children, relative to Chinese mothers, and American children produced more elaborations than Chinese children. Analyses of the contingencies of the conversations between mothers and their children revealed that the tendency to follow an elaboration with an elaboration was higher among American than among Chinese dyads. Thus, American mothers tended to elaborate their children's contributions and American children tended to elaborate their mothers' contributions in a truly coconstructive manner. This tendency was less prominent among the Chinese dyads.

To conclude that cross-cultural differences in narrative socialization are a major source of variance in adults' recollections of their childhoods, it would be necessary to find that relations with maternal style variables extend to children's independent memory narratives. Han et al. (1998) asked samples of Korean, Chinese, and American 4- and 6-year-old children to talk with an experimenter about recent, personally experienced events. American children had longer and more detailed narratives, relative to Korean children. Their narratives also included more details that distinguished

the specific episode under discussion from other, potentially similar, events. Chinese children's narratives were more comparable to those of American children, yet they were less detailed and less specific. American children also included in their narratives more information about their own and others' internal states (e.g., cognition terms, statements of preference, evaluations, emotion terms), relative to Chinese and Korean children. In addition, whereas children in all three culture groups frequently mentioned themselves in their narratives, American children had the highest proportion of mention of themselves relative to others. Finally, gender differences were observed in the American sample only: American girls produced more words, more words per proposition, more temporal markers, more descriptive terms, and more internal states terms than American boys.

Together, the results of Han et al. (1998) paint a picture of American children (and especially American girls) producing autobiographical narratives that are longer, more detailed, more specific, and more "personal" (both in terms of mention of self, and mention of internal states), than narratives by children from China and Korea. The pattern is consistent with expectations derived from the finding that in their conversations about past events, American mothers and their children are more elaborative and more focused on autonomous themes, relative to Chinese mothers and their children (Wang et al., 2000); and that Korean mothers and their children have less frequent and less detailed conversations about the past, relative to American dyads (Mullen & Yi, 1995). It is tempting to relate these findings to those observed in studies of adults' recollections of their childhoods (e.g., Mullen, 1994; Wang, 2001). As discussed by Han and her colleagues, "It is distinctly possible that the more elaborated content of American children's narratives, as compared with those of Asian children, contributes to the earlier first memories found in American adult populations" (Han et al., 1998, p. 710). Only prospective research will tell, however.

CONTINUITIES AND DISCONTINUITIES IN THE DEVELOPMENT OF EVENT MEMORY

As noted early in this chapter, historically, there were expectations of profound discontinuities in children's memories. Piagetian theory suggested that for the first 18 to 24 months of life, infants were incapable of what today is recognized as explicit memory (conscious recognition or recall). Across the preschool years, be-

cause they lacked operational structures, children were thought incapable of forming organized memory representations. Instead, the memory of the preschool-age child was described as "a medley of made-up stories and exact but chaotic reconstructions, organized memory developing only with the progress of intelligence as a whole" (Piaget, 1962, p. 187). In other words, Piaget suggested that even when children had constructed the capacity to represent past events, they still were without the cognitive structures needed to organize events along coherent dimensions for making the events memorable. He suggested that it was not until children approached the concrete operational period (at approximately 5 to 7 years of age) that they developed the ability to sequence events temporally.

The last 2 decades of the twentieth century produced theory and research that forced a radical revision of this perspective. It now is clear that at least by the second half of the 1st year of life, infants form relatively enduring explicit event memories; preschool-age children organize memories of both routine and one-time only events along coherent temporal dimensions. There remain, however, at least two points at which continuity in event memory development can be questioned: the first 6 months and the period of transition from infancy to early childhood.

Explicit Memory in the First 6 Months of Life

One of the most salient continuities in event memory is that the ability to remember events is apparent from very early in development. At least by 6 months of age, infants are able to retain explicit event memories over 24 hours. Whether the ability is present even earlier in development is unclear. Certainly there are data on memory earlier than 6 months of age. Infants perform well on tasks such as visual paired comparison and mobile conjugate-reinforcement. As noted, however, it is not clear that these tasks measure explicit memory. There also is evidence that infants only a few days old engage in imitation (of tongue protrusion and mouth opening; e.g., Meltzoff & Moore, 1977). Yet, whether neonatal imitation is supported by the same mechanisms as imitation in infants 6 months of age and older is a matter of debate. Whereas Meltzoff and Moore argue that the ability is continuous, others have suggested alternative mechanisms and explanations (e.g., fixed action patterns; Jacobson, 1979) and thus, discontinuity.

Given that there is no empirical resolution to the question, we are left with theoretical and conceptual

arguments as to whether the continuity in explicit event memory extends to the first months of life. Consideration of the timing and course of brain development introduces doubt that the continuity extends so far. As noted, aspects of the multicomponent network that supports explicit memory are late to develop. Development of the components implicated in consolidation of memories for long-term storage is especially protracted. As a result, recall over the long term may not be apparent until the second half of the 1st year of life. Critically, this argument does not imply that long-term explicit event memory suddenly “bursts forth” on the scene at 6 months of age. On the contrary, the prediction is of gradual emergence of the ability to retain more and more information over longer and longer delays. This is the pattern that is apparent beginning at 6 months. There is every reason to expect a similar pattern prior to 6 months of age, as the neural structures that support explicit memory begin their long course of maturation and development. This argument is consistent with that set forth by C. A. Nelson (1995, 1997, 2000) of “preexplicit” memory that depends on portions of the explicit memory network. It also is consistent with Mandler’s (1988, 1992, 1998) argument that although the tools necessary to form accessible representations of events and experiences are available shortly after birth, the products of their operation may not be apparent because the representations that are formed are so very fragile.

The Transition from Infancy to Early Childhood

The suggestion of discontinuity between infancy and early childhood is deeply ingrained theoretically. For a long time, the field was dominated by a perspective that suggested a shift in representational format at roughly 18 to 24 months of age. A modern version of the perspective is invoked as an explanation for the observation that even after language is available, children do not seem to talk about events from early in life. The apparent lack of later verbal accessibility of early memories has led to skepticism about the actual status of early, preverbal memories. For example, in Pillemer and White’s 1989 review of the literature on autobiographical memory and the phenomenon of childhood amnesia, they suggested that if early and later memories were qualitatively similar, then early memories “should become verbally expressible when the child has the ability to reconstruct preverbal events in narrative form” (p. 321; see also Nelson & Ross 1980; Pillemer, 1998a, 1998b). In the absence of such evidence, early memories are described as indicative of

the function of a “behavioral memory system” that in some cases, supports “early memory images (that) are persistent enough to influence feelings and behaviors after months or years” (Pillemer, 1998a, p. 115), but which are implicit, rather than explicit. This argument is, in effect, a modern version of the suggestion that older children’s (and adults’) inability to recall the events of their lives (verbally), is evidence that the capacity for explicit memory is late to develop.

The results of some studies suggest that even when children have gained the linguistic ability to describe events from the past, they do not do so. Peterson and Rideout (1998) interviewed children about trips to the emergency room necessitated by accidents that resulted in broken bones, burns, and cuts that required suturing. The accidents occurred when the children were 13 to 34 months of age; the interviews were conducted in the children’s homes shortly thereafter, and again 6 months, 12 months, and 18 or 24 months later. Children who were 26 months or older at the time of the experience provided verbal reports at all interviews. Although the children who were injured between 20 and 25 months were not able to describe their experiences at the time, they were able to provide verbal reports 6 months later. In contrast, among the children who were 13 to 18 months at the time of their injuries, none was able to provide a complete verbal account of the experience, even though, at the later interviews, they had the requisite language ability to do so. Peterson and Rideout attributed the youngest children’s difficulty verbally describing their experiences to unavailability of a verbal means of encoding at the time of the events (see also Myers, Perris, & Speaker, 1994; Simcock & Hayne, 2002). Studies such as these suggest that if events were not encoded with language, then language cannot be used to describe them.

The results of other studies suggest that the critical ingredient in later verbal accessibility is not the availability of language at the time of encoding of events, but the opportunity to augment nonverbal memory representations with language. This conclusion is drawn from a series of studies in which pre- and early verbal children exposed to multistep sequences in the context of elicited and deferred imitation were tested for verbal recall of them months later (Bauer, Kroupina, et al., 1998; Bauer, Wenner, et al., 2002). Children who were enrolled in Bauer et al. (2000) at the ages of 13, 16, and 20 months, and who participated in nonverbal tests of memory 1 to 12 months later, took part in a follow-up study at the age of 3 years. Because 3-year-olds can be expected to participate in verbal interviews (e.g., Fivush et al., 1987),

during the 3-year visit, the children were explicitly asked to describe the events they had experienced. The strongest predictor of verbal expression of memory at age 3 years was children's spontaneous verbal expression of memory at the earlier, nonverbal test: It explained 30% of the variance in children's elicited verbal recall at age 3 years (Cheatham & Bauer, 2005). Critically, variables from the time of initial experience of the events (age and verbal ability) failed to predict children's later verbal recall. These studies imply that the important ingredient in later verbal accessibility of early memories is not language at the time of encoding, but an opportunity to augment a nonverbal memory representation with language. In the case of the studies just described, that opportunity was presented by the earlier nonverbal recall test.

If early memories later can be described verbally, why then are there so few examples of verbal access to early, preverbal memories? The answer may lie in the conditions under which later verbal recall typically is tested. In Peterson and Rideout (1998), children were interviewed in their homes about events that had occurred in the emergency room; the interviews were conducted without the aid of any but verbal prompts and cues. Similarly, in Simcock and Hayne (2002), children's verbal recall was supported only by the experimenter's verbal prompts and photographs. As discussed earlier, there is a developmental progression in children's sensitivity to verbal and pictorial reminders of past events (Hudson, 1991, 1993). This raises the possibility that the failure to observe verbally accessible memories under these conditions may have been due not to the lack of availability of language at the time of encoding, but to failure to effectively reinstate the event memory, given the cues provided. In Bauer, Wenner, et al. (2002), children's recall was supported by the props that had been used to produce the multistep events. Props have proven to be effective cues for reinstatement even when they are presented in a context different from that in which they were encountered (originally encountered in the laboratory and used as cues in the children's homes: Bauer et al., 2004). Given effective reinstatement, newly acquired words can be mapped onto their past-event referents. In this way, preverbal memories may be "infused" with language, thereby permitting later verbal as well as nonverbal access to them.

The suggestion that, at least under some circumstances, early memories can be augmented by language and then verbally described raises the question of

whether, given the right cues, older children and even adults could be treated to a flood of memories from the first years of life. This is a highly unlikely scenario for at least three important reasons. First, as noted, the ability to retain and later retrieve explicit event memories likely does not reach "critical mass" until the second half of the 1st year of life. Thus, from the first 6 months, precious few—if any—memories survive.

Second, even once explicit memory becomes reliable and robust (near the end of the 2nd year of life), forgetting occurs. Because of changes in the basic mnemonic processes of consolidation and storage, in particular, that occur throughout the preschool years, the rate of forgetting is accelerated, relative to that in later childhood and early adulthood. As a result, although memories are formed, many are forgotten.

Third, as I have argued elsewhere (Bauer, 2006), the periods of later infancy and early childhood are marked by gradually increasing representation of the features that make event memories autobiographical and thus, long lasting. As described earlier in this chapter, there are conceptual developments that allow for formation of memories referenced to self that are distinctive and clearly of past events. There also are critical developments in language and in the socialization of narrative forms that facilitate not only the retelling of events and experiences but their very organization and, thus, maintenance and subsequent retrieval. The net effect is that it is only gradually, over the course of the preschool years, that children's autobiographical memories become prototypical of their class. Eventually, the rate of formation of prototypical autobiographical memories outstrips the rate at which events are forgotten. The result is the distribution of memories found in virtually every study of adults' retrospective reports of events from early in life: a relative paucity of memories from the first 3 to 4 years, followed by a steadily increasing number of memories of events that took place between ages 3 and 7 years (see Bauer, 2006, for further discussion).

Summary and Evaluation

Until the late 1970s, memory development was viewed as largely discontinuous. Infants were thought incapable of forming accessible memories and preschoolers' memories were thought to be disorganized. With the development of nonverbal means of assessing infants' event memories and the observation that preschoolers accurately remembered the events of their own lives, these perspectives changed dramatically. It now is clear that at

least by the second half of the 1st year of life, infants form enduring explicit event memories. Whether the ability extends to the first months of life as well is an unanswered question. However, consideration of the timing and course of brain development suggests that early in postnatal life, there may be narrow restrictions on the formation of lasting explicit event memories. Beyond the first months of life, continuities in event memory abound. Nonverbal and verbal tests of memory indicate that children form organized representations of events that they recall at later points in time. Under certain circumstances, early preverbal memories later are accessible to verbal report. Nevertheless, throughout the preschool years, the rate of forgetting is relatively high. In addition, it is only gradually that children's memories of events take on the features of prototypical autobiographical memories. Evidence of the adultlike distribution of autobiographical memories becomes apparent as the number of prototypical autobiographical memories formed begins to outpace the number of event memories forgotten (Bauer, 2006).

IS MEMORY FOR STRESSFUL OR TRAUMATIC EVENTS “SPECIAL”?

In discussions thus far, all events have been treated as essentially equal. The focus has been on developmental changes and characteristics of children that might affect their event memories. There has been no explicit discussion of whether some events are inherently more memorable than others, however. Within the literature on event memory, there is a fair amount of speculation that memories of events that were particularly stressful or traumatic are either quantitatively or qualitatively different from memories of nonstressful or nontraumatic events. There is not a definitive answer to this question, but several suggestions bear on it.

Memories of Stressful or Traumatic Events

The expectation that memories of stressful or traumatic experiences might be different from memories of nontraumatic experiences is deeply rooted. A classic basis for the expectation is the Yerkes-Dodson law of optimal arousal (Yerkes & Dodson, 1908). Briefly, a relation between level of arousal and performance is predicted, such that when arousal is either too low or too high, per-

formance will be impaired, relative to when arousal level is optimal. Stressful or traumatic experiences are expected to increase arousal, relative to benign events. Assuming that the level of arousal associated with a traumatic experience is high, but not too high, then application of the Yerkes-Dodson law leads to the prediction that the experience will be well remembered. If the level of arousal associated with the traumatic event exceeds the optimal level, then memory for the experience will be impaired (Easterbrook, 1959). In addition to the number of details remembered, there are suggestions that memories for traumatic and nontraumatic experiences differ qualitatively (see Goodman & Quas, 1997, for discussion). Some have indicated that memories of traumatic experiences have a vivid “flashbulb” quality (e.g., R. Brown & Kulik, 1977; Winograd & Neisser, 1992). Others have suggested that in traumatic circumstances, attention is focused on the central features of the event, with correspondingly poorer memory for peripheral features (e.g., Christianson, 1992).

For obvious practical and ethical reasons, researchers cannot intentionally subject children to highly stressful or traumatic events to study their memories for them. They can, however, examine children's memories for emergency medical treatments and prescribed medical procedures for insights on how stress and trauma affect event memory. Though socially sanctioned and performed for children's benefit, such measures nonetheless are perceived by children as unpleasant, painful, and frightening. Despite the associated stress and trauma, even young children remember these events. Peterson and Rideout (1998) reported that children who were as young as 26 months at the time of injuries that necessitated visits to the emergency room were able to provide accounts of the experiences 2 years later. Children's memories for natural disasters also have been a focus of research. Bahrck, Parker, Merritt, and Fivush (1998) found that 3- to 4-year-old children who experienced Hurricane Andrew provided lengthy accounts of it when they were interviewed within 6 months of the storm. Six years later, when the children were 9 and 10 years of age, they not only remembered the experience, but their accounts of it were more than twice as long as the accounts they had provided 6 years earlier (Fivush et al., 2004).

Whereas it is clear that young children remember traumatic experiences, the question of whether there are quantitative and qualitative differences between memo-

ries of traumatic and nontraumatic events remains open. One reason is that it is difficult to study relations between trauma and memory experimentally. An effective alternative to an experimental approach is the medical-procedures model, in which researchers compare, for example, the memory performance of children who endured a stressful medical procedure (e.g., voiding cystourethrogram flourosopy—VCUG) with that of children who experienced a substantially less stressful medical procedure (e.g., a pediatric examination; D. Brown, Salmon, Pipe, Rutter, Craw, & Taylor, 1999). A variant on the approach is to compare the memory performance of children who were more and less stressed while experiencing a painful medical procedure such as inoculation or the VCUG (e.g., Goodman, Hirschman, Hepps, & Rudy, 1991). Overall, researchers have found that stressful procedures are recalled at least as well, and in some cases, better than more benign procedures (e.g., Ornstein, 1995; see Fivush, 1998, 2002, for reviews). In some studies, however, children who experienced high levels of stress have been found to produce more memory errors, relative to children who were less stressed (e.g., Goodman & Quas, 1997).

The medical-procedures model has been very productive and informative. However, because it necessitates a between-subjects analysis, it does not permit direct comparison of memories of stressful or traumatic experiences and memories of more positive experiences from the same participant. Fivush, Hazzard, Sales, Sartati, and Brown (2002) provided just such a comparison. The researchers interviewed 5- to 12-year-old children about nontraumatic events, such as family outings, vacations, and parties; and stressful or traumatic events, such as serious illness or death, minor illness or injury, property damage, violent and minor interpersonal altercations, and parental separation. Overall, children's narratives about the stressful or traumatic and nontraumatic events were comparable in length. However, the children included more descriptions (adjectives, adverbs, possessives, and modifiers), and mentioned more objects and persons when recounting nontraumatic experiences than when recounting stressful or traumatic experiences. Conversely, the children provided more information about internal states (emotional, cognitive, and volitional states of self or other) when recounting traumatic relative to nontraumatic experiences. In addition, narratives about traumatic experiences were rated by the researchers as more narratively coherent, compared with narratives about nontraumatic experiences.

The results of this study suggest that the memory narratives about traumatic and nontraumatic experiences differ qualitatively, with narratives about traumatic events being more complete and better integrated, and more internally focused, relative to narratives about nontraumatic events.

Sales, Fivush, and Peterson (2003) examined conversations between parents (primarily mothers) and their 3- to 5-year-old children about two types of events: a positive event chosen by the parent (e.g., family vacation) and the stressful or traumatic experience of a medical emergency for the child, sufficient to necessitate a trip to the emergency room (e.g., cuts requiring stitches, broken bones). Both parents and their children spent proportionally more time discussing the causes of behavior (e.g., "What did you do to get hurt?" p. 192) in their conversations about traumatic events, relative to positive events. Conversely, both parents and children spent proportionally more time talking about emotions in their conversations about positive events, relative to traumatic events. In addition, when talking about the positive events, parents included a higher proportion of positively valenced, relative to negatively valenced, emotion; when talking about the traumatic medical emergencies, they included a higher proportion of negatively valenced relative to positively valenced emotion. Children's use of emotion language was too infrequent to support a parallel analysis.

The third investigation featuring a direct comparison of reports of traumatic and nontraumatic events is one in which mothers and their 3- to 11-year-old children were interviewed about a devastating tornado that hit the small, rural town of St. Peter, Minnesota (population 9,500), on March 29, 1998 (Ackil et al., 2003; Bauer, Stark, et al., 2005). Approximately 4 months after the tornado, mothers and their children were asked to talk about the storm and about two non-tornado-related events: one that had taken place within 3 months prior to the tornado, and one that had taken place since the storm, but that was not related to the tornado. Six months after the first interview (10 months after the storm), the dyads were interviewed again about the same three events, thereby permitting assessment of changes in event narratives over time. At both time points, narratives about the tornado were twice as long as narratives about the two nontraumatic events, which did not differ from one another. The lengths of the narratives did not differ between Session 1 and Session 2 for any of the events. Critically, even with conversational length controlled, conversations

about the traumatic event were more narratively complete and coherent, relative to conversations about the nontraumatic events. Moreover, the differences largely endured over the 6-month interval between sessions. Although the range in ages of the children in the study was large, age-related differences were not especially pronounced and there were no interactions with age at Session 1 and few at Session 2.

Summary

In the relatively young literature on event memory in children, there has been a lot of attention on and controversy surrounding whether stressful and traumatic events are remembered better than, not as well as, or the same as nonstressful and nontraumatic events. There have been surprisingly few direct comparisons of the question. It is clear that children remember stressful and traumatic events. There also are suggestions in the literature that the narratives that children provide about traumatic events are more coherent and perhaps more internally focused, relative to narratives about nontraumatic events. This characteristic could be expected to result in better memory for traumatic relative to nontraumatic events over time. These findings indicate that although children's memories for events of a highly emotional nature likely follow a developmental course similar to that for more benign events, they likely differ in important ways as well.

CONCLUSION AND DIRECTIONS FOR FUTURE RESEARCH

Though still in its "adolescence" at the time of the writing of this chapter, the field of study of developments in event memory is already quite mature. In the 1970s and early 1980s, researchers began to challenge the traditional assumption, derived from laboratory studies of memory for lists of words or pictures, that preschoolers were rather mnemonically inept. By asking young children to recall stories and to report on the events of their everyday lives, they learned that virtually as soon as they were able to participate in verbal tests of event memory, they "passed" these tests by providing temporally ordered reports of their experiences that included most if not all of the components of a complete narrative (the *who, what, where, when, why, and how* of events).

Findings of mnemonic competence in preschoolers, coupled with development of nonverbal means of assessing event memory in infants, led to challenges of another traditional assumption, that the period of infancy is devoid of the capacity to form, retain, and later retrieve explicit memories of past events. Studies using imitation-based tasks have revealed that at least by the middle of the 1st year, infants recall past events. By the end of the 2nd year, event memories are relatively robust and long lasting. Under some circumstances, memories likely encoded without the benefit of language survive the transition from infancy to early childhood and can be described verbally. Thus, in sharp contrast to expectations of developmental discontinuities in event memory, there is ample evidence that the capacity to remember past events develops early and continuously.

To say that the capacity to form, retain, and later retrieve event memories is early in developing is not to say that it does not change with age. On the contrary, throughout infancy and the preschool period there are changes along several dimensions, including the length of time over which children remember, the robustness of their memories, and the efficacy and productivity of different types of reminders. In addition, children's memories are affected by background knowledge that, in many cases, is related to age. As children gain verbal fluency and narrative competence, there also are changes in how much they report about events and in the quality of the stories that they tell about past experiences. Although research on the mechanisms of age-related change lags behind that designed to describe its trajectories, there are strong reasons to believe that the developments are linked with changes in the neural substrate that supports explicit memory, which in turn affects the efficiency with which memories are encoded, consolidated, stored, and subsequently retrieved. In addition, there is increasing evidence that changes in children's verbal reports of past events and perhaps their nonverbal "reports" as well are affected by aspects of their social worlds, including the narrative cultures that surround them.

The strides made in understanding developments in event memory have been significant. However, substantial and significant work remains to be done. To begin, we still need a great deal of descriptive work. Three areas stand out. First, research is needed to determine how the early memory abilities tapped by paradigms such as elicited and deferred imitation relate to the deliberate memory skills tested in educational settings and the auto-

biographical or personal memory skills that are so essential and prominent in social settings. Reliable and robust encoding, storage, and retrieval of memories is necessary, but not sufficient, for these later-developing capacities. Preliminary findings from ongoing studies in my own and other laboratories (Catherine Haden, Loyola University, and Peter Ornstein, University of North Carolina, Chapel Hill) suggest continuity between early developing recall memory skills and later strategic remembering. There already is strongly suggestive evidence that through conversations with more accomplished partners (e.g., parents), children capitalize on basic memory abilities to construct personalized narratives that form the basis for autobiography (K. Nelson & Fivush, 2000, 2004). Between now and the next *Handbook*, we may look forward to an expansion of these research efforts.

Second, as a result of the starting point, the largest proportion of work on event memory has been done with infants and preschool-age children. The event memory abilities of school-age and older children—and developmental changes therein—have been largely ignored. This needs to be remedied. Whereas changes in the school years may not be as dramatic as those in the periods of infancy and the preschool years, they are a significant part of the puzzle of how a fundamental cognitive capacity changes over the course of development.

Third, more attention needs to be paid to individual differences, which has never been the strong suit of research in cognitive development. The “usual suspects” of children’s gender and their levels of receptive and expressive language have not proven especially predictive of event memory performance. In contrast, important insights have been gained by giving attention to effects of variability associated with parental style and culture group differences, as well as to how children’s temperaments and the attachment history of dyads relate to developments in narrative abilities. Additional attention to individual differences is important not only to a full description of developmental change, but also can shed light on the mechanisms thereof. For example, the results of research with special populations of infants suggest that consolidation and storage processes are a major source of vulnerability in early event memory. Pursuing the “leads” suggested by these findings promises to inform theories of normative development.

Descriptive goals do not exhaust the menu for future research. We also can hope for advances in our knowl-

edge of explanatory mechanisms. Three areas in particular seem promising. First, it is desirable to expand the focus on links between brain and behavior. Relative to the adult literature—in which there has been significant progress establishing relations between structure and function—the developmental literature is far behind. Some neuroimaging techniques, such as positron emission tomography (PET) never will develop into workhorse paradigms for developmental research because they require ionizing radiation, the use of which is contraindicated in healthy children. Others, including event-related potentials and functional magnetic resonance imaging (fMRI), already are yielding insight into the neural generators of cognitive events. High-density arrays of electrodes permit identification of the origins of electrical signals recorded on the scalp (C. A. Nelson & Monk, 2001), and fMRI scans of the brain engaged in cognitive processing can be obtained from children as young as 7 years of age (Casey, Thomas, & McCandliss, 2001). Further expanding the arsenal with neural network models (Munakata & Stedron, 2001) and comparisons with performance by developing nonhuman animals (Overman & Bachevalier, 2001), will permit substantial progress in identification of the neural sources of specific behavioral change.

A second avenue to pursue in the quest to explain developmental changes in event memory is to explicitly recognize that it has multiple determinants. A reasonably complete yet still not exhaustive list of likely determinants of event memory includes those discussed in this chapter: language, self-concept, comprehension of temporal concepts for locating events in time, the ability to locate events in space, an understanding of the sources of knowledge, and the skills for conveying memories to others (Bauer, 2006; K. Nelson & Fivush, 2004). Because multiple factors contribute to developments in event memory, single causal models always will fall short of a full explanation of the timing and course of developmental changes. Models that explicitly recognize the multiple cognitive as well as multiple social influences on memory development will have more predictive utility.

Finally, and related to the point just made, progress in understanding the mechanisms of developmental change in event memory will be made when the full range of potential causes is examined in each major developmental period. At present, in infancy, most of the attention on the mechanisms of development is on neural changes

and their implications for the basic mnemonic processes of encoding, consolidation, storage, and retrieval. With a few noteworthy exceptions (e.g., Farrant & Reese, 2000), less attention is paid to the likely social determinants, such as patterns of interaction between caregivers and children. Conversely, in the preschool years, most of the attention on mechanisms of developmental change is on social determinants. Again, with a few notable exceptions (e.g., Brainerd et al., 1990), less attention is paid to potential changes in basic mnemonic processes. A complete account of age-related changes in event memory will require that the contributions of multiple different factors be evaluated across development. Movement in these directions will ensure that there is significant progress to be reported as the next edition of the *Handbook* goes to print.

Why do children think the way they do? What leads to the remarkable changes in thinking that they show with development? What accounts for the variation in thinking observed across children? These questions are challenging, but not intractable. Developmental researchers have made great progress in addressing such questions using a vast array of methods. These include behavioral, neuroimaging, and genetic studies, with both typically and atypically developing populations.

This chapter describes a set of *information processing* approaches that have also supported significant contributions to the study of fundamental development questions. Broadly speaking, these approaches treat thinking as the processing of information. When applied to development, these approaches thus focus on what information children represent, how they represent and process this information, how these representations guide their

behaviors, and what mechanisms lead to changes in these processes across development. Developmental change is often explained within information processing approaches in terms of self-modification processes, in which children's thinking and behaviors shape the way that they subsequently process information.

Information processing approaches have been associated with the use of formalisms that allow researchers to specify or simulate in detail the processes contributing to thinking and behavior. These formalisms may be viewed as varying along a soft-core to hard-core continuum (Klahr, 1989, 1992). *Soft-core* versions might include flowcharts and diagrams to describe models of children's thinking (e.g., Aguiar & Baillargeon, 2000; Case, 1986; Siegler, 1976), whereas *hard-core* versions are actually implemented in computational models. Computational models take the form of codes (e.g., mathematical equations and commands) that specify how a system transforms and responds to inputs; these codes can be run on a computer to observe the processing and behavior of the system under many different circumstances. As in earlier reviews (Klahr & MacWhinney, 1998), this chapter focuses on hard-core

The writing of this chapter was supported by NICHD Grant HD037163. I thank Robert Siegler, Randy O'Reilly, and members of the Cognitive Development Center at the University of Colorado, Boulder, for useful comments and discussion, and Karen Adolph for inspiration.

information processing approaches. For a review of other variants of information processing approaches, see Siegler and Alibali (2005).

This chapter first addresses the question: Why should anyone care about computational models of development? The discussion explains how such models have served as a complement to other approaches of studying development, to support many advances in understanding how change occurs. The chapter then describes some of the historical context that set the stage for computational modeling endeavors. An overview and example are provided for each of four types of information processing approaches to development: production systems, neural networks, dynamic systems, and ad hoc models. Some aspects of children's development (problem solving, language, and memory) have been investigated through more than one type of information processing model, allowing direct comparisons to be made about how such models have informed the study of development. Next, the chapter focuses on such comparisons. The chapter closes with a discussion of general issues in the information processing endeavor and promising directions for future work.

WHY MODEL?

At first blush, computational approaches seem to require more motivation and justification than perhaps all other prevalent approaches to the study of development, despite each approach having its unique strengths and limitations. Behavioral studies with children and adults are of obvious importance when the questions of interest concern how we behave and why, even though behavioral observations alone cannot specify the mechanisms underlying the behaviors. Neuroimaging approaches generate great excitement about the prospects of watching the brain as it thinks, despite providing only indirect measures of neural activity. Studies with special populations and patients with brain damage may shed light on not only atypical but also typical functioning, despite the many complexities involved in trying to make inferences about exactly what mechanisms have been impaired, preserved, and compensated for in such cases. And animal studies can support invasive measures and controlled environments not possible in human studies, even if the lessons learned may not always generalize to other species. All these methods are generally appreciated in the context of their strengths and their limitations.

Computational models of development, and of cognition and behavior more generally, similarly have their strengths and limitations, but their potential may be less apparent. After all, watching an artificial system on a computer as it develops and behaves does not have quite the impact of observing the behaviors of real children or nonhuman animals, or their corresponding brain images. So why model? Many compelling arguments and examples have been put forth to answer this question (e.g., Elman et al., 1996; Klahr, 1995; O'Reilly & Munakata, 2000; Simon & Halford, 1995a). A common theme to these answers is that it is challenging to understand how change occurs, an issue at the heart of developmental study (Siegler, 1989). Flavell (1984) noted, “[S]erious theorizing about basic mechanisms of cognitive growth has actually never been a popular pastime. . . . The reason is not hard to find: good theorizing about mechanisms is very, very hard to do” (p. 189). Computational models may provide a particularly useful tool for this challenging task.

One benefit of computational models may be most evident when considering other fields of study, such as meteorology and physics, where the need for models as a complementary approach is highly appreciated. Understanding the weather and the physical world requires comprehending complex interactions among many elements. Various phenomena emerge from such interactions, so that the whole is impossible to understand by considering the elements in isolation. As a simple example, consider two gears of different sizes that can interlock. To understand how they behave, it is insufficient to consider each in isolation. Instead, behavior emerges from the interaction of the two gears, with the smaller gear driving the larger gear to yield a decrease in rotational speed and an increase in torque. As the interactions among elements become more intricate, as in the weather and physics, computational models become increasingly important. Such models allow the observation and manipulation of interactions among elements and associated emergent phenomena. Similarly, models can be essential in helping us comprehend the intricacies of all the interacting elements that produce our thoughts and behaviors. And, understanding this complexity may be even more challenging during intense periods of change in thinking and behaving, as observed during childhood. Thus, one reason to use models in the study of development is the extraordinary *complexity* of the issues under question; development is far too complicated to be defined solely in terms of simple processes

that can be captured through purely verbal description. As other methods become increasingly sophisticated, providing large amounts of detailed information about our behaviors and their neural bases, computational models will only become more important in helping to make sense of this complexity.

A second answer to the question of “Why model?” focuses on the need to be explicit about assumptions and constructs in theory development and evaluation. Purely verbal theories may rely on constructs that are not specified well enough to be rigorously tested or understood. The Piagetian notions of assimilation and accommodation were criticized in this regard:

For 40 years now we have had assimilation and accommodation, the mysterious and shadowy forces of equilibration, the Batman and Robin of the developmental processes. What are they? How do they do their thing? Why is it after all this time, we know no more about them than when they first sprang on the scene? What we need is a way to get beyond vague verbal statements of the nature of the developmental process. (Klahr, 1982, p. 80)

Klahr (1995) also said of one of Piaget’s descriptions of assimilation and accommodation, “Although it has a certain poetic beauty, as a scientist, I do not understand it, I do not know how to test it, and I doubt that any two readers will interpret it in the same way.” Creating a working computational model of such processes forces one to address these issues explicitly and to confront aspects of the problem that might have otherwise been ignored. The resulting model can also be run to generate novel predictions. Thus, creating models can help make *explicit* theoretical assumptions, constructs, and predictions—an essential step in evaluating and advancing theory. Again, as other methods provide increasingly detailed information about brain and behavior, and various theories are formulated to make sense of such data, computational models will only become more important in assessing the viability of such theories.

A third reason to model is that computational models arguably allow the greatest levels of *control* for testing theories. A single variable, such as the firing rate of artificial neurons or exposure to particular words in the environment, can be manipulated in isolation to see the effects on the functioning and development of a simulated system. Multiple variables can be manipulated in a coordinated way to observe their interactions. This kind of control is essential for making headway on some of the thorniest questions in development. Debates about the roles of nature versus nurture, domain-general and

domain-specific learning mechanisms, and so on, often hinge on what could (or could not) be learned from general learning mechanisms and exposure to the typical environment. Could infants come to understand the physical world through general learning mechanisms and exposure to objects in the world? Do children require innate, language-specific learning mechanisms to make sense of the language surrounding them? The remarkable degree of control afforded by models allows researchers to test the role of factors in such debates in ways that would otherwise be impossible. As other methods reveal more and more potential factors affecting thought and behavior, models will become increasingly important for allowing a controlled and systematic investigation of the possible effects of such factors.

Finally, models can also be helpful for providing a *unified framework* for understanding behavior (e.g., Anderson et al., 2004; Newell, 1990; Rumelhart & McClelland, 1986b). Such unified frameworks can support more stringent testing because they can be evaluated across a range of behaviors instead of a single phenomenon. Unified frameworks can also encourage more parsimonious explanations, rather than what sometimes seems like a hodgepodge of explanations proposed across development. Infants show a gradual progression in their understanding of object permanence, the continued existence of objects after they are no longer perceptible (Piaget, 1954). Infants first show a sensitivity to object permanence in their looking times to unexpected events with hidden objects (Baillargeon, 1999; Spelke, Breinlinger, Macomber, & Jacobson, 1992), then by reaching for objects hidden in the dark (Goubet & Clifton, 1998; Hood & Willatts, 1986; Shinskey & Munakata, 2003), followed by reaching for objects hidden in the light (Piaget, 1952b). Later still, infants succeed in reaching for an object hidden in a new location after it was repeatedly retrieved from a different hiding location (Diamond, 1985; Piaget, 1954). Some accounts attribute each of these task-dependent developments to a different factor, with motor developments supporting successful reaching in the dark; problem-solving developments supporting search in the light; and working memory and inhibitory developments supporting successful searching with multiple hiding locations (e.g., Baillargeon, Graber, DeVos, & Black, 1990; Diamond, 1985; Willatts, 1990). Although each of these independent factors may contribute to the observed developmental progression, more unified developmental processes may also play a role. Models provide a natural framework for exploring such possibilities.

For all these reasons, models provide an important tool for understanding the complexity of development. Models are an essential complement to other methods, and vice versa. And, the need for models should only increase as we learn more about behavior and the brain, and must then formulate and evaluate increasingly complex theories of development.

HISTORICAL CONTEXT

In many ways, the history of information processing approaches to development parallels the history of information processing approaches more generally. These approaches developed as part of the cognitive psychology movement that served as a contrast to behaviorism, they began with relatively rigid notions of cognitive structures and processing, and they became increasingly dynamic and emergent as the field progressed. The behaviorism movement, which focused on explaining behavior without reference to mental processes, dominated psychological work during much of the first half of the twentieth century (Skinner, 1953; Watson, 1912). In sharp contrast, cognitive psychologists in the 1950s began embracing questions about the nature of inner thought processes (Bruner, Goodnow, & Austin, 1956; Chomsky, 1957). Within the field of cognitive psychology, some early information processing theorists focused on the computational bases for thought processes.

A critical step in the development of information processing approaches was the idea that cognitive theories could be stated (and run) as computer programs (Newell & Simon, 1972). Many cognitive theories (e.g., Anderson & Lebiere, 1998; Newell & Simon, 1972) were developed around the computer metaphor, with human cognition viewed as similar to processing in a standard serial computer (e.g., with cognitive processing separated from knowledge, in the same way that the processing machinery of a computer's central processing unit [CPU] is separated from knowledge structures in random-access memory [RAM]). However, the idea of stating cognitive theories as computer programs does *not* actually require that human cognition resemble processing on a computer. In the same way, computer models of the weather do not require that weather forces resemble computer processing. Instead, models can be completely distinct from the computers on which they are implemented and tested.

In fact, other information processing frameworks, such as neural networks and dynamic systems, increased

in prominence in part as challenges to some of the more rigid notions of cognitive processing associated with the computer metaphor. In neural network and dynamic system frameworks, the lines between knowledge and processing are relatively blurred. Much of cognitive processing occurs in parallel, rather than serially. And thinking unfolds in an emergent, dynamic way, through the interactions of many low-level processes. Over time, production systems have also incorporated some of these characteristics (e.g., Anderson, 1983).

Information processing approaches to development followed a similar chronology. With Piaget's (1952b, 1954) extensive observations and theorizing about children's thinking, the field of cognitive development was born. The relevance of information processing approaches for the study of development was noted early in their history:

If we can construct an information-processing system with rules of behavior that lead it to behave like the dynamic system we are trying to describe, then this system is a theory of the child at one stage of the development. Having described a particular stage by a program, we would then face the task of discovering what additional information-processing mechanisms are needed to simulate developmental change—the transition from one stage to the next. That is, we would need to discover how the system could modify its own structure. Thus, the theory would have two parts—a program to describe performance at a particular stage and a learning program governing the transitions from stage to stage. (Simon, 1962, pp. 154–155)

According to this view, developmental processes can be described in terms of programs that transform earlier stages into later ones, and the stages themselves can also be described in terms of a different set of programs. Many early production systems of development fit this view, in which programs for performance in a given stage were distinct from programs for transitions between stages (Baylor & Gascon, 1974; Klahr & Wallace, 1976; Young, 1976). Just as some rigid distinctions in cognitive processing were blurred over time within information processing approaches more generally, this distinction between performance and transition mechanisms in development has become more blurred as the field has progressed (Klahr & MacWhinney, 1998). In many recent information processing approaches, transition mechanisms operate throughout a model's development, and common processes contribute to a model's stable performance and transitions between stable periods.

The point about distinguishing between models and computers has not always been appreciated in the context of information processing models of development. Such approaches have been criticized because “A system that cannot grow, or show adaptive modification to a changing environment, is a strange metaphor for human thought processes which are constantly changing over the life span of an individual.” (Brown, 1982). Because models and the computers they run on are distinct, this criticism can apply to computers without applying to the computational models running on them (Klahr & MacWhinney, 1998). This point should become clear in the context of the numerous adaptively modifying models described in this chapter.

Because the information processing umbrella is so broad, including a wide range of cognitive theories, many other historical developments were fairly specific to particular variants of information processing approaches. Advances in neurobiology and neurally inspired models and theories (Hebb, 1949; McCulloch & Pitts, 1943; Rosenblatt, 1958; Shepherd, 1992) were particularly informative for the development of neural network approaches. Advances in the understanding of complex systems at the biological, mathematical, and psychological levels (Kuo, 1967; Lehrman, 1953; Lewin, 1936; von Bertalanffy, 1968; Waddington, 1957) laid the foundation for dynamic systems approaches.

Building on such foundations, and on the key idea that cognitive theories can be stated as computer programs, other major contributions in the history of information processing approaches took the form of introductory texts, which often included computational models for the reader to explore. Such introductory texts played a large role in widely disseminating ideas behind production systems (Anderson, 1976; Newell & Simon, 1972), neural network models (McClelland & Rumelhart, 1986; Rumelhart & McClelland, 1986b), and dynamic systems approaches (Kelso, 1995). Similarly, introductory texts arguably generated a great deal of interest and activity in investigating developmental questions through information processing approaches, with neural networks (Elman et al., 1996; Plunkett & Elman, 1997), dynamic systems (Thelen & Smith, 1994), and production systems (Klahr & Wallace, 1976).

OVERVIEW AND EXAMPLE OF EACH KIND

This section focuses on four major types of information processing approaches: production systems, neural net-

works, dynamic systems, and ad hoc models. Each type is first considered in isolation, in terms of the basic assumptions and components of the approach, and the kinds of applications to development that have been investigated, with one example considered in detail. At the end of this section, broad comparisons are drawn across some of these types of information processing approaches. The next section provides more detailed comparisons, by evaluating different models of the same developmental phenomena.

Production Systems

There are many variations of production systems, such as SOAR (Newell, 1990), ACT-R (Anderson & Lebiere, 1998), and 3CAPS (Just & Carpenter, 1992).

Basics

As described in many sources (e.g., Anderson, 1993; Klahr, Langley, & Neches, 1987; Klahr & MacWhinney, 1998; Newell & Simon, 1972), production systems focus on cognitive skills that take the form of production rules. Production systems consist of two interacting structures:

1. *Production memory:* This is the system’s enduring knowledge, and consists of a large number of condition-action (or IF-THEN) rules called *productions*. The conditions specify the circumstances under which the production applies. In the case of number conservation (Piaget, 1952a), the condition for one production might be: “If you have a goal of stating the numerical relation between two collections, and the collections had the same number of objects before a transformation and the transformation did not involve adding or subtracting objects” (Klahr & Wallace, 1976). The actions specify the actions to be taken under those circumstances. The corresponding action for the number conservation example might be: “then the rows still have the same number of objects.” The conditions and actions for productions can apply to either the external world or to mental states.
2. *Working memory:* This is the system’s representation of the current situation and consists of a collection of symbol structures called working memory *elements*. Information in working memory may come from both the external world and through the actions associated with productions.

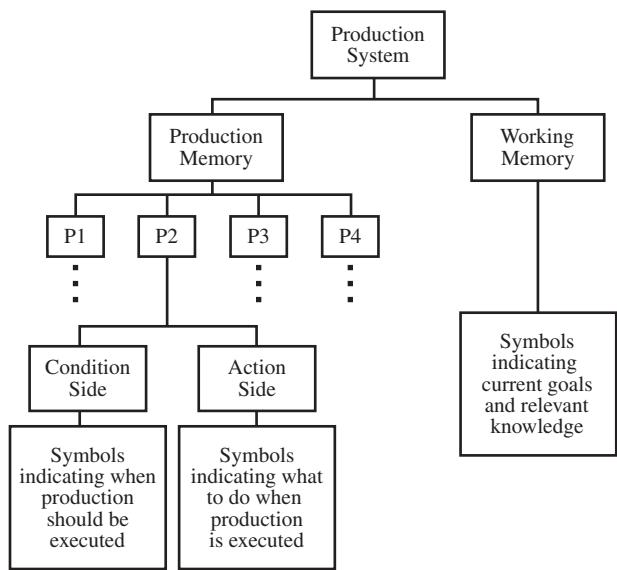

Figure 10.1 The organization of production systems. *Source:* From *Children's Thinking*, fourth edition, by R. S. Siegler and M. W. Alibali, 2005, Upper Saddle River, NJ: Prentice-Hall. Reprinted with permission.

The organization of these structures is shown in Figure 10.1.

Distinct processes relate production memory and working memory as follows:

1. *Recognition or matching process:* This process finds productions with conditions that match information in working memory. This process can lead to conflict, because several productions may have conditions that match the current state of working memory, and a single production may match the current state of working memory in different ways.
2. *Conflict resolution process:* This process selects which of the matching productions will be applied.
3. *Act process:* This process applies the actions of the selected productions.

This process works iteratively, with each action leading to new information in working memory, so that the three-step cycle begins again. This processing has both parallel and serial components. The search for productions with conditions that match the contents of working memory occurs in parallel. The execution of actions occurs in serial.

Learning in these production systems takes the form of the creation and modification of productions as a result of experience. For example, redundant steps may be

dropped from productions, and two productions may be combined into one, as a result of experience.

Applications to Development

Production systems have been used for understanding many different aspects of cognitive development, including higher level cognitive processes such as problem solving across different domains (e.g., Klahr & Siegler, 1978; Klahr & Wallace, 1976; Simon & Halford, 1995a; van Rijn, van Someren, & van der Maas, 2003). This kind of tradition is evident in some more recent production systems models. Jones, Ritter, and Wood (2000) used production systems to investigate different theories of what leads to developmental improvements on a problem-solving task that requires constructing a pyramid from 21 wooden blocks. Production systems may provide the most natural fit for modeling such processes, given the way in which higher level information can be represented in production memory. However, as discussed in subsequent sections, other models can be applied to the study of such higher level processes as well. And as discussed next, production systems can be applied to the study of arguably more basic forms of processing.

One example concerns infants' understanding of number. Can infants add and subtract? Do they "innately possess the capacity to perform simple arithmetical calculations" (Wynn, 1992)? Some researchers have argued that the answer is yes, based on infants' looking times to events that lead to expected or unexpected outcomes. In one event, infants see one toy sitting on a puppet stage. A screen is then raised, occluding the toy. Infants then see another toy being placed behind the screen. The screen is then dropped, revealing either two toys (an expected event) or one toy (an unexpected event). Five-month-old infants look longer at the unexpected event (Wynn, 1992). Control conditions demonstrate that infants do not simply prefer to look at outcomes with one toy over outcomes with two toys. Thus, one interpretation is that infants look longer at the unexpected outcome based on their computation of $1 + 1 = 2$; after computing that two toys should be on the stage, they look longer at outcomes that violate this expectation.

However, this interpretation is controversial. Many alternative explanations have been proposed for infants' longer looking times to unexpected outcomes. Infants might respond based not on the number of objects on the stage, but on some other factor that varies along with number, such as surface area (Feigenson, Carey, &

Spelke, 2002) or contour length (Clearfield & Mix, 1999; Mix, Huttenlocher, & Levine, 2002). Alternatively, infants might accurately track the objects without performing arithmetic computations (Simon, 1997). Or, infants might look longer at unexpected outcomes due to artifacts of the habituation procedures used in such studies, with infants responding on the basis of which displays are more familiar (L. B. Cohen & Marks, 2002).

Information processing approaches and computational models may be particularly useful in such cases of controversy. Models can help to clarify the assumptions of each theory, and exactly how they explain observed behaviors. Models of alternative accounts can serve as existence proofs that observed behaviors can arise through means other than those proposed. Such models can also be probed and manipulated to assess whether competing accounts represent true alternatives, or whether at core they are relying on common processes.

A production system model was put forth as an implementation of a “nonnumerical” account of infant behavior in violation-of-expectation studies (Simon, 1998). This model simulated infants’ longer looking to unexpected outcomes, based on domain-general processes: memory, individuation, object permanence, and spatiotemporal representations. Thus, the model was put forth as an existence proof of how infants’ responses can be understood without attributing numerical representations to them.

The model relied on creating indexes for each object encountered: physical object indexes for visible objects, and memory object indexes for objects that become hidden. The memory object indexes copied the spatiotemporal characteristics of the physical object indexes, and supported the formation of predictions. When such predictions were violated, longer looking times resulted due to searches for other possible matches in the display. The productions supporting this process are described in Table 10.1.

This production system model simulated infants’ looking times to standard “addition” ($1 + 1 = 2$) and “subtraction” ($2 - 1 = 1$) events. The workings of the model, which can be closely inspected, thus suggest the following possibility (Simon, 1997). Infants can encode spatiotemporal information about objects, use such information to individuate different objects, represent the continued existence of objects when hidden, and compare what they remember to what they see. These processes can support the recognition of an unexpected

TABLE 10.1 Productions

Longer looking to unexpected events is driven by the final production, which requires extra actions of checking additional locations for information when expectations are violated:

P1: **If** you have newly created physical object indexes and preexisting memory objects, **then** set a goal of comparing the predicted and actual states of the world.

P2: **If** your goal is to compare the predicted and actual states of the world, **then** set a goal of carrying out a one-to-one match process for each prediction.

P3: **If** your goal is to compare the predicted and actual states of the world, **and** you know the result of that comparison, then terminate looking.

P4: **If** your goal is to carry out a one-to-one match process for a prediction, **then** set a goal of seeing if a preexisting memory object matches a physical object.

P5: **If** your goal is to see if a preexisting memory object matches a physical object, **and** a match occurs, then verify the prediction for that preexisting memory object and move on to predictions for other preexisting memory objects.

P6: **If** your goal is to see if a preexisting memory object matches a physical object, **and** a match does not occur, **then** search other locations for other possible physical object matches.

Adapted from Simon’s (1998) nonnumerical production system model of infant behavior in violation-of-expectation studies.

event, without requiring numerical representations or calculations. Thus, a “ $1 + 1 = 1$ ” event can be recognized as unexpected simply because an object and another object are expected, but the display reveals only an object. In the same way, the sudden disappearance of an object can be recognized as unexpected, simply because an object was expected, and not because $1 - 0 = 1$.

The working production system model allows various questions to be asked of this nonnumerical account. Is a nonnumerical account sufficient to explain the range of behaviors observed in infants, and could these be simulated within a single model? Would Simon’s (1997) model be able to simulate infants’ sensitivity to the ordinal relations of numbers (Brannon, 2002)? These kinds of questions highlight strengths of information processing approaches and computational models; the explicitness of assumptions can lead to a honing of theoretical claims (e.g., what it means for processes to be numerical or nonnumerical) and testing of behavioral predictions.

Neural Networks

Neural network models are also known as connectionist or parallel distributed processing models. Each of these

names captures aspects of how processing occurs in these models, in parallel across a network of interconnected nodes.

Basics

There are many variations of neural network models (e.g., Arbib, 2002), but all models share the common features of units and weights (McClelland & Rumelhart, 1986; O'Reilly & Munakata, 2000; Rumelhart & McClelland, 1986b):

- *Units* are neuronlike entities that represent information through their activity, which can be communicated to other units.
- *Weights*, or connections, link units to one another. The strength of connections changes through learning, in a manner akin to changes in the efficacy of synapses with learning.

Information is represented in neural network models in terms of patterns of activation across units. Units are typically organized into layers, such as an input layer that represents information available in the environment, an output layer that represents the network's actions or decisions, and hidden layers in between that allow patterns of activity to be transformed between the input and output layers. The activity of any given unit is a function of the activity of other units and the strength of the connections between units.

Representations of information in neural networks are often distributed, graded, and interactive. For example, a network's representation of the concept of number might be distributed across multiple units in the network, which also participate in the representation of related concepts (e.g., quantity and counting). These units can vary in their levels of activation, supporting gradedness in the strength of the associated concepts. And, because of the connections that send activity from one unit to another, networks of units can be highly interconnected, leading to interactive representations that can have large effects on one another.

Learning occurs through changes to connections between units. A number of learning algorithms have been investigated through neural network models. Two broad classes can be delineated (O'Reilly & Munakata, 2000): error-driven and self-organizing learning. Error-driven learning is guided by the goal of reducing errors, mea-

sured as a function of the difference between target activations and a network's actual activations. Such targets can come from various sources, such as a teacher explicitly correcting a student's behavior, the environment providing a target signal for one's expectations about what will happen next, and a person's goal for a motor action providing a target signal for the attempted motor action. Backpropagation (Rumelhart, Hinton, & Williams, 1986a) is one of the most common variants of error-driven learning algorithms.

Self-organizing learning entails forming representations that capture important aspects of the environmental structure, based on patterns of simultaneous activation among processing units. Hebbian learning algorithms (e.g., Oja, 1982), whereby "units that fire together, wire together," are one of the most common forms of self-organizing learning algorithms. Algorithms have also been developed that combine error-driven and self-organizing learning, and demonstrate how each benefits from the other (O'Reilly & Munakata, 2000).

Applications to Development

Neural network models have been applied to a broad range of domains in the study of cognitive development (see reviews in Elman et al., 1996; Munakata & McClelland, 2003; Quinlan, 2003; Shultz, 2003), including language (Elman, 1993; Plunkett & Marchman, 1993; Seidenberg & McClelland, 1989), categorization (Mareschal & French, 2000; Rogers & McClelland, 2004), and object knowledge (Mareschal, Plunkett, & Harris, 1999; Munakata, McClelland, Johnson, & Siegler, 1997). Many of these models have been focused on understanding the kinds of learning processes and representational changes that support the changes observed in infants and children during development. Most of these models have focused on typical development. However, as discussed next, neural network models can also be informative in the study of atypical development, given their abilities to capture nonlinear dynamics and emergent properties of complex developing systems (Morton & Munakata, 2005).

In the study of developmental disorders, the nature-nurture debate takes a familiar form. Early arguments pitted genetic contributions against environmental ones, whereas now researchers generally agree that both contribute in important ways. Nonetheless, two contrasting perspectives can still be identified (Karmiloff-Smith,

2005). A *modular* approach assumes (implicitly or explicitly) a static view of brain function, in which neural systems or modules are innately specified for particular functions. From this perspective, developmental disorders arise due to genetic alterations that target particular associated cognitive functions. As a result, a developmental disorder may lead to specific cognitive impairments, similar to those observed in cases of adult brain damage. In contrast, within the neural network framework, it is more natural to consider particular functions emerging in particular brain areas through a highly interactive process of development. Rather than different brain regions simply having their functions prespecified, they develop as they do in part because of how other regions are developing and through small differences in start state. From this perspective, developmental disorders emerge through genetic alterations leading to small changes in low level properties of a system's start state that interact with processes of development (Karmiloff-Smith, 1998).

Information processing approaches and computational models may be particularly useful for investigating the complexity of such emergent processes. A number of neural network models have demonstrated how small, quantitative differences in the starting state of systems can lead through a process of development to qualitative differences in outcome (Harm & Seidenberg, 1999; Joanisse & Seidenberg, 2003; Oliver, Johnson, Karmiloff-Smith, & Pennington, 2000; O'Reilly & McClelland, 1992; Thomas & Karmiloff-Smith, 2002, 2003). Because of the complexity of the developmental process, damage to a system early in development can lead to very different behaviors than damage to the same system late in development (Thomas & Karmiloff-Smith, 2002, 2003).

One model demonstrated how deficits in syntactic processing, observed in individuals with specific language impairment (SLI), can arise through development from small disturbances in phonological representations (Joanisse & Seidenberg, 2003). The model simulated the sentence comprehension profile of individuals with SLI across sentences of varying complexity. Thus, the model demonstrated how apparently specific deficits can arise through low-level variations, rather than the genetic specification of cognitive modules.

The model's task was to map sequences of words onto their meanings. The model consisted of four layers: a phonological input layer, two hidden layers, and a se-

mantic output layer. The hidden layers sent and received activity from one another, which allowed information to be maintained across several time steps. These layers thus supported the network's working memory, which could aid in the mapping of a word onto its meaning. To explore the effects of small differences in start state, two versions of this model were trained: an intact version, and a version in which the phonological inputs to the network were distorted through the addition of a small amount of noise.

These networks were trained on a corpus of 40,000 sentences that varied in syntactic complexity. Sentences were presented one word at a time, and the networks had to identify the meaning of and syntactic dependencies between each word to activate an appropriate set of units in the semantic output layer. For example, the sentence "John says Bill likes himself" was presented to the network as "John" "says" "Bill" "likes" and "himself." After the presentation of the final word "himself," the network was trained to activate the meaning of this word in this context: the [MALE], [REFLEXIVE-PRONOUN], [HUMAN], and [BILL] units of the semantic output layer. After training, syntactic processing was tested using novel sentences that were not part of the training corpus. The test set included sentences with reflexives that could only be resolved syntactically (e.g., "Harry says Bob likes himself"), and similar sentences but with nouns or reflexives modified so that the reflexive could be resolved with the help of gender information (e.g., "Sally says Bob likes himself").

The intact network performed near ceiling on both sets of sentences, simulating the performance of typical individuals. In contrast, the network with phonological deficits showed a selective deficit in resolving reflexives based on syntactic information alone, simulating the performance of individuals with SLI. Thus, a low-level deficit in phonological processing led to selective grammatical deficits. Specifically, the deficit in phonological processing made it more difficult for the network to form and maintain consistent representations in working memory. For sentences such as "Harry says Bob likes himself," in which the meaning of "himself" could only be resolved on the basis of syntactic information, the network's working memory representations were insufficient to resolve the sentences. In contrast, for sentences such as "Sally says Bob likes himself," which could be resolved on the basis of syntactic and semantic information, the network's working memory

representations were more robust to noise, so that these sentences could still be resolved.

Dynamic Systems

Dynamic systems approaches focus on understanding complex, nonlinear changes in systems over time, through both verbal description and formal simulation.

Basics

There are many variations in this approach (e.g., von Bertalanffy, 1968; Fischer & Bidell, 1998; Kelso, 1995; Smith & Thelen, 1993; van der Maas & Molenaar, 1992), but most include some form of the following ideas:

- Behavior is multiply determined, influenced by processes at multiple levels, within the organism and between the organism and the environment.
- Systems are softly assembled (Kugler & Turvey, 1987), flexibly adapted in a self-organizing manner, rather than being hard/wired or programmed.
- Some resulting states are more stable than others, and constitute “attractors.”

In the case of walking, movements are viewed as softly assembled based on factors such as the environment, level of arousal, leg mass, and so on (Thelen & Ulrich, 1991). Certain patterns are more stable than others (e.g., walking, trotting, and galloping in the case of quadrupeds). This kind of dynamic systems approach contrasts with the notion of a central pattern generator that endogenously generates the neural activation patterns that drive locomotion. Within the dynamic systems framework, one goal is to understand the processes at multiple levels that contribute to behavior, and how different parameter values of those processes lead to different attractors and behaviors.

Applications to Development

Dynamic systems approaches have been adopted to investigate aspects of development (Lewis, 2000; Thelen & Smith, 1994, 1998) from early work on personality development (Lewin, 1935, 1936), to seminal work on motor development (Thelen, Kelso, & Fogel, 1987), to more recent work in domains that might be considered more cognitive (Thelen, Schöner, Scheier, & Smith, 2001; van Geert, 1998). Much of the work in this tradition has taken the form of verbal theories, using dynamic systems constructs as a metaphor for reconceptualizing

development (Spencer & Schöner, 2003). This is a useful and important step, but implemented models should aid in the assessment of this approach and comparison to alternatives.

One set of implemented simulations focused on cognitive growth (van Geert, 1991, 1993, 1998). The overall approach with these models was to identify a set of relevant variables in the domain of interest, express the relations between these variables in mathematical equations, assign parameter values in the equations, and then run the equations to test the fit of the model’s developmental trajectory to the observed behavioral data. When good fits were observed, the models served as a demonstration that development might proceed as hypothesized, in terms of the posited variables, relations, and parameter values.

A specific model focused on lexical and syntactic growth in children (van Geert, 1993). In this case, the relevant variables might include things like the number of words and different syntactic rules acquired at a given point in time. Various parameters to be set in the equations included growth rate (the amount of growth over a specific time interval), and feedback delay (which affected how quickly a given state of the system affected subsequent states). One curve to be fit characterized the number of words in a child’s lexicon week by week (Dromi, 1986). Poor fits to the empirical data were obtained with no feedback delay; better fits were obtained with a feedback delay of 2 weeks and growth rate of .71 for the early part of the empirical curve, and with a feedback delay of 1 week and growth rate of .35 for the later part of the empirical curve. Models of this sort have also been applied to fitting curves of various general aspects of development, including discontinuous change (van Geert, 1998).

Clear strengths and weaknesses have been identified with this type of dynamic systems model (Aslin, 1993; Thelen & Smith, 1998). One strength is forcing experimenters to think about their systems in precise ways, by collecting detailed data that are amenable to dynamic models and carefully considering potential contributing components, their relations, and relevant parameter values. Like all models, these models can also lead to empirical predictions that can be tested. However, some examples of this kind of modeling approach have been criticized for being “theory-rich and data-poor” (Thelen & Smith, 1998), with much of the models’ components, interactions, and parameters being largely hypothetical.

As a result, the process of curve-fitting may be too unconstrained to be informative (Aslin, 1993).

Ad Hoc Models

Ad hoc models refer to models focused on the information processing demands of the domain under consideration, without being constrained by all the assumptions and claims of global frameworks, such as production system, neural network, and dynamic systems approaches (Klahr & MacWhinney, 1998). Ad hoc models can employ a wide variety of architectures and learning algorithms. For this reason, they cannot readily be compared as a group against other frameworks, and so will not be focused on beyond this section.

Ad hoc models have proven useful in the investigation of strategic development (e.g., Shrager & Siegler, 1998; Siegler & Shipley, 1995; Siegler & Shrager, 1984). Such models have demonstrated how relatively simple processes can support the discovery of new strategies and the making of adaptive choices among strategies—two abilities that children show very early (e.g., Adolph, 1997) and reliably (Siegler, 1996).

A unified model focused on choosing among strategies *and* developing new strategies; these processes had previously only been simulated in isolation across separate models (R. Jones & VanLehn, 1991; Neches, 1987; Siegler & Shipley, 1995; Siegler & Shrager, 1984). The unified model was called SCADS, for Strategy Choice and Discover Simulation (Shrager & Siegler, 1998). This model focused on the development of simple addition strategies and captured many aspects of children's behavior on addition problems, including choosing adaptively among diverse strategies and discovering the same strategies in the same sequence and manner as children do.

The model comprised three broad components:

1. An associative learning strategy choice component that represented strategies as sets of operators (e.g., "choose addend, say addend, clear echoic buffer, count out fingers to represent addend") and recorded statistics about the speed and accuracy of strategies.
2. A working memory system that maintained traces of each strategy's execution and results, so that they were available for analysis.
3. A metacognitive system that analyzed strategies, identified potential improvements, and generated new strategies by recombining operators from exist-

ing strategies. This metacognitive system had three components: an attentional spotlight that increased resources allocated to new strategies, strategy-change heuristics that eliminated redundancy and recognized the importance of order of operations in strategies, and goal-sketch filters that prevented the execution of invalid strategies.

The model began each run with only two strategies: retrieval (providing an answer based on memory) and the sum strategy (put up the number of fingers corresponding to one addend, count, put up the number of fingers corresponding to the other addend, count, and finally count all the fingers up). The sum strategy was chosen often initially, because the system did not have strong enough associations between problems and answers to use retrieval. Attentional resources were needed in this early use of the sum strategy. With continued practice, attentional resources were freed so that the system could discover new strategies. If the strategies passed the goal sketch filters (which required both addends to be represented and used in reporting a result), the strategies were kept. If the strategies were efficient and accurate, they were used more and more. New strategies were also discovered through the elimination of redundant steps in existing strategies. The shortcut sum strategy (put up fingers for both addends and count them once) was formed from the sum strategy, by dropping the redundant steps of first counting the fingers for each addend. Next, the redundancy of counting the first addend could be dropped to simply state the value of that addend and count from there. This strategy was more efficient when starting with the larger addend, leading to the min strategy (counting up from the larger addend).

From these basic processes, the model chose adaptively among diverse strategies and discovered the same strategies in the same sequence and manner as children. The adaptive choice reflected the model's associative learning of the strengths of various strategies, based on their associated speeds and accuracies. The model's strategy discovery process was based on fairly simple constraints: satisfying the basic goal sketch, eliminating redundancy, and attending to the importance of order of operations. These constraints were sufficient to yield the same strategies that children use. Moreover, because these processes could occur whenever attentional resources were available, the model discovered new strategies in a manner paralleling that of children; for

example, following correct as well as incorrect performance, and without requiring trial-and-error learning. The model discovered new strategies in the same order as children, in part through dropping redundant steps from one strategy to create a new strategy.

In this way, the SCADS model provided insight into the possible processes underlying children's strategy discovery and choice. What might otherwise seem like mysterious processes may be driven by relatively basic processes of associative learning and heuristic knowledge use.

General Comparisons across Frameworks

Comparisons among information processing approaches are most straightforward in the context of different models of the same phenomenon, which is the focus of the next section. This section first briefly considers some general comparisons that may be drawn across production systems, neural network, and dynamic systems approaches. This is a difficult exercise, given the many varieties of each type of information processing approach. It is no coincidence that others who have attempted such comparisons have introduced them as "open to extensive criticism" (Thelen & Bates, 2003) or noted that others are likely to question and argue with the comparisons (Anderson & Lebiere, 2003). The same applies to the current comparison, summarized in Table 10.2. Dynamic systems approaches could be viewed as an overarching theory that includes dynamic models of all kinds, including neural network models as one particular case. And, for each characterization listed for each approach, exceptions can probably be found. But these characterizations capture some general differences between these approaches as they have typically been investigated.

Representations

Historically, these three approaches have been quite different in their treatment of mental representations.

Production systems focused on a symbolic level of representations, with working memory consisting of symbol structures and production memory taking the form of If-Then propositions. Neural network models focused on a subsymbolic level of representations, the "microstructure of cognition" (Rumelhart & McClelland, 1986b) with representations distributed across connections and patterns of activation. Dynamic systems researchers largely eschewed the "R-word," because of its possible connotation of a static entity sitting in the head (see discussion in Spencer & Schöner, 2003; Thelen & Bates, 2003).

Again, none of these characterizations are absolute. Production systems have incorporated continuous and noisy activation values (e.g., Anderson & Lebiere, 1998; Just & Carpenter, 1992), and neural network models have been used to address the development of symbol-like rules (Rougier, Noelle, Braver, Cohen, & O'Reilly, 2005). And some recent dynamic systems models have investigated representations, at a subsymbolic level, in terms of particular states of a system at particular times (Spencer & Schöner, 2003).

Relative Strengths and Weaknesses

Each approach has its relative strengths and weaknesses, which in some cases may be viewed as trade-offs, where one feature is emphasized at the expense of another. Production systems may have a relative strength in simulating flexible behavior because complex behaviors can be handled through sequences of productions (e.g., Taatgen, 2002), and symbolic representations can be used flexibly across variations in perceptual input. However, the flexibility of these models might come at the cost of being less suited to capture emergent effects in cognition. Small changes in perceptual processing can lead to large changes at the cognitive level, as explored in the study of developmental

TABLE 10.2 Comparison of Three Major Information Processing Frameworks

	Production Systems	Neural Networks	Dynamic Systems
Representations	Symbolic	Subsymbolic	Initially unaddressed, now subsymbolic
Relative strength	Flexible behavior	Biological plausibility	Embodiment
Relative weakness	Emergent effects	Abstraction	Learning
Strongest track record	Higher level cognition (e.g., problem-solving)	Language (e.g., reading)	Motor (e.g., locomotion)

Note: These characterizations are not absolute, and exceptions exist, as described in the text.

disorders. These emergent effects may be better captured by nonproduction systems models, in which knowledge is represented in ways that are less flexible and more tied to specific lower level processes. Neural networks may have a relative strength in biological plausibility, in terms of the mapping between the computational elements of units and weights and biological elements of neurons and synapses, and in the development of biologically plausible learning algorithms and architectures (e.g., O'Reilly & Rudy, 2001). However, because of the way that these models learn based on particular experiences, with units becoming committed to representing specific information, the knowledge in such models has been criticized for not being sufficiently abstract (Marcus, 1998). Dynamic systems models may have a relative strength in their focus on embodiment, and the effects on cognition and development of being situated in a physical body. However, development in these models is often simulated through changes to external control variables, without explanation of how such changes come about. As a result, such models have not addressed learning processes that might underlie such changes.

Again, these characterizations are relative. Production systems have yielded predictions about neural function that have been tested through neuroimaging studies (Fincham, VanVeen, Carter, Stenger, & Anderson, 2002). Neural network models have been used to address questions about processes of abstraction and generalization (Christiansen & Curtin, 1999; Munakata & O'Reilly, 2003; Rougier et al., 2005; Seidenberg & Elman, 1999). And learning has been incorporated into some dynamic systems models (van Geert, 1993).

Strongest Track Record

Finally, these three approaches have differed in their domains of application. Production systems approaches arguably have their strongest track record in simulating aspects of higher-level cognition, such as problem solving. Neural network models have addressed many aspects of language, whereas dynamic systems approaches have probably had their greatest impact in the study of motor processing. Such distinctions may be based in part on how readily different modeling approaches can fit the empirical phenomena. However, these approaches also have some overlap in their domains of application, or the next section of this chapter would not be possible.

DETAILED COMPARISONS: DIFFERENT MODELS OF THE SAME PHENOMENA

This section compares different types of models that have been applied to understanding the same developmental phenomena, across the domains of problem-solving, language, and memory. In the problem-solving domain, children's development on the Piagetian balance scale task (Inhelder & Piaget, 1958) has been investigated through production systems and neural network approaches. In the domain of language, children's developing abilities to conjugate the past tense of verbs has been investigated through neural network and production systems approaches. Finally, in the domain of memory, infants' memory for hidden objects as assessed through the Piagetian A-not-B task (Piaget, 1954) has been investigated through neural network and dynamic systems approaches. In each case, the insights afforded by each modeling approach are compared and contrasted.

Problem Solving: The Balance Scale Task

Children appear to pass through qualitatively different stages in solving certain tasks (Case, 1985; Piaget, 1952b). In the balance scale task (Inhelder & Piaget, 1958), children view a scale with weights on each side at particular distances from the fulcrum, and they must decide which arm of the scale will fall when supports underneath the scale are released. Children initially answer problems randomly, using no apparent rule about the physical properties of weight and distance to guide their decisions. They then employ different information to help them solve the task, progressing through four rules (Figure 10.2, Siegler, 1976, 1981). With Rule I, children attend to only the amount of weight on each side of the fulcrum. With Rule II, children also attend to the distance of weights from the fulcrum, if weights are equal on each side of the fulcrum. With Rule III, children consider both weight and distance information in all cases, but when this information conflicts, children make a random prediction. Finally, Rule IV represents mature knowledge of the task, which requires the computation of torque (sum of weights times distances).

Models of many different flavors have been applied to understanding children's performance on the balance scale task (Newell, 1990; Sage & Langley, 1983; Schmidt & Ling, 1996; Shultz, Schmidt, Buckingham, & Mareschal, 1995). For purposes of comparison,

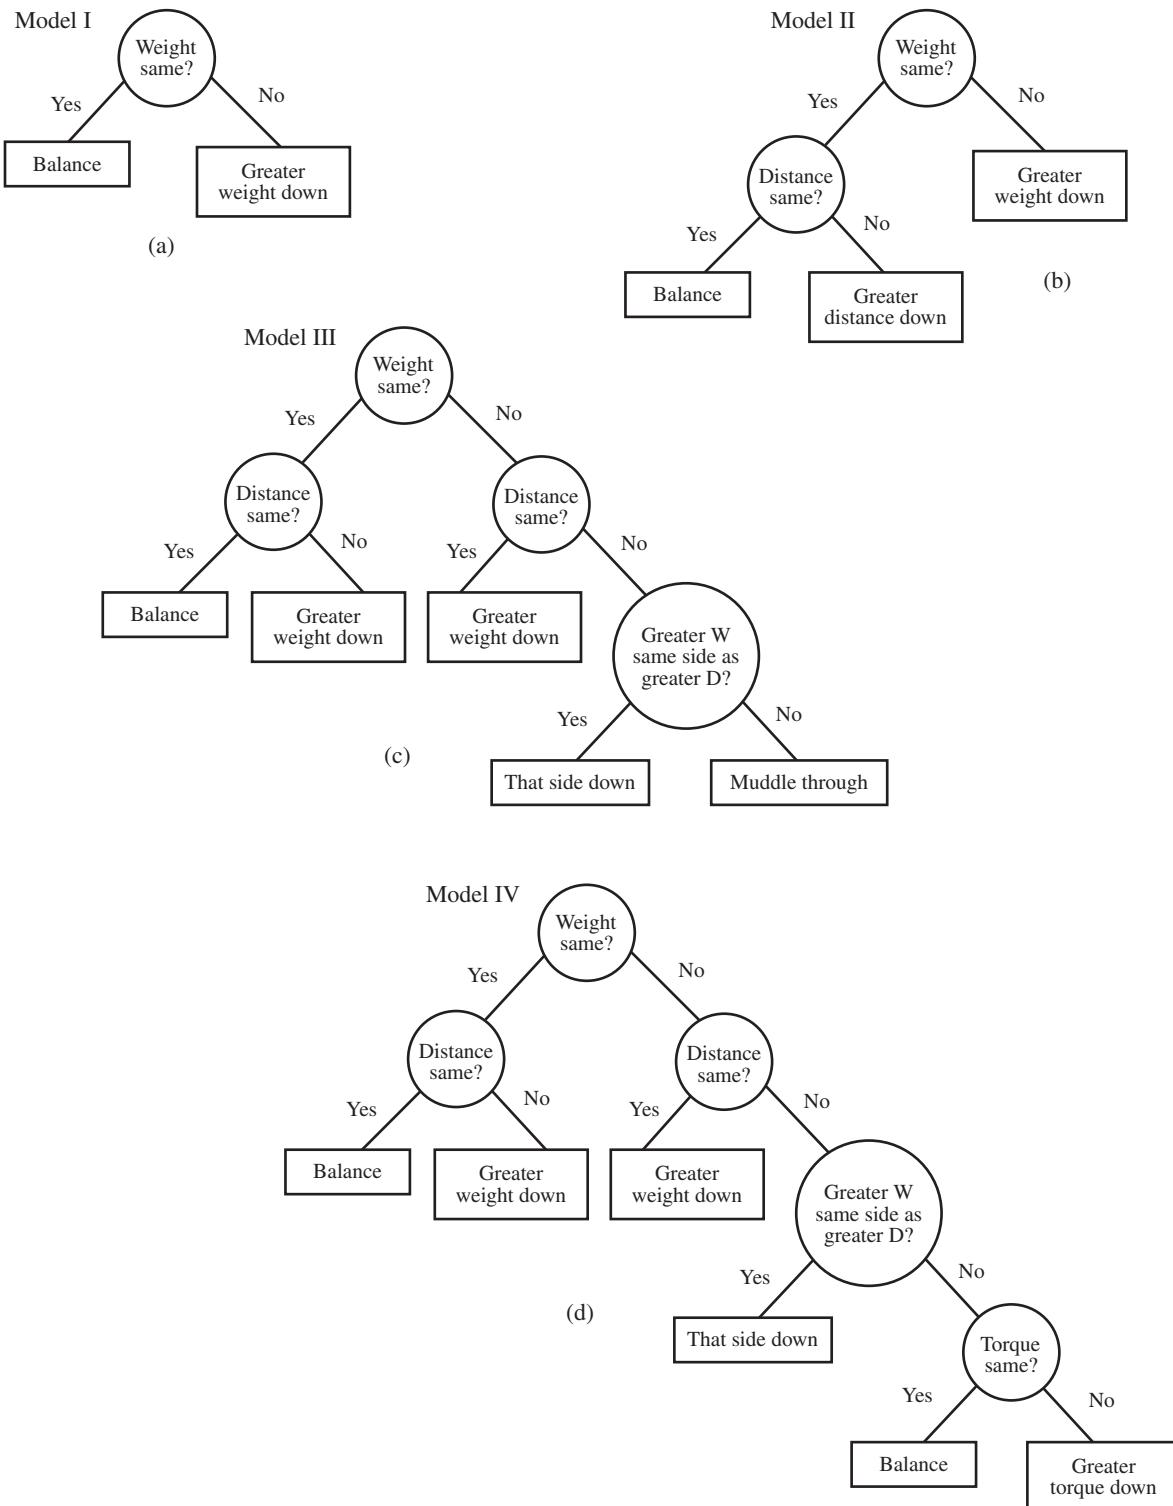

Figure 10.2 Decision tree representation of children's rules on the balance scale task. *Source:* “The Representation of Children’s Knowledge” (pp. 61–116), by D. Klahr and R. S. Siegler, in *Advances in Child Development and Behavior*, volume 12, H. W. Reese and L. P. Lipsitt (Eds.), 1978, New York: Academic Press. Reprinted with permission.

the current discussion focuses on an early production system model (Klahr & Siegler, 1978), a subsequent neural network model (McClelland, 1989, 1995), and a recent production system model (van Rijn et al., 2003).

Early Production System Model

The early production system model of balance scale performance (Klahr & Siegler, 1978) focused on the productions and operators required to carry out the four rules used by children on the balance scale task. Thus, this model provided a more precise characterization of the dynamics of processing underlying the decision tree representation shown in Figure 10.2.

The productions for models employing each of the four rules are listed in Figure 10.3. For each production, the conditions are shown on the left and the actions are

Model I

P1: ((Same W) → (Say “balance”))
 P2: ((Side X more W) → (Say “X down”))

Model II

P1: ((Same W) → (Say “balance”))
 P2: ((Side X more W) → (Say “X down”))
 P3: ((Same W) (Side X more D) → (Say “X down”))

Model III

P1: ((Same W) → (Say “balance”))
 P2: ((Side X more W) → (Say “X down”))
 P3: ((Same W) (Side X more D) → (Say “X down”))
 P4: ((Side X more W) (Side X less D) → muddle through)
 P5: ((Side X more W) (Side X more D) → (Say “X down”))

Model IV

P1: ((Same W) → (Say “balance”))
 P2: ((Side X more W) → (Say “X down”))
 P3: ((Same W) (Side X more D) → (Say “X down”))
 P4: ((Side X more W) (Side X less D) → (get Torque))
 P5: ((Side X more W) (Side X more D) → (Say “X down”))
 P6: ((Same Torque) → (Say “balance”))
 P7: ((Side X more Torque) → (Say “X down”))

Transitional requirements

	Productions	Operators
I → II	add P3	add distance encoding and comparison
II → III	add P4, P5	
III → IV	modify P4; add P6, P7	add torque computation and comparison

Figure 10.3 Production system representations of children’s rules on the balance scale task (Klahr & Siegler, 1978). W = Weight and D = Distance. *Source:* From “Information Processing” (pp. 631–678), by D. Klahr and B. MacWhinney, in *Handbook of Child Psychology*, volume 2, fifth edition, W. Damon (Editor-in-Chief), and D. Kuhn and R. S. Siegler (Eds.), 1998, New York: Wiley. Reprinted with permission.

shown on the right. The conditions all check for same-ness or difference, in weight, distance, or torque. When the conditions for a production match the information in working memory, the associated action (saying which side will go down) is produced. In the simplest model (employing Rule I), if the information in working memory indicates that the two sides have the same weight, P1 will fire and the response will be to say that the two sides balance. If the information in working memory indicates that one side has more weight than the other, P2 will fire and the response will be to say that side will go down.

The models become more elaborated to capture more advanced rule use (Figure 10.3). The model employing Rule II has an additional production, whereby if the two sides have the same amount of weight but one side has more distance, the response will be to say that side will go down. Based on this specification of what is required to use each rule, it is straightforward to see what modifications are required to progress from one model to the next (bottom of Figure 10.3). Transitioning from Rule I to Rule II requires adding the production that responds based on unequal distance when the weights are equal, and adding operators that encode and compare distances. This model did not actually simulate such transitions however.

Neural Network Model

Subsequent models have focused more attention on the transitions between rules. A neural network model of the balance scale task (McClelland, 1989, 1995) demonstrated how stage-like progressions from one rule to the next can result from small, successive adjustments to connection weights.

The model (Figure 10.4a) consisted of an input layer representing weights and distances on the left and right sides of a balance scale, a hidden layer with separate units for representing weight and distance information, and an output layer representing the choices for which side should go down: left, right, or balance (if the activations of the two output units were similar). The input layer represented weight and distance information in terms of localist patterns of activation for each side of the balance scale, with each unit corresponding to a certain number of weights or a certain distance from the fulcrum. In the problem shown in Figure 10.4, there are four weights located two pegs from the fulcrum on the right side. These are represented through activation of the corresponding units in the input layer (the 4th weight unit and the 2nd distance unit for the right side).

This model was presented with many balance scale problems of this sort. It received greater exposure to

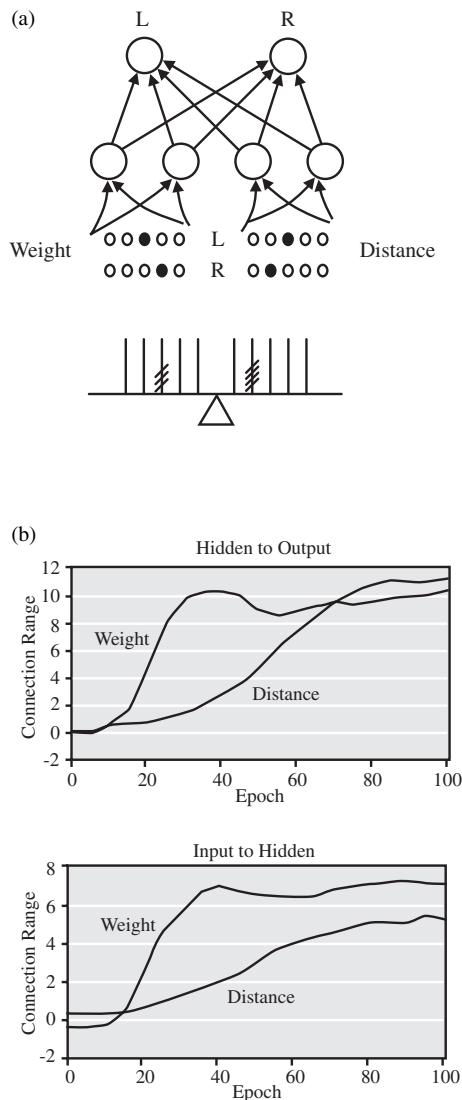

Figure 10.4 A neural network model of the balance scale problem: (a) architecture and inputs corresponding to the balance scale problem shown, (b) connection-based knowledge about weight and distance on the balance scale, as a function of learning through exposure to training examples. Incremental changes in connections from the input to the hidden layer (bottom) and from the hidden to output layer (top) support stage-like transitions between rules. *Source:* From “Parallel Distributed Processing: Implications for Cognition and Development” (pp. 8–45), by J. L. McClelland, in *Parallel Distributed Processing: Implications for Psychology and Neurobiology*, R. G. M. Morris (Ed.), 1989, Oxford, England: Oxford University Press. Reprinted with permission.

problems where weight predicted the outcome than to problems where distance predicted the outcome, reflecting the possibility that children have more experience with the effects of variations in weight than with the effects of variation in distance. The model learned

according to the backpropagation learning algorithm: The model activated responses to each problem that was presented to it (which could be viewed as predictions about balance scale outcomes), and its connections were adjusted to reduce errors—the discrepancy between the model’s output and the actual outcome. Based on this experience, the model progressed from random responding to Rule I behavior, from Rule I to Rule II behavior, and from Rule II to Rule III behavior. This progression was stage-like, in that the model showed relatively stable performance on each rule, punctuated by relatively rapid transitions between rules.

Why did the model display stage-like transitions? The network’s initially random weights were slowly modified with each experience to reduce the discrepancies between the network’s predictions about balance scale problems and the actual outcomes. The network first began to develop representations of weight in its hidden layer, given the greater predictive power of this factor in the problems presented. Early in this process, the network’s output still reflected random answers because the connections from between the input, hidden, and output layers were not yet sufficiently meaningful. As these connections became more fully formed, units became more distinct in their activation patterns, such that changes to connections could proceed rapidly to stage-like improvements in the network’s performance. Figure 10.4b shows these accelerations in the connection weight changes for the connections from the input to the hidden layer (bottom) and from the hidden layer to the output layer (top). The accelerations in the connections for the weight information correspond to the transition to the Rule I stage, and the accelerations in the onset of the distance information correspond to the transitions to Rules II and III. In this way, incremental weight adjustments in neural networks can result in small representational changes that then support relatively fast learning, producing stage-like behavior.

Although the model simulated children’s stage-like progression from no-rule behavior to Rule I, Rule II, and Rule III behaviors, it did not capture a clear transition to the most sophisticated Rule IV; instead, at the end of training, the model vacillated between Rules III and IV. This might reflect that a different kind of learning (e.g., based on explicit teaching) may underlie the transition to Rule IV use (McClelland, 1995).

Recent Production System Model

A recent production system model of the balance scale task (van Rijn et al., 2003) was aimed at addressing

several possible limitations with earlier models. Although McClelland's neural network model relied on learning from errors to drive developmental transitions, children can show transitions in their balance scale performance in the absence of feedback. A small percentage of children switched from Rule I to Rule II after being presented with problems that highlighted distance information, without any feedback (Jansen & van der Maas, 2001). These problems involved gradually and systematically increasing the distance between weights and the fulcrum across problems, and then decreasing this distance. In this sequence, 4% of the children switched from Rule I to Rule II and back again at the same point in the sequence (as distance increased and as it decreased); 3% switched from Rule I to Rule II and back again at different points in the sequence; and 9% switched from Rule I to Rule II as the distance difference increased and did not switch back to Rule I. To capture such effects, a model would need to learn not only in response to error feedback.

In addition, the production system model was aimed at capturing qualitative transitions between rules. Although McClelland's model was characterized as capturing stage-like progressions based on quantitative underlying changes, it has been criticized for not being truly stage-like. This model has been criticized for not showing qualitative transitions between rules (Raijmakers, van Koten, & Molenaar, 1996) and for not following a distinct set of rules as analyzed through a statistical technique of latent class analysis (Jansen & van der Maas, 1997).

Van Rijn et al.'s (2003) production system model was aimed at capturing these kinds of phenomena, as well as the basic developmental progression observed from Rule I to Rule IV. The model was composed of IF-THEN productions and knowledge in the form of declarative memory chunks. There were three main factors underlying the model's behavior and development:

- 1. Mechanisms:** These included processes such as the composition of new production rules, and the updating of the values associated with such productions (their utility), as well as with declarative memory chunks (their activation levels). Another mechanism was the general strategy of solving balance scale problems by searching for differences between the left and right sides of the balance scale.
- 2. Task-specific concepts (weight, distance, addition, and multiplication):** These were represented as chunks in

declarative memory, with their availability mediated by the activation of these chunks.

- 3. Capacity constraints:** These limited the number of differences the model could search for in trying to solve balance scale problems.

The concepts and capacity constraints were manipulated in the model to simulate differences across development (Figure 10.5). The task-specific concepts (weight, distance, etc.) were made available to the model at different points in its development, through changes to the activation of the declarative chunks representing those concepts. The capacity limitations were manipulated so that early in development models could search for only one difference between the two sides of the balance scale, whereas later in development, they could search for more than one difference. The concepts and capacity manipulations were motivated by empirical observations about children's encoding (Siegler, 1976; Siegler & Chen, 1998) and developmental theories about capacity (Case, 1985).

The model simulated the progression from Rule I to Rule IV and showed stable performance with each rule. Before any of the task-specific concepts were sufficiently activated, the model could only generate answers by guessing, which led to poor performance and low utility associated with this strategy. As soon as the

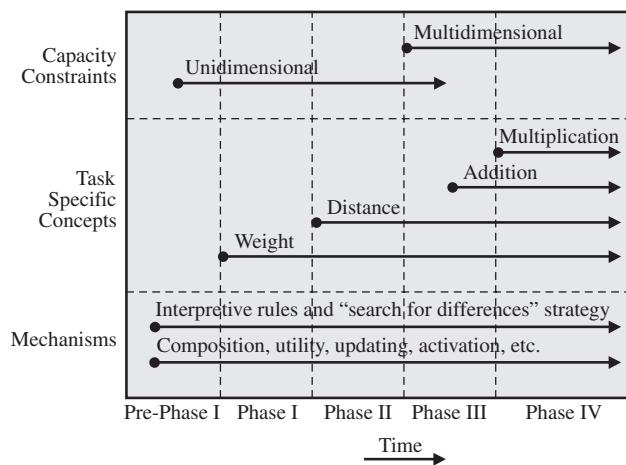

Figure 10.5 Availability of components in the van Rijn et al. (2003) production system model of the balance scale task. *Source:* From “Modeling Developmental Transitions on the Balance Scale Task,” by H. van Rijn, M. van Someren, and H., van der Maas, 2003, *Cognitive Science*, 27, pp. 227–257. Reprinted with permission.

weight concept became available, the model thus began to use this concept (Rule I). When the distance concept became available, the capacity constraints limited the model to attending to only one dimension at a time. This led to the model attending to distance only if the weights were equal (Rule II). When the model's capacity increased to include more than one dimension, the model then considered weight and distance (Rule III). Finally, when the concept of multiplication became available, the model could then progress to computing torque (Rule IV). Behaviors associated with each of the rules were stable, based on the availability (or lack) of task-specific concepts and capacity, and the utility associated with production rules.

The model also simulated the finding that transitions from Rule I to Rule II may occur in the absence of feedback, and it showed the three types of transition patterns observed behaviorally (Jansen & van der Maas, 2002). As in the behavioral studies, the model was presented with sequences of problems with increasing and then decreasing distance differences, without feedback. The activation formula was revised to include a saliency term, computed as a function of the distance difference. As a result, problems with bigger distance differences were more salient, and led to increased activation of the distance concept. As soon as the distance concept became sufficiently activated, the distance values were used in solving the problem. That is, the model transitioned from Rule I to Rule II. If this occurred while the distance difference was increasing across problems, distance would continue to be used because the concept's activation would be greater from both the previous problem and the increased salience of distance information on the current problem. When the distance differences began to decrease across problems, the distance concept's total activation also began to decrease. Differences between models (e.g., in activation updating) contributed to whether or when this distance concept activation became so low that the model reverted back to Rule I.

Comparison of Models

A distinct difference among the models of the balance scale previously discussed is whether they attempted to account for the transitions between rules. The earliest model (Klahr & Siegler, 1978) did not, while subsequent models (McClelland, 1989, 1995; van Rijn et al., 2003) did. The fact that both of the subsequent models attempted to account for transitions demonstrates that this is not a distinction between neural network and produc-

tion system models. However, these models attempted to address transitions in notably different ways. The neural network model explained transitions in terms of the same kinds of learning mechanisms applied in a consistent way across experience, with stages arising through changes in representations and how they could be used. In contrast, the production system model explained transitions through the introduction of new knowledge and capacity. On the one hand, these could be viewed as conflicting explanations; the production system model posited changes that are viewed as unnecessary within the neural network. On the other hand, these could be viewed as explanations at different levels; perhaps changes in the production system model could be implemented through changes at the neural network level. For example, apparent changes in capacity can emerge from learning about specific tasks (MacDonald & Christiansen, 2002). Specific models should prove useful in investigating such potential points of contact and contrast between approaches.

Another difference between these models concerns the behaviors that were viewed as central for the models to explain. Although capturing stage-like transitions was central to both McClelland's (1989, 1995) and van Rijn et al.'s (2003) models, these approaches may differ in exactly how stage-like the target behavior was viewed to be. As mentioned, the stage-like progression of McClelland's model was criticized for not being sufficiently stage-like (Jansen & van der Maas, 1997; Rajmakers et al., 1996). This criticism was based in part on the statistical technique of latent class analysis, which was used to try to assess the number and kind of rules leading to observed behaviors on balance scale problems. However, this statistical technique and associated conclusions have been criticized on multiple grounds (Siegle & Chen, 2002). The rules identified through the latent class analysis technique can be very unstable, even within a short test session in which problems are presented in a consistent way. Thus, it is not clear that such analyses truly reveal stable rules being used by children. Furthermore, these techniques have been used to make claims about the abruptness of transitions between rules; however, they would need to be applied to longitudinal data to make such claims, which has not been done.

Other differences between the models might be reconciled in a relatively straightforward way. The van Rijn et al. (2003) model is presented as unique in accounting for transitions between rules in the absence of feedback. This represents an important advance, given that other

models had not simulated this effect. However, other models might be able to accommodate such findings in much the same way that van Rijn et al.'s model did. Van Rijn et al.'s model increased activation of the distance concept with increasing distance differences; in the same way, if McClelland's model were to increase activation of distance processing units, it might lead to similar results. Such a finding would be consistent with the manipulation and conclusions from the van Rijn et al. model. Another possibility is that different models might provide different explanations, or different levels of explanation, for the finding that children can transition between rules in the absence of feedback. For example, neural networks might account for such findings through self-organizing learning algorithms (e.g., Hebbian learning algorithms) that do not rely on feedback.

Language: The Past Tense

In addition to progressing through different stages as described in the balance scale case, children sometimes show U-shaped curves in their developmental trajectories. As these children learn, they first get worse at a task, moving from a higher level of performance to a lower level, and then ultimately progressing back up to a higher level. This kind of behavior should provide important constraints on theories of development, and has been the subject of much discussion (e.g., Zelazo, 2004).

In the case of language learning, children can show a U-shaped learning curve in their production of the past tense inflection for irregular verbs, such as "go." They may initially produce the correct inflection ("went"), but then go through a period where they make overregularizations (saying "goed"), and finally produce correct inflections again. Why children show such U-shaped curves in the learning of the past tense has been the source of considerable debate (e.g., Marcus et al., 1992; McClelland & Patterson, 2002b; Pinker & Prince, 1988; Pinker & Ullman, 2002; Plunkett & Marchman, 1993). In what follows, we consider answers provided through investigations with neural network (e.g., Rumelhart & McClelland, 1986a) and production system models (Taatgen & Anderson, 2002).

Neural Network Models

Neural network models of past tense learning have been used to investigate how U-shaped learning curves might arise through a single representational system, which handles both regular and irregular verbs (Daugherty &

Seidenberg, 1992; Hare & Elman, 1992; MacWhinney & Leinbach, 1991; Plunkett & Juola, 1999; Plunkett & Marchman, 1991, 1993, 1996; Rumelhart & McClelland, 1986a). Such models have been presented with the task of mapping word stems (such as "go") onto their past tense forms ("went"), and have learned through error-driven algorithms. Thus, they learned from changes to connection weights that reduced the discrepancies between their outputs and target outputs. Although children do not often receive explicit error feedback on their syntactic errors (Pinker, 1984), they might receive implicit feedback by comparing their guesses about what inflected form they would hear with what they actually heard.

Rumelhart and McClelland (1986a) presented the first attempt to explain the U-shaped overregularization curve in a single representational system. This model consisted primarily of two layers that mapped a phonological input representation of a word stem to a phonological output representation of the past tense of that stem. With repeated exposures to words, connections in this network were adjusted until the model was able to produce the past tense forms of both regular verbs and exceptions. The network also included a fixed encoding network on the input side that converted representations from a string of individual phonemes to conjunctive representations of phonemes, and a fixed decoding network on the output side that performed the reverse conversion. In this single system, the same units and connections were used for processing regulars and exceptions. As a result, the model naturally handled a key aspect of exception words: They tend to show similarities with regular words, and thus have been termed "quasi-regular" (McClelland & Patterson, 2002b; Plaut, McClelland, Seidenberg, & Patterson, 1996). The majority of exception past tenses in English end in /d/ or /t/ (e.g., had, told, cut, slid, taught), as do regular past tenses. Of the exception past tenses that do not show this pattern, most are quasi-regular in other ways, such as in preserving the consonants from the stem in the past tense form (e.g., sing-sang, rise-rose). Given this structure to the language, the model could leverage the same units and connections developed for mapping the regular past tense in forming past tenses of exception words.

The model also simulated the U-shaped overregularization curve (Figure 10.6); however, it was heavily criticized for relying on questionable manipulations in the training set for this effect (Pinker & Prince, 1988). The model was initially trained on a corpus of 10 verbs (8 ir-

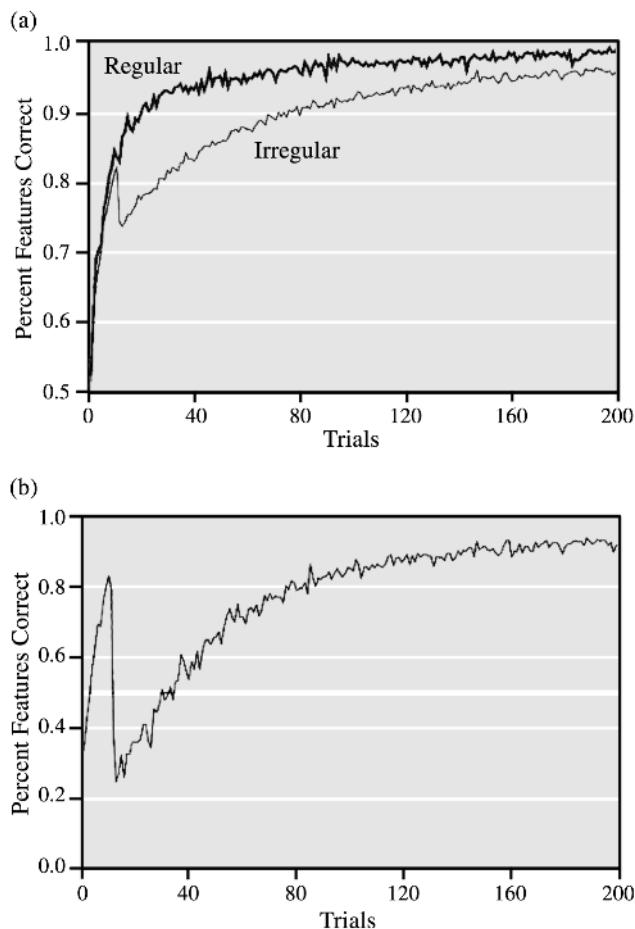

Figure 10.6 Performance of a neural network model of past tense learning broken down by (a) proportion of correct responses and (b) overregularization (computed as irregular correct/irregular correct + irregular regularized). *Source:* From “On Learning the Past Tenses of English Verbs” (pp. 216–271), by D. E. Rumelhart and J. L. McClelland, in *Parallel Distributed Processing: Vol. 2. Psychological and Biological Models*, J. L. McClelland, D. E. Rumelhart, and PDP Research Group (Eds.), 1986, Cambridge, MA: MIT Press. Reprinted with permission from MIT Press.

regular and 2 regular); then 410 verbs (most of which were regulars) were suddenly added to the corpus. This sudden addition of regular words drove the onset of overregularization, as connection weights were adjusted to reduce errors on regular words. These changes led to an increased tendency of the model to regularize in forming the past tense, even with exception words. However, there is no evidence of such a shift in the input to children.

As reviewed elsewhere (e.g., O'Reilly & Munakata, 2000; Taatgen & Anderson, 2002), subsequent neural

network models have aimed to demonstrate how U-shaped overregularization curves can result without questionable manipulations of the training corpus. These models have provided various advances, such as incorporating semantic constraints (e.g., Joanisse & Seidenberg, 1999) and investigating interactions in the acquisition of verb and noun morphology (Plunkett & Juola, 1999). However, these models have not been completely successful in capturing the U-shaped pattern of learning. Models using a static training corpus failed to show an early correct period before overregularization (MacWhinney & Leinbach, 1991; Plunkett & Marchman, 1991). Other models that did show the full U-shaped overregularization curve included manipulations of the training environment (Plunkett & Juola, 1999; Plunkett & Marchman, 1993). Some of these manipulations were not necessary for models to show U-shaped learning (Plunkett & Marchman, 1996). And, attempts were made to justify some manipulations by drawing a distinction between what children perceive and produce and a subset of this information (which served as input to the networks) that drives children's learning (Plunkett & Marchman, 1993). However, a more complete account would show how a model internally focuses on such a subset of information, rather than relying on external manipulations of the training environment.

Production System Model

A production system model of learning the past tense (Taatgen & Anderson, 2002) was used to investigate how U-shaped learning curves might arise through a dual representational system—one system that memorizes specific examples, and a second system that learns the rule to produce regular past tenses (Marcus et al., 1992; Pinker & Prince, 1988). The production systems approach focused on the costs and benefits of regular and irregular verbs. Regular verbs have an advantage in memory demands since only one rule needs to be remembered, whereas irregular past tense words have an advantage in usually being slightly shorter than regular past tense words. Thus, each type of verb has associated costs and benefits. The particular strategy used for forming the past tense at any given time depends on the balance between such costs and benefits, which is a function of the frequency of the words and the previous success of different strategies.

The model began with three strategies for producing a past tense from the stem of a verb:

- 1. Retrieval:** The model retrieved the past tense from declarative memory, if it was sufficiently active.
- 2. Analogy:** The model retrieved a past tense from memory and used it as a template. This strategy was implemented through two rules, the first focusing on the suffix (e.g., “ed”), the second focusing on the stem (e.g., “walk”). The first rule retrieved a past tense from memory; if the past tense had a suffix, it was copied into the suffix for the current word’s past tense. If the goal was to produce the past tense of “walk” and the model retrieved the past tense “followed” from memory, the “ed” suffix from “followed” would be copied into the suffix for the past tense of “walk.” The second rule retrieved a past tense from memory; if the stem was identical in the past and present tense forms of that word, the stem for the current word’s past tense was copied in an analogous way. That is the stem for the past tense was set to be identical to the stem for the present tense. If the goal was to produce the past tense of “walk” and the model retrieved the past tense “followed” from memory, the model would set the stem for the past tense of “walk” to be the same as the stem for the present tense (“walk”), because the stem was identical in “followed” and “follow”. This rule was relatively costly.
- 3. Zero strategy:** The models simply used the stem as the past tense.

New production rules were learned by combining two rules into one rule after they had been used consecutively. And, the number of retrievals from declarative memory was restricted to one per rule, so that when rules were combined, what was retrieved through one rule was substituted into the new rule. The regular rule was produced under the following circumstances: The first analogy rule (which set the suffix) retrieved a regular past tense from memory, and then the second analogy rule (which copied the stem) was used. The new combined rule that resulted set the suffix to “ed” and copied the stem from the current word.

The model was presented with the 478 verbs (89 irregular, 389 regular) that children or their parents use (Marcus et al., 1992), according to their frequency (Francis & Kucera, 1982). For each word, the model’s goal was to produce the past tense. The model learned by adding past tenses it perceived and produced to its declarative memory, by producing new production rules, and by updating its production rules based on their execution times. None of the three initial rules (zero, re-

trieve, and analogy) was particularly effective at the start. Before the model knew how to inflect any verbs, retrieval and analogy failed, so the model could only use the zero rule, producing the stem of a word as the past tense.

Changes in the model’s production rules across learning are shown in Figure 10.7. As the model learned more examples, retrieval became a more viable strategy, for words that were sufficiently active in memory. Higher frequency words were more active, and thus more likely to be retrieved. When words were not sufficiently active to be retrieved, analogy was a viable strategy, since other words could be retrieved as templates.

The model required a certain amount of experience before new rules such as the regular rule appeared, for two reasons. First, the model could form new rules only after it had sufficient experience with the component rules. Second, to learn the regular rule, the model needed to select a regular verb in applying the analogy rule. The chances of this happening were relatively low because the regular verbs were relatively low frequency, and the analogy rule was not used that often because it was costly. Once the regular rule was learned, however, its efficiency made it a viable approach as learning progressed. Retrieval remained the dominant rule, but if the words were not sufficiently active in memory, the regular rule would be applied. With continued learning, most words had sufficient activation in declarative memory for their past tenses to be retrieved, and the

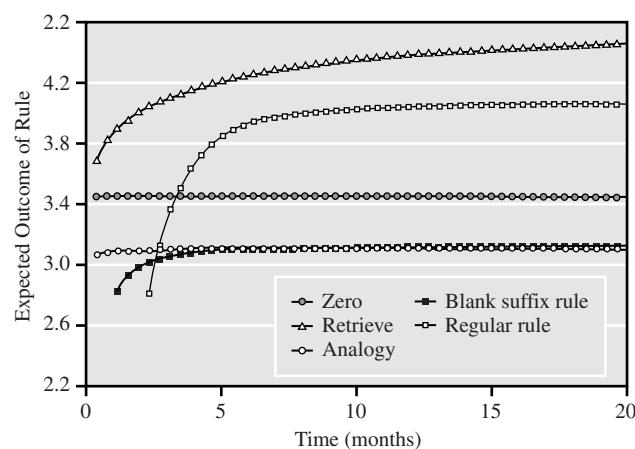

Figure 10.7 Expected outcomes of rules for the production systems model of past tense learning. *Source:* From “Why Do Children Learn to Say ‘Broke’? A Model of Learning the Past Tense without Feedback,” by N. A. Taatgen and J. R. Anderson, 2002, *Cognition*, 86, pp. 123–155. Reprinted with permission.

regular rule was used only for low-frequency regulars and novel words.

The model's performance is shown in Figure 10.8. The model improved its performance on regular verbs (shown in both graphs), through both retrieval and regular rule use. Coincident with learning of the regular rule, the model showed a dip in its performance on irregular verbs, shown in the top graph as a decrease in "Irregular correct" and an increase in "Irregular regularized," and in the bottom graph through a standard measure of overregularization: irregular correct (irregular correct + irregular regularized). This model was also able to simulate individual differences in children's overregularization in terms of differences in environmental input; the greater the ratio of inputs from the environment relative to inputs

from the child's own production, the less overregularization models showed.

Comparison of Models

The production systems and neural network models both approach past tense learning in terms of producing past tenses from stems. However, these approaches differ in multiple ways and are based on different assumptions about the basis for learning. First, the neural network models learned through error signals, which may be based on discrepancies between a child's understanding of past tense words and what is actually heard in the environment. In contrast, the production system model learned to adjust its rule use based on internal feedback about what it had done. It also stored the past tenses that it had produced and perceived. Second, the neural network models learned through a single representational system that handled both regulars and exceptions; in each case, past tenses were produced through activation of shared units, and were learned through changes to shared connection weights. In contrast, the production system model relied on a dual representation system, one that memorized specific examples and another that learned the regular rule.

Each model may be viewed in terms of its relative strengths and weaknesses. Taatgen and Anderson's (2002) model better captured what is known about the frequencies of different words in the environment, whereas most neural network models relied on changes in the statistics of the training corpus to yield U-shaped developmental curves (Plunkett & Juola, 1999; Plunkett & Marchman, 1993; Rumelhart & McClelland, 1986a). This criticism can also be applied to some symbolic past tense models (Ling & Marinov, 1993), so that it is not specific to neural network models. However, neural network models using backpropagation or other error-driven algorithms may be uniquely dependent on such changes in the environmental input to produce U-shaped learning curves of the past tense (O'Reilly & Hoeffner, submitted). Without such environmental changes, error-driven models might be expected to show no early correct period with exception words or no worsening in performance (overregularizations) across time. If the environmental input led to regulars dominating learning, the weights would favor the regular form of the past tense, so models should overregularize early in learning without showing an early correct period. If, instead, the environmental input provided enough experience with exceptions to support an early correct period, the exceptions

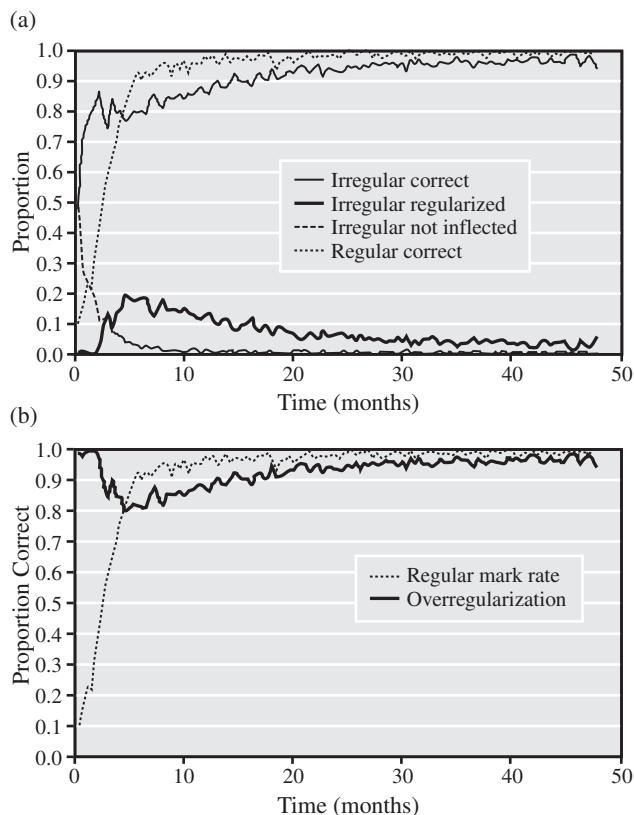

Figure 10.8 Performance of the production systems model of past tense learning broken down by (a) proportion of responses and (b) overregularization (computed as irregular correct/irregular correct + irregular regularized) and regular mark rate (computed as regular correct/regular correct + regular incorrect). *Source:* From "Why Do Children Learn to Say 'Broke'? A Model of Learning the Past Tense without Feedback," by N. A. Taatgen and J. R. Anderson, 2002, *Cognition*, 86, pp. 123–155. Reprinted with permission.

should thus be sufficiently dominant to not be overwhelmed by the regulars. In this case, there might be no worsening in performance (overregularizations) with time and learning of the regular past tense. In other domains, error-driven learning models with fixed training environments have shown U-shaped developmental curves (Rogers & McClelland, 2004). However, it remains to be seen whether the environmental structure that leads to such curves is relevant to domains such as learning of the past tense.

A relative strength of the neural network models is their ability to capture important commonalities across regular and exception words, such as the tendency to end in /d/ or /t/ as discussed earlier. Again, such commonalities were handled very naturally in neural network models because connections that supported such endings to past tense forms were shared across regular and exception words. In contrast, the production systems model generated past tenses through the use of one production at a time, which prevented it from leveraging any learning of the regular past tense that would be applicable to learning of exceptions (McClelland, Plaut, Gotts, & Maia, 2003). For any given word, the past tense would be formed either by a production that used the regular rule or by a production that was specific to that word as an exception. There could be no benefit on exception words that shared properties with regulars. This is problematic, given that exceptions tend to be quasi-regular, but might be remediable in such production system models if processing were distributed across multiple, shared productions (McClelland et al., 2003).

Taatgen and Anderson (2002) discuss another difference between models: The production system model could learn its incorrect productions, which may explain why children sometimes do not respond to corrections to their production. Taatgen and Anderson (2002) point out that existing neural network models of past tense production would have difficulty simulating this effect, because no learning occurs based on productions per se, and experience with the correct information should lead to rapid learning of the correct past tense. However, error-driven learning is not always rapid, as evidenced by stage-like stable periods of performance in the balance scale case. In addition, self-organizing neural network models have been shown to learn from their incorrect productions (e.g., McClelland, 2005), and such mechanisms have been incorporated into neural network models of past tense learning (O'Reilly & Hoeffner, submitted; discussion in O'Reilly & Munakata, 2000).

Thus, this difference may not be an inherent one between neural network and production systems approaches.

Finally, the models differ in their levels of analysis, although in some ways they are closer to one another than earlier competing accounts. Graded learning in production rules (Taatgen & Anderson, 2002) is more in line with graded activations of representations (Rumelhart & McClelland, 1986a) and contrasts with earlier, sharper distinctions (e.g., graded versus discrete) between competing accounts (McClelland & Patterson, 2002a). Much of the earlier debates focused on comparing dual representation accounts that were unimplemented (Marcus et al., 1992; Pinker, 1991)—and thus less well specified and less amenable to testing—with single representation accounts that had a fairly extensive history of implementation (Daugherty & Seidenberg, 1992; Hare & Elman, 1992; MacWhinney & Leinbach, 1991; Plunkett & Juola, 1999; Plunkett & Marchman, 1991, 1993, 1996; Rumelhart & McClelland, 1986a). The availability of implemented models of competing accounts should help advance the debate about the mechanisms underlying children's U-shaped past tense learning curves, and inform the study of language learning and cognitive development more generally.

Memory: The A-not-B Task

The final domain in which comparable models are considered in this chapter is infants' memory for objects that are presented and then hidden. As described, infants show a gradual task-dependent progression in their sensitivity to the continued existence of such objects. Infants appear sensitive to object permanence in violation-of-expectation studies with hidden objects within the first few months of life (Baillargeon, 1999; Spelke et al., 1992), but they fail to search for hidden objects for several more months (Goubet & Clifton, 1998; Piaget, 1954), even after developing the requisite motor and problem-solving skills for retrieving the objects (Munakata et al., 1997; Shinskey & Munakata, 2001; Spelke, Vishton, & von Hofsten, 1995).

Even after infants successfully search for objects hidden in a single location, they fail the Piagetian A-not-B task (Piaget, 1954; Marcovitch & Zelazo, 1999; Wellman, Cross, & Bartsch, 1986). In this task, infants watch as an object is hidden in one location (the A location). Typically, infants are allowed to search for the object, and these A trials are repeated several times. Then, infants watch as the object is hidden in a new location

(the B location). Infants often perseverate, reaching back to the previous hiding location instead of the correct one, making the A-not-B error. Infants make such errors from as soon as they begin reaching for hidden objects. And, they continue to make them as they develop, with only a longer delay period needed after the object is hidden before infants are allowed to reach to produce the error in older infants (Diamond, 1985).

Even as infants reach perseveratively to a previous hiding location for a toy, they occasionally gaze at the correct hiding location (Piaget, 1954; Diamond, 1985; Hofstadter & Reznick, 1996). Further, in violation-of-expectation variants of the A-not-B task, infants look longer when a toy hidden at B is revealed at A than when it is revealed at B, following delays at which they would nonetheless search perseveratively at A (Ahmed & Ruffman, 1998).

We next describe and compare neural network and dynamic systems models of the A-not-B error.

Neural Network Model

A neural network model of the A-not-B error (Munakata, 1998; see also Morton & Munakata, 2002; Stedron, Sahni, & Munakata, 2005) was built on a distinction between active and latent memory traces in the neural network framework (see also J. D. Cohen, Dunbar, & McClelland, 1990; J. D. Cohen & Servan-Schreiber, 1992). Active traces take the form of sustained activations of network processing units (roughly corresponding to the firing rates of neurons), and latent traces take the form of changes to connection weights between units (roughly corresponding to the efficacy of synapses). According to the active-latent account:

- Latent memory traces, subserved primarily by posterior cortical regions, form when organisms change their biases toward a stimulus after processing it, so that they may respond differently to the stimulus on subsequent presentations. For example, after infants repeatedly attend to a hiding location and reach there, they lay down latent traces biasing them toward that location, making them more likely to reach there in the future. These latent traces are not accessible to other brain areas, because synaptic changes in one part of the brain cannot be communicated to other areas. Rather, latent traces can only influence processing elsewhere in the system in terms of how they affect the processing of subsequent stimuli, and resulting patterns of activation.

- Active memory traces, subserved primarily by prefrontal cortical regions, result when organisms actively maintain representations of a stimulus. For example, infants in the A-not-B task might maintain active memory traces for the most recent hiding location of an object. Unlike latent traces, such active representations may be accessible to other brain areas in the absence of subsequent presentations of the stimulus, because neuronal firing in one region can be communicated to other areas.
- Perseveration and flexible behavior can be understood in terms of the relative strengths of latent and active memory traces. The increasing ability to maintain active traces of current information, dependent on developments in prefrontal cortex, leads to improvements in performance on tasks such as A-not-B.

As described in detail elsewhere (Munakata, Morton, & Stedron, 2003), this active-latent account is motivated by behavioral and neuroscience data supporting the existence, localization, and development of these distinct types of representation (e.g., Casey, Durston, & Fosella, 2001; J. D. Cohen et al., 1997; Fuster, 1989; Miller & Desimone, 1994; Miller, Erickson, & Desimone, 1996). This account also shares several features with and builds on existing accounts of perseveration (e.g., Dehaene & Changeux, 1991; Diamond, 1985; Roberts, Hager, & Heron, 1994; Wellman et al., 1986).

The network consisted of two input layers that encoded information about the location and identity of objects, an internal representation layer, and two output layers for gaze/expectation and reach (Figure 10.9a). The gaze/expectation layer could respond (update the activity of its units) throughout the A-not-B task, whereas the reaching layer could respond only when the hiding apparatus was made available for a choice. This constraint was meant to capture that infants are allowed to reach at only one point during each A-not-B trial, when the apparatus is moved to within their reach, whereas they may gaze and form expectations (which may underlie longer looking to impossible events) throughout each trial.

The network's feedforward connectivity included an initial bias to respond appropriately to location information, so that the network would look to location A if something were presented there. The network also developed further biases based on its experience during the A-not-B task. Learning occurred according to a Hebbian learning rule, such that connections between units

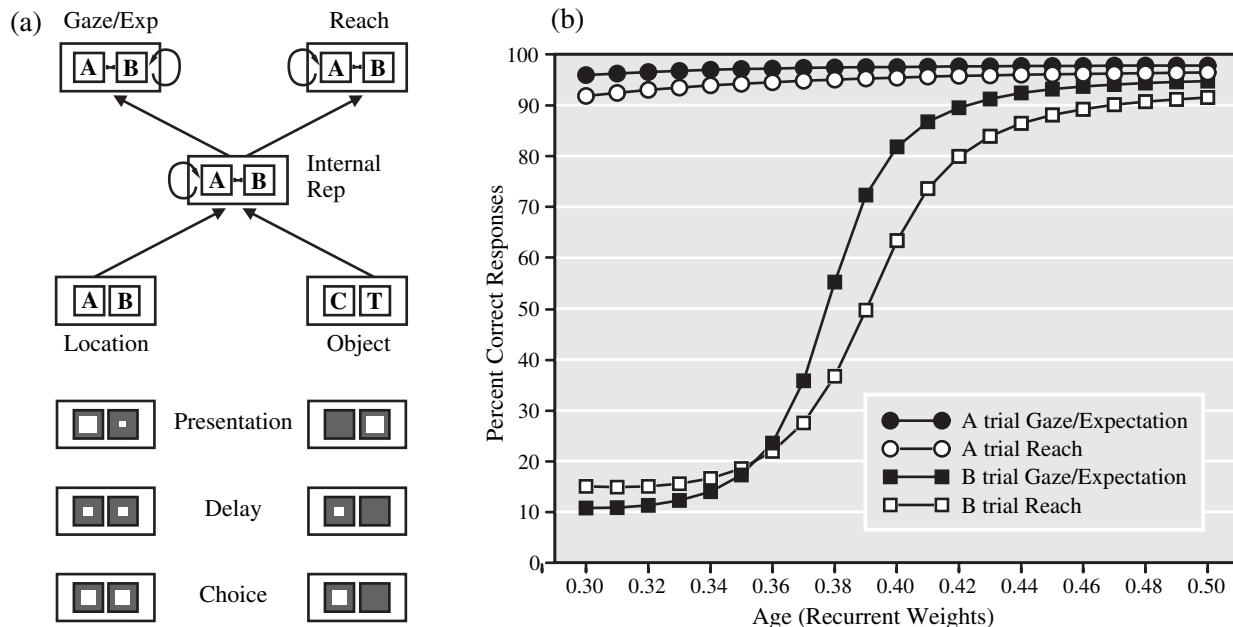

Figure 10.9 A neural network model of the A-not-B task: (a) Simplified architecture and elements of an A trial: The activation level of the input units for the three segments of the trial is shown by the size of the white boxes. The “Object” input indicated whether a cover (“C”) or toy (“T”) was visible. (b) Performance as a function of age: On A trials, the network is accurate across all levels of recurrence shown. On B trials, the network responds non-perseveratively only as the recurrent weights get stronger. The network responds correctly through gaze/expectation earlier in development than through reaching. *Source:* From “Infant Perseveration and Implications for Object Permanence Theories: A PDP Model of the Task,” by Y. Munakata, 1998, *Developmental Science*, 1, pp. 161–184. Reprinted with permission.

that were simultaneously active tended to be relatively strong. The network’s latent memory thus took the form of these feedforward weights, which reflected the network’s prior experiences and influenced its subsequent processing.

Each unit in the hidden and output layers had a self-recurrent excitatory connection back to itself. These recurrent connections were largely responsible for the network’s ability to maintain representations of a recent hiding location. The network’s active memory thus took the form of maintained representations on the network’s hidden and output layers, as supported by its recurrent connections. To simulate gradual improvements with age in the network’s active memory, the strength of the network’s recurrent connections was increased. This manipulation might be viewed as a proxy for experience-based weight changes that have been explored elsewhere (e.g., Munakata et al., 1997).

The simulated A-not-B task consisted of four pretrials (corresponding to the practice trials typically provided at the start of an experiment to induce infants to

reach to A), two A trials, and one B trial. Each trial consisted primarily of three segments: the *presentation* of a toy at the A or B location, a *delay* period, and a *choice* period (Figure 10.9a). During each segment, patterns of activity were presented to the input units corresponding to the visible aspects of the stimulus event. The levels of input activity represented the salience of aspects of the stimulus, with more salient aspects producing more activity. For example, the levels of input activity for the A and B locations were higher during *choice* than during *delay*, to reflect the increased salience of the stimulus when it was presented for a response.

Like infants, the model made the A-not-B error (successful reaching on A trials with perseverative reaching on B trials), improved with age, and showed earlier sensitivity on trials in its gaze/expectation than in its reach (Figure 10.9b). The network performed well on trials at all ages because latent changes to the feedforward weights, built up over previous trials in which the network represented and responded to A, favored A over B. These latent memories thus supported enough activity at

A that the network's ability to maintain activity at A had little effect on performance. In contrast, the network's ability to maintain activity for the most recent hiding location was critical to its performance on trials, because the network had to maintain a representation of B in the face of the latent bias to respond to A. In particular, the network's connection weights had learned to favor activity at A over B, based on repeatedly attending and responding to the location. With weak recurrent connections, the active memory for B faded during the *delay*, and the network perseverated to A. Stronger recurrent weights allowed older networks to maintain an active memory of B during the delay. These networks were thus better able to hold information about a recent hiding location in mind, rather than simply falling back to biases for previous locations.

The network's greater sensitivity in its gaze/expectation than in its reach can be understood in terms of the different rates of responding in these systems and their interaction with graded strengths of active memories of the correct location. As the network became increasingly able to maintain active representations of a recent hiding location, the gaze/expectation system was able to take advantage of this information with its constant updating, showing correct responding during *presentation* and *delay*, which carried over to *choice*. In contrast, the reaching system was only able to respond at *choice*. Because the network's active memory for the most recent location faded with time, by the *choice* point, the network's internal representation reflected more of the network's latent memory of A. The gaze/expectation system was thus able to make better use of relatively weak active representations of the recent hiding location. In the same way, infants may show earlier success in gaze/expectation variants of the A-not-B task because they can constantly update their gazing and their expectations. As a result, they can counter perseverative tendencies on B trials by gazing at and forming expectations about B during the *presentation*, *delay*, and *choice* trial periods. In contrast, infants can only reach at the *choice* point, by which time their memories have become more susceptible to perseverative biases.

Dynamic Systems Model

The dynamic systems approach to understanding the A-not-B error reflects many of the hallmarks of dynamic systems approaches more generally, as discussed earlier. Infants' knowledge of hidden objects is viewed as softly assembled within the particular task context, rather than

taking the form of enduring concepts that infants have or do not have. Whether infants err is multiply determined, influenced by factors such as age and delay as already mentioned, but also by many others including number of A trials (Marcovitch & Zelazo, 1999; Smith, Thelen, Titzer, & McLin, 1999) and distinctiveness of hiding locations (Bremner, 1978; Wellman et al., 1986).

A dynamic systems model of the A-not-B error (Thelen et al., 2001) focused on motor planning fields, where visual input and motor memory are integrated, and decisions to reach (e.g., to location A or B) are generated. According to this account:

- Three types of inputs are provided to the motor planning field: Task input (e.g., the location, distinctiveness, and attractiveness of targets at the A and B locations), specific input (e.g., the transient drawing of attention to the B location), and memory input (the history of all previous reaches).
- Motor planning fields evolve over time, based on their prior states and the inputs to the system. Different sites in the field interact, with close sites exciting one another, and more distant sites inhibiting one another. Activations are thresholded, such that only sites with certain levels of activation participate in these interactions.
- Perseveration and correct reaching arise as a function of these interactions in the motor planning fields. In the equations specifying these interactions, small quantitative changes in parameters can lead to qualitative differences in reaching (e.g., to the previous A location or to the correct B location).

As described in detail elsewhere (Thelen et al., 2001), this dynamic systems account was motivated by behavioral and neuroscientific studies supporting the notion of graded, continuously evolving motor plans (Fisk & Goodale, 1995; Georgopoulos, 1995; Hening, Favilla, & Ghez, 1988).

The model dynamics are specified mathematically, with separate equations for computing the task input, specific input, and memory input to the motor planning field. These inputs are then summed. The state of the motor planning field at any given time is a function of those summed inputs and the previous state of the motor planning field.

A key parameter in these equations sets a resting level to the motor planning field. This resting level has important effects on the degree to which the system is

driven by inputs to it. With a small value, strong input is required for sites to have sufficient activity to reach threshold and contribute to the motor planning field dynamics. With larger values, additional sites can reach threshold and contribute to these dynamics. Self-sustained excitation in the absence of continual input may be possible under such circumstances.

Two runs of this system with different values are shown in Figure 10.10, with a younger model (with lower value) shown in the upper panel and an older model (with higher value) shown in the lower panel. The task, specific, and memory inputs are shown in the left columns of each panel, and are identical across the two runs. The task input reflects the existence of two identical lids at locations A and B, present across the trial. The specific input reflects attention being drawn to location B transiently, only at the start of the trial. The memory input reflects the longer-term memory of previous trials at A.

The corresponding motor planning fields at the two different ages show different patterns. Although both show greater activation at B than at A at the start of the trial (while there is specific input at B as attention is drawn to the B location), this activation is weaker in the younger model. This activation decays across the delay in the younger model, so that by the end of the delay, activation is greater at A, leading to an incorrect reach. In contrast, the greater activation at B in the older model is maintained during the delay, leading to a correct reach.

These differences in performance were driven solely by changes to the resting level of the motor planning field. With lower resting levels, fewer sites can reach threshold and contribute to the motor planning field dynamics. As a result, the system relies relatively strongly on the input coming into it for sites to have sufficient activity. As the trial unfolds, the system thus shows greater activation at A, because it has greater input from the memory input. In contrast, with higher resting levels, more sites can reach threshold and contribute to the motor planning field dynamics. As a result, the system relies less on the input coming into it for sites to have sufficient activity. Instead, neighboring sites in the system have sufficient activity to stably excite one another. As a result, as the trial unfolds, the system is less sensitive to the greater memory input for A, and can maintain activation for B.

This model did not specifically simulate the differences observed in the measures of the A-not-B task (e.g., reaching versus gazing versus expectation). How-

ever, such differences might be captured naturally within such models, in terms of different equations to capture the distinct dynamics of different behaviors (Theelen et al., 2001), which would lead to differences in motor planning fields and memory input.

Comparison of Models

These neural network and dynamic systems models of the A-not-B task have important similarities and differences (Munakata & McClelland, 2003; Munakata, Sahni, & Yerys, 2001; Smith & Samuelson, 2003; Theelen et al., 2001). In terms of similarities, first, both models focus on the importance of stability in activation dynamics, particularly the stability of currently relevant information. In both models, development was simulated through changes to a single parameter affecting this stability (strength of recurrent connections in the neural network model, and resting level in the dynamic systems model). Small changes to the single parameter in each model led the models to progress from reaching perseveratively to an old location to reaching successfully to a new location. Second, both models could account for a wide range of A-not-B findings beyond those covered here. In both cases, the models could naturally capture why so many factors affect performance, through the influence of such factors on the basic components guiding behavior in the models (e.g., activity levels). Third, both models have been extended to explain cases of perseveration in older children (Morton & Munakata, 2002; Schutte & Spencer, 2002). Fourth, both models have led to novel predictions that have since been supported (e.g., Munakata & Yerys, 2001; Spencer, Smith, & Theelen, 2001). In some cases, the models have led to the same prediction. Both models led to the prediction that infants should show a U-shaped pattern of development on the A-not-B task if younger infants could be tested. That is, infants should first show worse performance with increasing age, and then better performance. This prediction has been confirmed (Clearfield & Theelen, 2000). The models are thus compatible in many ways.

The main substantive differences concern the focus of the models. An important difference is in the focus on learning in the neural network model versus embodiment in the dynamic systems model (see Elman, 2003; Spencer & Schöner, 2003, for discussion of this general issue). Neural network models tend to stress learning as the engine of change in development, whereas in many dynamic systems models, developmental differences

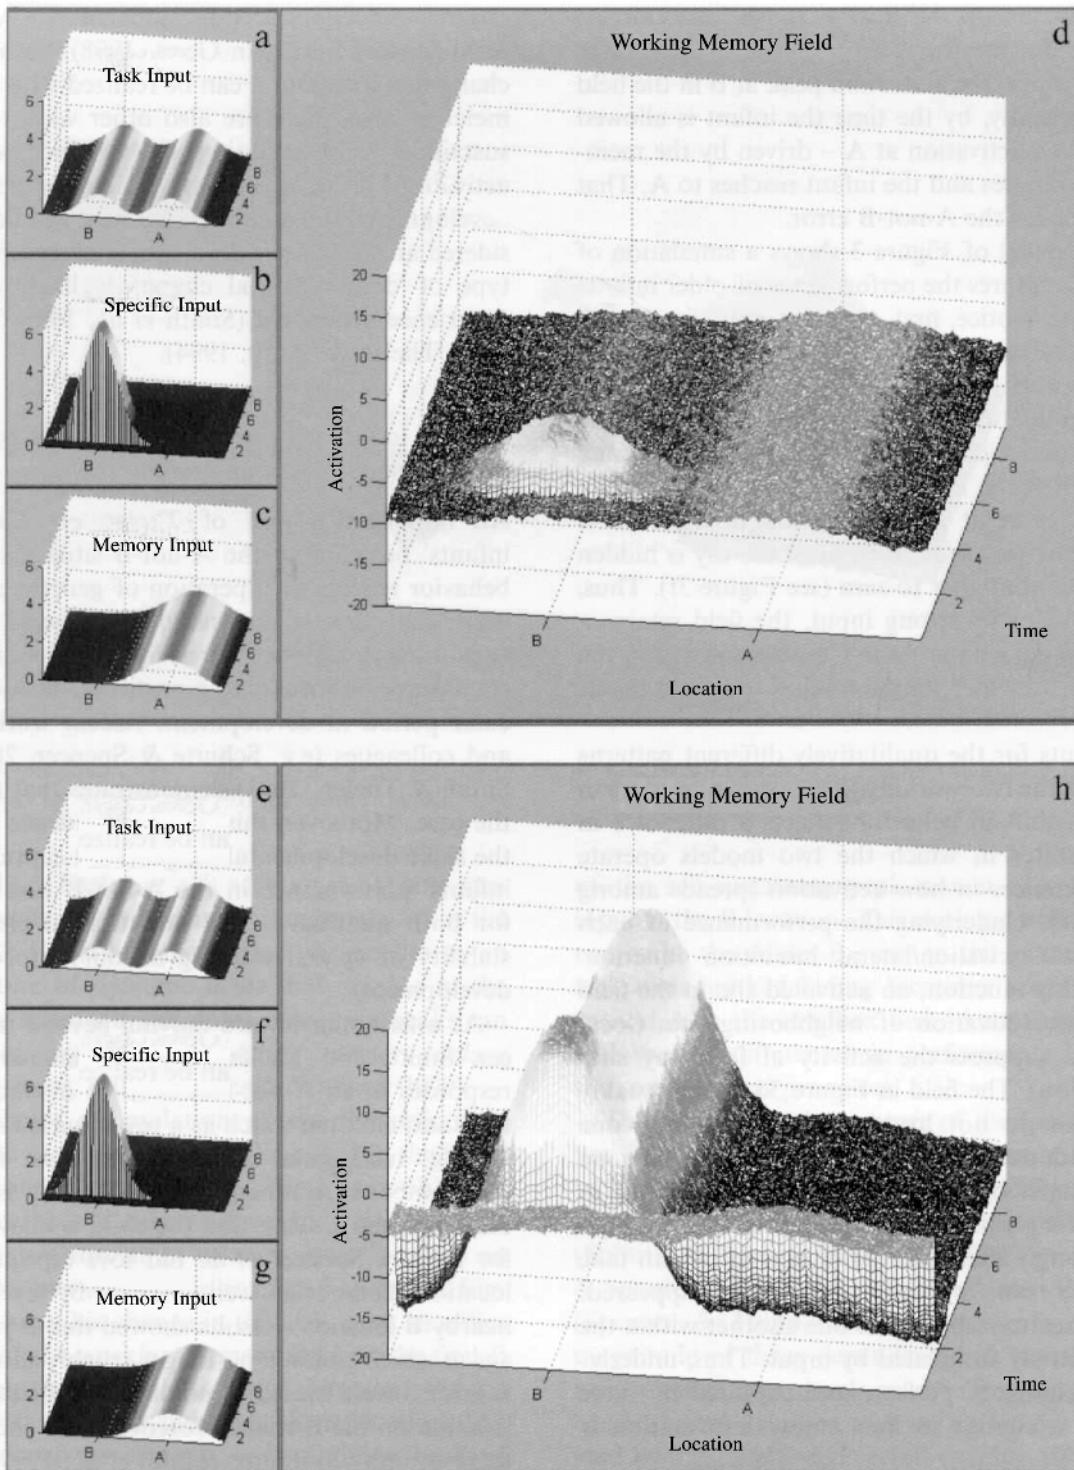

Figure 10.10 Dynamic systems account of the A-not-B error. The two panels correspond to the model at two ages (two different levels of the resting activity level). Each panel shows the three inputs to the model in the left column, and the resulting motor planning field on the right. In each graph, the x-axis represents location, the y-axis represents time, and the z-axis represents activation. Motor planning fields are referred to as “working memory fields.” *Source:* From “The Dynamics of Embodiment: A Field Theory of Infant Perseverative Reaching,” by E. Thelen, G. Schöner, C. Scheier, and L. B. Smith, 2001, *Behavioral and Brain Sciences*, 24, 1–86; Adapted from “Bridging the Representational Gap in the Dynamic Systems Approach to Development,” by J. P. Spencer and G. Schöner, 2003, *Developmental Science*, 6, pp. 392–412. Reprinted with permission.

are attributed to differences in a control variable whose change as a function of age is assumed but not explained. In the neural network model of the A-not-B task, recurrent connections supporting active representations are posited to increase over the course of experience; the details of how experience may shape such changes have been investigated in various neural network models of object knowledge (e.g., Mareschal et al., 1999; Munakata et al., 1997). In contrast, in the dynamic systems model of the A-not-B task, an external control variable changes as a proxy for development, without an explanation of what leads to such changes. On the other hand, dynamic systems approaches have tended to emphasize the importance of embodiment, with factors such as reaching kinematics, body posture, and so on affecting behavior, whereas such factors have not typically been incorporated into neural network models. The dynamic systems model of the A-not-B task uses specific equations to try to capture some of the dynamics specific to reaching. Although looking behaviors are not simulated, these might require different equations to capture the unique dynamics of the oculomotor system. In contrast, in the neural network model of the A-not-B task, the looking and reaching components of the system are identical aside from how often they update.

Another important difference between the two models concerns the focus on motor planning dynamics in the dynamic systems model versus distinct types of representations in the neural network model. In the dynamic systems model, all inputs are summed to yield their contribution to the motor planning field. The resulting unified field is viewed as an essential aspect of embodiment. In contrast, in the neural network framework, information may be represented in qualitatively different ways (e.g., in synaptic changes versus in the firing of populations of neurons). These distinct kinds of representation may interact in complex ways that are not captured in a single planning field representation.

Additional differences between the models exist, but seem less inherent to the two modeling approaches and so could likely be reconciled. The dynamic systems model includes noise (e.g., the model occasionally reaches to B on A trials), whereas the neural network model does not. The neural network model represents input in terms of a unified representation of the visible environment, whereas the dynamic systems model separates the input into task (static) and specific (transient) inputs.

GENERAL ISSUES

As reviewed in this chapter, information processing approaches have helped to inform the study of development in many ways. However, the contributions from such approaches have perhaps not always been appreciated to their fullest extent. This final section covers potential criticisms of models that may contribute to this underappreciation, responses to such criticisms, and directions for future modeling work that may have significant impact on our understanding of development.

Why Model? (Revisited)

Criticisms have been raised to discount the possible contributions of models. In evaluating any specific model, these criticisms are important to keep in mind; however, it is misguided to use them to discount the entire modeling endeavor and what can be learned from models. This argument may become clearest when comparing the process of constructing models with the process of constructing theories. The importance of constructing theories to understand data has long been appreciated across diverse fields. In the study of behavior and cognition, Newell (1973) argued, “You can’t play 20 questions with nature and win,” in a chapter by the same name. He reasoned that you cannot hope to fully understand the complexity of the human mind by simply posing yes/no questions and collecting data ad infinitum to try to determine the answer. A richer and more complete theoretical model is needed.

Potential criticisms of models could also be applied to theories. In the case of theories, the natural reaction is likely to be one of trying to determine how to address the criticisms and develop better theories, rather than abandoning the entire endeavor of formulating and testing theories. The same reaction is arguably warranted in the case of models.

The Indeterminacy Problem

A common criticism of computational models is that they are powerful enough to simulate anything, so their ability to simulate human behavior is uninteresting (Roberts & Pashler, 2000). Relatedly, multiple different models can be constructed to simulate the same behavior, the indeterminacy problem. They all work and they can’t all be right, so the models are too powerful. As a result, simply getting a model to work does not tell us

anything about the processes underlying behavior and development. Although these are important considerations, they should help shape the evaluation of models, instead of challenging the modeling endeavor altogether.

First, criticisms about too much power and indeterminacy are relevant for any attempts at scientific theorizing and are not unique to computational models. There are multiple competing verbal theories—of language development, memory development, and so on—that can explain the same data. These theories may be powerful enough to explain such data (as well as new data as it is provided), in part because of the flexibility of positing new constraints on the theories as new data become available.

However, this does not mean that the process of developing theories tells us nothing, in the same way that issues of power and indeterminacy do not mean that developing models tells us nothing. Instead, competing theories and models can be evaluated according to many more criteria than simply accounting for a set of data. For example, which theories or models provide the most coherent, principled account of the data, as opposed to requiring post hoc adjustments to account for each finding? Which provide unique predictions that have been tested and confirmed? Which generalize best to findings outside of those targeted for the theory/model? When multiple models are constructed to address the same phenomena (as in the cases of the balance scale task, past tense learning, and the A-not-B task considered here), this process may be particularly useful in highlighting the relative strengths and weaknesses of different approaches, even if all the models can simulate the main behaviors of interest.

Second, although computational models are very powerful, the contributions from some models have come from instances where they fail. The effects of brain damage in adults can be studied by lesioning corresponding areas or processes in working models (e.g., J. D. Cohen, Romero, Farah, & Servan-Schreiber, 1994; Farah et al., 1993; Farah & McClelland, 1991; Haarmann et al., 1997; Kimberg & Farah, 1993; Plaut, 1995). In these cases, the models were trained to perform correctly, but were informative in how and why they performed incorrectly after damage. Similarly, atypical functioning can be incorporated into models during their development, to observe the effects on the overall system and to compare developmental disorders to cases of adult brain damage (Thomas & Karmiloff-Smith, 2002, 2003). Again, the

original models were trained to perform correctly, but the models were informative in their failures with alterations during different stages of development. Finally, in other cases, failures of models have provided insight into the need for multiple, specialized information processing systems to satisfy computational trade-offs (McClelland, McNaughton, & O'Reilly, 1995; O'Reilly & Munakata, 2000).

Models Are Too Complex

A related criticism is that models are too complex; given how difficult it is to understand why they behave the way they do, how could they possibly help us to understand child development?

Again, scientific theories in general may be subject to the same criticism. Purely verbal theories might have so many factors, caveats, interactions, and so on that they seem to yield little in the way of understanding what is happening in the child. In fact, when theories seem less complex than models, this may only reflect vagueness about the details of how the theory actually works—exactly the kind of details that must be confronted when constructing models.

However, criticisms of unwieldy complexity do not mean the processes of scientific theorizing or computational modeling should be abandoned. Rather, specific theories and models can be evaluated according to whether they provide coherent and principled accounts. If a complex model or theory simply accounts for existing data, without contributing to a greater understanding of behavior, then the complexity is not worth the cost. However, if a complex model or theory not only accounts for existing data, but provides a satisfying account of the principles guiding behavior, then the cost of the complexity may be worth the benefits to understanding. Again, models may be particularly useful in this trade-off, because complex phenomena can be captured and understood in such models.

Models Are Too Simple

Another common criticism of models is that they are too simple, so they are unrealistic and cannot inform the study of child development. This criticism might be aimed at various aspects of models, such as the way that they represent the child's environment, the task of interest, the child's thought processes, the underlying biology, and so on.

Such criticisms are relevant for any attempts at scientific theorizing and are not unique to computational models. One verbal theory might not pay sufficient attention to the role of social interactions in a child's development, while another theory might fail to make contact with underlying biological mechanisms or even seem to directly contradict what is known about the underlying biology. However, such limitations are typically viewed as challenges to particular theories, rather than to the whole process of scientific theorizing. In the same way, limitations to particular models should not be viewed as challenges to the whole modeling endeavor.

Models (and theories) are by definition simplifications. Factors that are thought to be relevant are incorporated so that they can be manipulated and tested, while other factors are not incorporated. Thus, simply pointing to a way in which a model is simplified does not constitute a clear challenge to the model. Instead, the more important question is whether the simplifications miss factors that are critical to the behavior of interest, and if so, what are those factors and what role do they play? Models can be particularly useful tools for informing such questions in scientific theorizing, because models help to make explicit which factors are thought to be relevant and which not, and to then support the testing of the roles played by both the factors of interest and other factors.

Models Are Reductionistic

Finally, another common concern is that models are reductionistic, focusing on low-level mechanisms that cannot possibly capture or inform the study of the richness of human cognition and development. This point also is relevant to scientific theorizing more generally. There is a tendency for sciences to become more reductionistic as they progress. Early in the biological sciences, ephemeral, vitalistic theories were common, where components were posited without physical evidence for them. With the advent of modern molecular biology, the underlying physical components (proteins, nucleic acids, etc.) could be measured and localized, and theories updated accordingly. Reductionism of this sort—reducing complex phenomena into their simpler underlying components—is an inherent part of the scientific process. Verbal theories may reduce the richness of human behaviors down to low-level mechanisms in just the same way as models; models may simply be more explicit about this reduction.

In both cases, the essential consideration may be the complementary process of understanding the complexity

that emerges from the interaction of simpler underlying components. Understanding the component pieces alone may not be sufficient for understanding the whole. A complementary process has been emphasized across different theoretical frameworks. Predecessors to dynamic systems theory (von Bertalanffy, 1968) emphasized the importance of relationships among biological elements and the resulting system that required a level of description distinct from that for the individual elements. Physiological psychologists (Teitelbaum, 1967) advocated complementary processes of analysis (dissecting and simplifying to understand basic elements of a system) and synthesis (combining elements to understand their interactions). And, some neural network approaches (O'Reilly & Munakata, 2000) have emphasized that reductionism requires a complementary process of *reconstructionism*. Understanding neurons is not sufficient for understanding human cognition; human cognition emerges from the complex interaction of such components. Thus, the larger phenomenon must be reconstructed from an understanding of the pieces.

Future Directions

How can information processing approaches and computational models continue to inform our understanding of development? Constructivist models, all-purpose models, multiple models, and accessible models represent directions for future work that seem particularly promising.

Constructivist Models

Piaget emphasized constructive processes in development, whereby children play an active role in their own development rather than simply being passive recipients of their environments. Children can shape their environments and the kinds of stimuli that are available to learn from, through their actions. Infants who reach for objects receive different sensory information about the objects than infants who simply gaze at the objects. The language children produce affects the language directed at them, the problem-solving skills children demonstrate might affect the kinds of activities they are presented with, and so on.

In contrast, much work within the information processing approach to development has focused on how children react to and learn from a fixed set of stimuli, with less attention given to the complementary process of children affecting their environments. Most models are fed their inputs, stimulus after stimulus, regardless of what they output. Language learning models see sen-

tence after sentence, no matter how poorly the models do in their comprehension. Similarly, models see the same objects in their environments regardless of how they behave toward the objects.

A promising direction for future work thus focuses on models that shape their environments (Schlesinger & Parisi, 2001). How these models behave influences their subsequent inputs, rather than receiving a fixed stream of inputs.

All-Purpose Models

Most models are designed for and tested on a single task within a single domain, such as the balance scale task, learning the past tense, or searching for hidden objects. Typically, a single model sees only this single task during the course of its development. Again, in contrast, children face a multitude of tasks across a range of domains each day. Capturing this important aspect of processing requires models that take in a variety of types of information and determine how to appropriately process them to perform successfully across numerous tasks (discussion in, e.g., Karmiloff-Smith, 1992; Newell, 1973).

One model representing a step in this direction focused on the effects of engaging in one task versus multiple tasks across development (Rougier et al., 2005). The tasks in this simulation included naming objects, matching objects, and making different kinds of comparisons among objects. Although these are only a small subset of the numerous tasks children face, they represent more variety than models are typically presented with, and they allowed an exploration of the developmental effects of multitasking. The primary finding was that training on multiple tasks led to the formation of more abstract, flexible knowledge representations, which could be generalized to new situations. Thus, such models may yield insight into the developmental progressions leading up to the unique flexibility of human knowledge.

Multiple Models

Another important step in future work will be the continued comparison of models. Given the indeterminacy problem, it is not enough to have models that simulate data (or theories that account for data). Models must be compared along many other dimensions to support an assessment of how they inform an understanding of behavior and development. This comparison process will be relevant for competing models of the same type (e.g., two production system models of the balance scale task) and for models of different types, which may or may not

be compatible. This chapter focused on contrasts between production systems and neural network models, and between dynamic systems and neural network models, with both important similarities and differences noted. Future work should include additional types of comparisons among the four information processing approaches discussed here and more abstract Bayesian models (Anderson, 1990; Gopnik, 2005; Oaksford & Chater, 1994), more detailed neurobiological models (Medina & Mauk, 2000), and hybrid models that incorporate both production systems and neural network components (Hummel & Holyoak, 1997).

Such comparative work can be very difficult, just as it can be difficult to systematically compare the strengths and limitations of verbal theories. Nonetheless, in both cases such comparisons are critical for advancing the field. Three factors may aid in the ability to make such comparisons in the case of information processing models. The first is the training of researchers who are well versed in multiple modeling paradigms. This will be supported by attempts to compare modeling paradigms explicitly (Anderson & Lebiere, 2003; Spencer & Thelen, 2003). A second step that may make comparing models more feasible is adversarial collaboration (Mellers, Herwig, & Kahneman, 2001), whereby researchers with different theoretical perspectives agree on criteria and methods for testing their perspectives, and then collaborate on conducting such tests. Finally, the process of comparing models should become easier as research models are made available for others to investigate.

Accessible Models

Finally, making information processing and computational modeling work more accessible is another important step for yielding the biggest impact on the understanding of development. Although this kind of work has yielded many insights, as demonstrated through the examples reviewed in this chapter, this work has not always been easily accessible to researchers in the field. Part of this problem may be inherent to these approaches, and to any other formal approaches that require the understanding of an overall framework to provide the context of any individual account or simulation. In a commentary chapter in Simon and Halford's (1995b) edited volume of information processing chapters, Klahr (1995) described the collection as:

not always easy reading. Compared to the standard fare of developmental theory, these chapters introduce a bewildering variety of technical terms, concepts, notation, and

representations. Understanding them requires a familiarity with a technical language that is unlikely to have been a major part of the graduate training of most developmentalists. Both production systems and connectionist models [and he could add dynamic systems to the list!] involve new concepts, new terminology, even new reading styles (when following an account of how a model is organized, how it runs, and how it is matched to the data). p. 368

Although he concluded that these chapters were “worth the struggle” (and hopefully the same applies to this chapter), it will be important to address the accessibility problem where possible in future work. Better methods of analyzing and presenting information processing approaches and computational models may help to clarify their contributions. Clearer graphical representations have been and will continue to be an essential component in this process for conveying the dynamic processes of changes to productions in production systems, to neural network connections and what they come to represent, and to dynamic systems variables and how they interact. And, the more explicit the links can be between processes in information processing models and processes in the child, the better. Explanations of models’ behaviors can sometimes be steeped in modeling or information processing terms, without the additional step of explicitly specifying what these processes correspond to in the child. Finally, information processing and computational modeling approaches may become more accessible as the simulations become more readily available, in terms of both basic models that help to illustrate key components of the overall framework, and research models that investigate particular questions of scientific interest. The greater availability of such models will allow more people to manipulate them on their own and observe the effects, so that their contributions can be more accessible.

CONCLUSION

To return to the questions this chapter opened with: Why do children think the way they do? What leads to the changes they show across development, and to the variations observed across children? This chapter has reviewed insights into such questions from information processing approaches and computational models. These contributions span a range of domains (e.g., problem solving, language, and memory) and patterns of developmental change (e.g., stage-like progressions, U-shaped

learning curves, and task-dependent progressions). Different information processing approaches and models provide different answers to fundamental developmental questions. However, they share a common focus on what information children represent (whether symbolic or sub-symbolic), how they represent and process this information (whether through productions or distributed patterns of activity), how these representations guide their behaviors (whether in an abstract, flexible way or in a task-dependent, softly assembled way), and what mechanisms lead to changes in these processes across development (e.g., the combination of productions, the introduction of new knowledge and capacity, or learning mechanisms applied in a consistent way across experience). Many interesting challenges and questions remain in the attempt to understand the behaviors simulated in these models, as well as many behaviors that have yet to be addressed through models. Each information processing account and each computational model raises new questions about children’s thinking and development, but these are likely productive questions. Addressing them should be an essential step toward understanding the processes contributing to development. The rigorous test bed of information processing explorations should continue to be instrumental in this endeavor.

This chapter is based on three propositions: (1) Learning is central to child development, (2) microgenetic analyses yield unique information about learning, and (3) the information yielded by microgenetic analysis is helping to create a vibrant new field of children's learning. The remainder of the chapter provides arguments and evidence for these three propositions, as well as describing the new field of children's learning.

Preparation of this chapter was supported in part by grant HD19011 from the National Institutes of Child Health and Human Development and grant R305H020060 from the U.S. Department of Education. Thanks also go to the following individuals for helpful comments about an earlier draft of this chapter: Jennifer Amsterlaw, Zhe Chen, Thomas Coyle, James Dixon, Kathryn Fletcher, Emma Flynn, David Geary, Annette Karmiloff-Smith, David Klahr, Deanna Kuhn, Kang Lee, Anne McKeough, Patrick Lemaire, Patricia Miller, Bethany Rittle-Johnson, Wolfgang Schneider, Jeff Shrager, Patricia Stokes, Matija Svetina, Erika Tunteler, and Han van der Maas. I would also like to thank my dedicated and hard-working research team who put many hours into this project: Theresa Treasure, Mary Wolfson, and Jenna Zonneveld.

THE CENTRALITY OF LEARNING TO CHILDREN'S DEVELOPMENT

Learning is basic to human existence in all periods of life, but it is especially so in childhood. Its centrality is now recognized even for changes that were once attributed entirely to maturation, such as the beginning of reaching, kicking, and stepping (Thelen & Corbetta, 2002). The very concept of childhood can be defined in terms of learning: Childhood is the period of life in which learning is the primary goal.

The reasoning underlying this perspective can be appreciated by contrasting the relative importance of performance and learning in adulthood to their relative importance in childhood. Adulthood is the period during which performance is primary: Adults' success in doing their jobs, in choosing a mate, in child rearing, in deciding where to live, and even in mundane tasks such as driving has profound implications for themselves and their families. Considerable learning also takes place during adulthood, of course, but adults' performance in the here and now is foremost. A farmer who makes unwise planting and harvesting decisions and whose crops

fail is not a successful farmer even if he learned from his less successful decisions the year before, nor is a driver successful who learned enough to improve from six traffic accidents to three from one year to the next. In contrast, a farmer who makes wise planting and harvesting decisions is successful even if he learns nothing, as is a driver who avoids all accidents but whose skill remains unchanged.

The balance between learning and performance is very different in childhood. Children have more to learn than do adults, and the capabilities they need to acquire include many that are fundamental to their future: comprehension and production of language; acquisition of fundamental concepts such as time, space, number, and mind; academic competencies such as reading, writing, and mathematics; emotional control; social interaction skills; and so on. Thus, the adage "the work of childhood is learning" embodies an important truth. In contrast, children's absolute level of performance rarely matters in and of itself. It is unfortunate if a kindergartner lags behind in knowledge of numbers and letters, or does not work and play well with others, but the problem is serious only if it continues. A kindergartner who has made substantial progress toward catching up with her classmates in knowledge of letters and numbers or in getting along with other children, but who still does less well than most of them, has had a good year—unlike the driver who reduced his traffic accidents from six to three.

Although the process of learning always has been central within children's development, the study of learning only sometimes has been central within the field of child development. From the 1930s through the 1960s, children's learning was a booming area of developmental psychology. Then the area went into eclipse. A sense of the magnitude and rapidity of the shift is conveyed by the chapters on children's learning in two successive editions of the *Handbook of Child Psychology*, both written by the same authority, Harold Stevenson. First consider Stevenson's evaluation of the state of the field in the 1970 *Handbook*, near the end of the boom in the study of children's learning:

The number and quality of studies on children's learning published each year have continued to increase. . . . By now there have been so many studies of children's learning that it is impossible to review them adequately in one chapter. . . . Because of the vast number of publications, no attempt is made to include all possibly relevant studies. (pp. 849, 851, 852)

Now consider Stevenson's (1983) evaluation 13 years later, after the boom ended:

By the mid-1970s, articles on children's learning dwindled to a fraction of the number that had been published in the previous decade, and by 1980, it was necessary to search with diligence to uncover any articles at all. (p. 213)

Indicative of this change, the length of Stevenson's review of the literature on children's learning decreased from 90 pages in 1970 to 23 pages in 1983. This change did not just reflect one man's opinion. In the 1970 *Handbook* volume that focused on cognitive development, 10 of the 19 chapters included learning as an index entry; in the corresponding volume of the 1983 *Handbook*, only 2 of the 13 chapters included such an entry.

Since the publication of the 1983 *Handbook*, the pendulum has swung back—somewhat. On one hand, the prominence of learning within the field of developmental psychology remains far less than its prominence within children's lives. On the other hand, the amount of research on children's learning has increased, and the quality of this research has been high enough to create an exciting new field of children's learning. The present chapter first provides a brief overview of the history of research on children's learning, then examines how microgenetic methods have helped reinvigorate the area, and then examines the new field of children's learning that is emerging.

History

Early Flowering

The rise of learning theories within developmental psychology came later than in experimental psychology and the learning theory approach never became as dominant (White, 1970). Nonetheless, learning theories were a major force in developmental psychology for many years, shaping what was studied, how it was studied, and how the results were interpreted. Many early studies of children were direct extensions of previous learning theory studies of rats, pigeons, or human adults. For example, in the 1946 edition of the *Handbook*, Munn's chapter on children's learning included the observation:

Investigations of learning in children, rather than introducing new problems and essentially novel techniques, have followed the leads of animal and adult human

psychology. . . . In many investigations of learning inclusion of children has been merely incidental. (pp. 370, 371)

Consistent with this perspective, Munn's chapter focused in large part on topics emphasized within the adult and animal experimental psychology of the day: conditioning, paired associate learning, motor learning, and so on.

The emphasis within the field of children's learning on theories and methods imported from experimental psychology continued for many years. Consider the similarity between the evaluation just quoted and that of Stevenson (1970), a quarter century later:

Research on children's learning is for the most part a derivative of psychological studies of learning in animals and human adults. Although the impetus for studying children's learning is related to practical concerns in the educating and rearing of children, the field characteristically has been dominated by the methods and problems of the experimental psychologist. . . . The close alliance with experimental psychology has been productive. (p. 849)

It is easy to recognize these influences of learning theory on a wide variety of prominent developmental research of the 1950s and 1960s. For example, Hull's (1943) and Spence's (1952) approaches to discrimination learning led to the developmental research on the same topic of Kendler and Kendler (1962) and Zeaman and House (1967); the social learning approach of N. E. Miller and Dollard (1941) led to the developmental research of Bandura and Walters (1963) and Rosenblith (1959); the operant conditioning approach of Skinner (1938) led to the developmental research of Bijou and Baer (1961) and Siqueland and Lipsitt (1966); and so on. Thus, although Stevenson's (1970) characterizations of the field of children's learning as both derivative and productive might seem contradictory, both descriptors seem justified.

Dormancy

The withering of the field of children's learning after 1970 reflected both its own limitations and the emergence of attractive alternatives. Learning theory emphasized simple nonverbal tasks that bore only an abstract resemblance to problems that children encounter in the world outside the laboratory. The intent was to measure basic learning processes that occur in a wide range of situations, but the tasks and experimental paradigms

differed so greatly from everyday ones that it was uncertain if the learning processes used in and out of the lab shared more than a label. For example, numerous learning theory studies of concept formation required children (or adults or nonhuman animals) to choose between pairs of objects that varied in size, shape, color, and the side on which they appeared (e.g., Levine, 1966; Restle, 1962). The correct answer was whatever the experimenter said it was; the rule could be as simple as "Choose the larger one" or as complex as "Choose either a large T on the left or a small X on the right or a large X on the left or a small T on the right." The degree of similarity between the processes used to acquire such arbitrary concepts and those used to acquire natural concepts such as "animal" or "mountain" is far from clear. In addition, the lack of ecological validity of these tasks was so extreme that it created increasing dissatisfaction with the whole learning theory enterprise among a wide range of psychologists.

Developmental psychologists also were dissatisfied for several other reasons. One was the portrayal of children as passive, inactive organisms whose learning lacked distinctive characteristics. Brown, Bransford, Ferrara, and Campione noted in their 1983 *Handbook* chapter that learning theories assumed that the same basic principles could be applied universally across all kinds of learning, all kinds of species, and all ages. Not surprisingly, investigators who did not believe in developmental or species differences in learning did not discover much about them. This issue was evident quite early. Munn (1946) noted, "So far as discovering anything fundamentally new concerning the learning process is concerned, the investigations on learning in children have failed" (p. 441). Although Munn recognized that this might be attributable to the tasks and procedures that were used, he concluded that "A more likely reason, however, is that the phenomenon of learning is fundamentally the same, whether studied in the animal, child, or adult" (p. 441). Some later learning theory approaches did attempt to explain developmental differences in learning (e.g., Kendler & Kendler, 1962), and their efforts attracted considerable interest for a time, but increasing numbers of developmentalists had become disillusioned with learning theory and were looking in other directions.

The marginalization of the field of children's learning reflected not only the deficiencies of learning theories but also the emergence of attractive alternative

approaches that did not emphasize learning. The most influential alternative was Piaget's theory, particularly as distilled in Flavell's (1963) book "The Developmental Psychology of Jean Piaget." Piaget's theory was not new, of course, but Flavell's clear and compelling presentation greatly expanded its appeal. Unfortunately, for the study of learning, Piaget (1964) drew a sharp distinction between learning and development, a distinction that relegated learning to a subordinate position. For example,

I would like to make clear the difference between two problems, the problem of development in general and the problem of learning. I think these problems are very different, although some people do not make the distinction. The development of knowledge is a spontaneous process, tied to the whole process of embryogenesis. Learning presents the opposite case. In general, learning is provoked by situations—provoked by a psychological experimenter; or by a teacher, with respect to some didactic point; or by an external situation. It is provoked, in general, as opposed to spontaneous. In addition, it is a limited process—limited to a single problem, or to a single structure. (p. 20)

It is worth noting that not all classic theorists shared Piaget's rather dismissive attitude toward learning. Theorists such as Werner (1948, 1957) and Vygotsky (1934/1962) viewed short-term change as a miniature version of long-term change, generated by similar underlying processes and characterized by identical sequences of qualitatively distinct stages. This view is basically similar to the present perspective. However, Piaget's theory was so dominant at the time, and his observations of age-related changes so interesting, that they shifted attention toward children's thinking and away from their learning. This shift affected not only adherents of Piaget's theory but critics as well. Thus, approaches that originated as alternatives to Piaget's theory, such as core knowledge approaches (Spelke & Newport, 1998), differed in many ways from the Piagetian perspective but maintained the focus on knowledge rather than learning.

A second major influence on the field of cognitive development, information processing theories, also shifted attention away from children's learning, though for a different reason. Information processing approaches recognized learning as a central problem and as crucial for understanding how development occurs.

However, their agenda was first to describe children's knowledge states at different ages and only then to focus on how transitions occur. This perspective is aptly captured in Simon's (1962) suggestion,

If we can construct an information processing system with rules of behavior that lead it to behave like the dynamic system we are trying to describe, then this system is a theory of the child at one stage of development. Having described a particular stage by a program, we would then face the task of discovering what additional information-processing mechanisms are needed to simulate developmental change—the transition from one stage to the next. (p. 632)

As with Piaget's theory, this approach led to many fascinating discoveries regarding how children think at different ages. In addition, some researchers who adopted an information-processing perspective did advance intriguing hypotheses about transition processes in cognitive development (e.g., Klahr & Wallace, 1976). In general, however, the information processing theory of the 1960s and 1970s, like Piagetian theory, shifted attention away from how children learn.

Scientific approaches create their own momentum. The intriguing findings on children's existing knowledge generated by Piagetian, information processing, and core knowledge approaches led to many controversies. These controversies, in turn, generated new intriguing findings and new controversies regarding what children do and do not understand at particular ages, especially in infancy and the preschool period (e.g., Haith & Benson, 1998; Spelke & Newport, 1998). The development of innovative methods for studying infant cognition added to this trend, because it allowed examination of fundamental issues that could not be studied previously.

These trends produced a large body of excellent research that greatly broadened understanding of development. However, they also entailed a serious cost: an imbalanced portrayal of children that focused on static states rather than change. This tendency was evident in Piagetian, information processing, and core knowledge approaches alike; all focused primarily on skills and knowledge at particular ages rather than on the processes through which children acquired the skills and knowledge. The imbalance is understandable—knowledge states are easier to describe than change processes, and describing them is crucial for establishing the changes

that need to be explained. However, the prolonged emphasis on documenting static states resulted in a distorted description of development, one in which children appeared to spend far more time being than becoming.

Germination

After a period in which children's learning received little attention, some far-sighted investigators began to envision a new field of children's learning. For example, Brown, Bransford, Ferrara, and Campione (1983) noted the same trend toward reduced focus on learning as Stevenson (1983), but they also predicted that the metaphor of children as active organisms who devise strategies to pursue their goals would form the foundation of a new field of children's learning. They foresaw that the study of memory for rich and varied real world content would provide a useful model for this new field, and they anticipated the emergence of several specific issues that have become central in the area. How do the characteristics of the learner, the nature of the material, and the criterion task combine to determine learning? Why do children fail to transfer useful strategies to new content? What develops to allow older children to learn many types of material more effectively than younger children?

A further insight of Brown et al. (1983) was anticipating the role that microgenetic studies would play in the resurgence of the field of children's learning. They suggested that after documenting age-related changes in thinking, researchers would go on:

to attack the problem of development head-on . . . by observing learning actually taking place within a subject over time. This is essentially the microgenetic approach advocated by Vygotsky (1978) and Werner (1961). . . . The revived interest in microgenetic analysis of both adult (Anzai & Simon, 1979) and children's (Karmiloff-Smith, 1979a, 1979b) learning enables psychologists to concentrate not only on qualitative descriptions of stages of expertise but also to consider transition phenomena that accompany the progression from novice to expert status. (p. 84)

The history of the past 20 years indicates the presence of Brown et al.'s (1983) predictions. Again, changes within the *Handbook* document this trend. Learning assumed a considerably larger role in the 1998 *Handbook* than in its 1983 predecessor. M. H. Johnson (1998) noted that rather than neural development being largely prespecified, as once was assumed, the develop-

ing brain changes according to the input that it encounters; that is, the developing brain changes with learning. Aslin, Jusczyk, and Pisoni (1998) focused on how children learn to segment speech into words, and also how learning leads them to lose their early ability to discriminate some phonemic contrasts that are absent from their native language. Gelman and Williams (1998) focused on how conceptual constraints influence learning in core domains. Maratsos (1998) argued that contrary to the view that people are born with a universal grammar that only requires a small amount of tuning, the remarkably idiosyncratic and variable nature of natural grammars demands a great deal of highly specific learning. Rogoff (1998) examined how children learn through participation in socially important activities, and Klahr and MacWhinney (1998) reviewed computational models of children's learning.

Several developments contributed to this change in *Handbook* coverage and to the more general resurgence of the field of children's learning. One was the increasing influence of theories that see development as rising in large part out of learning. These include dynamic systems, sociocultural, and information processing theories. Such theories have motivated increasing amounts of empirical research on learning. For example, dynamic systems theory motivated researchers to examine whether acquisitions that traditionally had been viewed as a function of the child's developmental stage, such as object permanence, could be explained by learning within the specific experimental situation, such as learning of particular arm movements and activation of particular representations. Smith, Thelen, Titzer, and McLin's (1999) and Spencer and Schutte's (2004) empirical demonstrations that such explanations were viable created a new way of conceptualizing object permanence.

Another important contributor to the resurgence of the field of children's learning has been methods capable of tracing the process of learning while it occurs. Microgenetic methods in particular have made possible increasingly nuanced understanding of children's learning. The availability of such methods, together with videotape recorders and other useful technologies, allow theorists to raise questions about the dynamics of development that otherwise would be impossible to answer, such as what happens immediately before a child makes a discovery and whether periods of transition are accompanied by especially high variability.

Other methods are also being used to study learning. They include operant conditioning (Saffran, Aslin, &

Newport, 1996; Stokes & Harrison, 2002), elicited imitation (Bauer, Chapter 9, this *Handbook*, this volume), formal modeling (Munakata, Chapter 10, this *Handbook*, this volume), and brain imaging (Nelson, Chapter 1, this *Handbook*, this volume). In addition, microgenetic methods are being used to study adults' learning (Anzai & Simon, 1979; Staszewski, 1988), as well as that of children. Limitations of space, together with the presence in this volume of the chapters by Nelson, Bauer, and Munakata, contributed to the decision to focus the present chapter on contributions of microgenetic studies to understanding of children's learning.

MICROGENETIC METHODS FOR STUDYING LEARNING

Scientific methods and theories exert reciprocal influences. Typical cross-sectional and longitudinal methods, which sample the thinking of children at different ages, reinforce and are reinforced by theories that emphasize such questions as "By what age do children understand _____?" and "Does X develop before, after, or concurrently with Y?" In contrast, the cross sectional and longitudinal methods are less useful in testing theories that emphasize such questions as, "Through what processes do children learn _____?" and "Is Strategy X transitional to Strategy Y?" The problem is that observations of emerging competence in cross-sectional and longitudinal studies are too widely spaced to yield detailed information about the learning process. For example, a longitudinal design might involve observing children's performance on the false belief task at 3, 4, and 5 years. The year between observations would severely limit the information that could emerge regarding the processes through which children's understanding of false belief improves.

Essential Properties

This is where microgenetic methods are essential: for answering questions about *how* learning occurs. Microgenetic methods have three main properties:

1. Observations span the period of rapidly changing competence.
2. Within this period, the density of observations is high, relative to the rate of change.

3. Observations are analyzed intensively, with the goal of inferring the representations and processes that gave rise to them.

The second property is especially important. Densely sampling changing competence during the period of rapid change provides the temporal resolution needed to understand the learning process. If children's learning usually proceeded in a beeline toward advanced competence, such dense sampling of ongoing changes would be unnecessary. We could examine thinking before and after changes occurred, identify the shortest path between the two states, and infer that children moved directly from the less advanced one to the more advanced one. Detailed observations of ongoing changes, however, indicate that such beelines are the exception rather than the rule (Siegler, 2000). Cognitive changes involve regressions as well as progressions, odd transitional states that are present only briefly but that are crucial for the changes to occur, generalization along some dimensions from the beginning of learning but lack of generalization along other dimensions for years thereafter, and many other surprising features. Simply put, the only way to find out how children learn is to study them closely while they are learning.

The logic of densely sampling changes as they occur is not unique to the microgenetic approach; the same logic underlies a number of other methods. One example is neural imaging methods such as fMRI. The dense temporal sampling of brain activity allowed by increasingly powerful magnets and software has led to many insights into the neural substrate of performance (e.g., Casey, 2001). Other neural techniques such as single cell recording are based on the same logic, as are behavioral techniques such as eye movement analysis (Just & Carpenter, 1987). In all cases, the dense sampling of performance over time allows insights into cognitive processes.

Applicability

Microgenetic designs are broadly applicable along multiple dimensions:

- *Ages of participants:* Microgenetic methods have proven useful for studying people of all ages: infants (Adolph, 1997), toddlers (Chen & Siegler, 2000), preschoolers (P. H. Miller & Aloise-Young, 1995), elementary school children (Schauble, 1996), college

students (Metz, 1998) and older adults (Kruse, Lindenberger, & Baltes, 1993).

- **Domain:** Microgenetic analyses have proven useful for studying development in highly diverse domains: problem solving (Fireman, 1996), attention (P. H. Miller & Aloise-Young, 1995), memory (Schlagmüller & Schneider, 2002), theory of mind (Flynn, O'Malley, & Wood, 2004), scientific reasoning (Kuhn, Garcia-Mila, Zohar, & Anderson, 1995), mathematical reasoning (Alibali, 1999), spoken language (Robinson & Mervis, 1998), written language (Jones, 1998), motor activity (Spencer, Vereijken, Diedrich, & Thelen, 2000), and perception (Shimojo, Bauer, O'Connell, & Held, 1986). In addition to these applications to the study of cognitive development, investigators have begun to apply microgenetic analyses to social development (e.g., Lavelli & Fogel, 2002; Lewis, 2002).
- **Setting:** Microgenetic methods are applicable not only in laboratory settings but also in naturally occurring contexts and classrooms. For example, they have been used to study infants' kicking and reaching in their cribs (Thelen & Corbetta, 2002), young children's learning of narrative skills in preschool and first-grade classes (McKeough, Davis, Forgeron, Marini, & Fung, 2005; McKeough & Sanderson, 1996), and fourth graders learning math skills in a collaborative learning context (Taylor & Cox, 1997). (For a review of applications of microgenetic methods to classroom research, see Chinn, in press.)
- **Theoretical underpinning:** Microgenetic studies have proven useful for testing predictions of all of the major theories of cognitive development: Piagetian (Karmiloff-Smith & Inhelder, 1974; Saada-Robert, 1992), neo-Piagetian (Fischer & Yan, 2002; McKeough & Sanderson, 1996), dynamic systems (Lewis, 2002; Thelen & Corbetta, 2002), theory (Amsterlaw & Wellman, 2004; Flynn et al., 2004), sociocultural (Duncan & Pratt, 1997; Wertsch & Hickmann, 1987), and information processing (Schlagmüller & Schneider, 2002; Siegler & Svetina, 2002). This is not coincidence. Part of the reason that these approaches are viewed as major developmental theories is that they make important predictions about how change occurs. Such predictions often can be tested most precisely through microgenetic studies, in which changes are observed in detail.

Despite these large variations in age groups, content areas, settings, and investigators' theoretical orientation, microgenetic studies of children's learning have

yielded surprisingly consistent findings. As Kuhn (2002) observed:

Although the empirical findings that microgenetic research has produced are both interesting and consequential, the single most striking thing about them is their consistency. This consistency has been maintained despite variations in methodology and despite the wide range of content areas to which the method has been applied. Consistency of this sort is unusual in developmental psychology. (p. 109)

Other reviewers of the microgenetic literature (P. H. Miller & Coyle, 1999; Siegler, 2000) have been struck by this same consistency of research findings. Ironically, it may reflect the correctness of one of the core beliefs of the earlier generation of learning theorists: More regularity may be present in how people learn than in what they know at a given age. Prominent developmental theories, such as the Piagetian, neo-Piagetian, and theory-theory approaches, have been based on the assumption that substantial regularities in thinking are present at particular ages, either across all areas of thinking or within broad domains, such as psychology or biology (Case & Okamoto, 1996; Piaget, 1952; Wellman & Gelman, 1998). The evidence for such regularities in thinking at particular ages is mixed at best (Siegler, 1996).

In contrast, the consistent findings yielded by microgenetic studies suggest that considerable regularity may be present in how children learn. This regularity in findings regarding children's learning has been noted in reviews of studies that have not used microgenetic methods as well as in ones that have. For example, R. Gelman and Williams (1998) highlighted the importance of constraints for facilitating learning in all types of domains, both biologically privileged and nonprivileged. Similarly, Keil (1998) and Wellman and S. Gelman (1998) emphasized formation of causal connections as crucial to children's learning in a broad range of domains. The greater regularity in studies of learning is likely due to their eliminating a number of sources of variability that limit investigators' ability to demonstrate commonalities in thinking across different problems: differences in wording of questions, task difficulty, amount of direct experience with each task, similarity to better-understood tasks, motivational properties, and so on. Thus, yet another reason for focusing on children's learning is that doing so promises to help overcome the fractionation of the field of developmental psychology and to identify common underlying principles.

Table 11.1 lists a number of the most consistent and important phenomena that have emerged within micro-

TABLE 11.1 Twenty Major Findings about Children's Learning

1. Substantial within-child variability is present during all phases of learning and at every level of analysis: associations, concepts, rules, strategies, and so on.
2. Within-child variability tends to be greatest during periods of rapid learning, though substantial variability is present in relatively stable periods as well.
3. Within-child variability tends to be cyclical, with periods of lesser and greater variability alternating over the course of learning.
4. Within-child variability is substantial at all ages from infancy to older adulthood.
5. Initial within-child variability tends to be positively related to subsequent learning.
6. Learning reflects addition of new strategies, greater reliance on relatively advanced strategies that are already being used, improved choices among strategies, and improved execution of strategies.
7. Learning tends to progress through a regular sequence of knowledge states that parallel those that characterize untutored development.
8. The path of learning is usually similar for learners of different ages and different intellectual levels.
9. Learning often includes short-lived transitional approaches that play important roles in the acquisition of more enduring approaches.
10. New approaches are generated following success as well as failure of existing approaches.
11. For most types of learning, older and more knowledgeable children learn more quickly, and show greater appropriate generalization, than younger children.
12. The rate of change is of human scale: faster than connectionist models imply, but slower than most symbolic models imply.
13. New approaches usually are used inconsistently; discovery of new approaches tends to be the beginning of learning rather than the end.
14. Once new approaches have been generated, their rate of uptake is positively related to the degree to which their accuracy is superior to that of existing approaches.
15. The breadth of change also is of human scale, including everything from instantaneous to extremely gradual generalization.
16. The likelihood of choosing any given approach can be increased either by increasing the strength of that approach or by weakening the strength of competing approaches.
17. Causal understanding plays a crucial role in learning.
18. Requests to explain observations often promote learning above and beyond the effects of feedback and practice.
19. The mechanisms underlying the effects of explanatory activity include increased likelihood of learners generating any explanation, increased persistence of explanatory efforts, and diagnosis and repair of flaws in mental models.
20. Learning often proceeds with little or no trial and error; conceptual understanding often allowing children to reject inappropriate strategies without ever trying them.

genetic studies of children's learning. Each of the phenomena is discussed in some depth later in the chapter.

History

Both the name *microgenetic* and the idea of microgenetic designs appear to have originated with Heinz Werner (Catan, 1986). Werner (1948) hypothesized that cognitive changes over diverse time spans, ranging from milliseconds to years, include important commonalities. Therefore, in the mid-1920s, he began to perform what he labeled "genetic experiments," that is, experiments aimed at describing the sequence of states within psychological events (this use of the term *genetic*, like Piaget's description of himself as a "genetic epistemologist," is based on the original definition of genetic as "pertaining to genesis or origins.") For example, Werner (1940) described how repeated presentation of a sequence of 12 ascending, initially indiscriminable tones eventually allowed people to form a representation in which the tones could be discriminated. Because the very rapid sequence of such mental states was believed to parallel the much slower sequence of states in development with age, the experiments were also labeled "mi-

crogenetic." Soviet contemporaries, including Vygotsky (1930/1978), cited with approval Werner's genetic experiments and argued for studying concepts and skills that were "in the process of change" (p. 65) rather than ones that were "fossilized" (p. 68).

Despite this promising beginning, the microgenetic method was rarely used in the ensuing years. The first spate of modern microgenetic articles appeared in the 1970s and early 1980s. Among the early adopters were Karmiloff-Smith and Inhelder (1974), Wertsch and Hickmann (1987), Karmiloff-Smith (1979b), and Kuhn and Phelps (1982). This last study was particularly important because it was the first microgenetic experiment that included all three defining features listed earlier.

Although classifications of studies as microgenetic inevitably are somewhat subjective, the prevalence of microgenetic studies clearly has increased greatly in recent years. Of the 105 studies classified as microgenetic for purposes of this review, only 10 were published before 1985. The growing frequency of microgenetic studies has several likely sources. One is the increasing emphasis on learning within prominent theories of cognitive development. Another is the increasing availability and sophistication of video recording technology and software and

hardware tools that allow faster extraction of information than was possible until recently. A third is the increasingly broad range of tasks for which precise age norms have been established, thus setting the stage for microgenetic studies.

Probably the most important reason for the increased prevalence of microgenetic methods, however, is that it has become apparent that the value of the precise data on cognitive change that microgenetic designs yield more than offsets the time and effort required to obtain the data. Consider how the data obtained in microgenetic studies have allowed investigators to address one fundamental issue: how children discover new strategies. Microgenetic methods, unlike other developmental designs, allow identification of the exact trial on which each participant first used the new approach. Identifying the trial on which a new approach was first used allows examination of the nature of the discovery: whether a child was excited about the innovation, whether the child was even aware of having used a new approach, and whether he or she could explain why the new approach was advantageous. Knowing exactly when the new approach was first used also allows examination of performance just before the discovery: what types of problems preceded the discovery, whether the child failed to solve the immediately preceding problems, whether the child was taking an unusually long time to solve those problems, and so on. Moreover, knowing when the discovery was made allows examination of performance just after the discovery: how consistently the child used the new strategy on the same type of problem, how broadly the child generalized the new strategy to other types of problems, how efficiently the child executed the new strategy, and how all of these dimensions of performance changed as the child gained experience with the new approach. These are the benefits that are leading increasing numbers of investigators to use the microgenetic approach to study children's learning.

Methodological Issues

Microgenetic studies raise a variety of methodological issues, including ones of experimental design, strategy assessment, and data analysis.

Issues of Experimental Design

Because microgenetic studies generally require coding strategy use or other units of behavior on a great many trials, the distribution of experimental designs used in

such studies differs from the overall distribution of experimental designs in the field. Quite a few microgenetic studies employ single subject designs, either with or without instruction (e.g., Agre & Shrager, 1990; K. E. Johnson & Mervis, 1994; Schoenfeld, Smith, & Arcavi, 1993). In one such case, Lawler (1985) described his daughter's learning of how to debug simple computer programs, solve simple arithmetic problems, and play tic tac toe over 90 sessions during a 4-month period. In another such study, Robinson and Mervis (1998) analyzed Mervis' son's acquisition of grammatical and lexical forms over almost 400 sessions over 13 months.

Another common type of microgenetic design involves focusing on the learning of a relatively small number of participants over a substantial period without any experimental intervention (e.g., Saada-Robert, 1992; Thelen & Ulrich, 1991). For example, Spencer et al. (2000) observed four infants' reaching in a free-play situation twice per week between 3 and 30 weeks of age and every other week between 32 and 52 weeks of age. Shimojo et al. (1986) study of 16 infants' acquisition of binocular depth perception over 31 weekly sessions between 1 and 8 months is another example. Thus, microgenetic methods can be applied to studying change over relatively long as well as relatively short time periods, and to study changes that might be described as "developmental," because they do not involve explicit experimental interventions, as well as changes that do involve such interventions and thus are more prototypic of "learning studies."

A third common microgenetic design involves presenting children with an unusually high density of an experience, with the goal of speeding up the typical developmental process, thus allowing more detailed analysis of change than would otherwise be possible (e.g., Siegler & Jenkins, 1989). This type of design, like the first two, does not include a control group, because the focus is on the way in which the change occurs rather than on establishing the effectiveness of the experience relative to changes that might have happened anyway. Examples of this design include Karmiloff-Smith's (1979b) study of changes within a single session in children's drawing of route maps, Kuhn, Schable, and Garcia-Mila's (1992) study of changes in 10-year-olds' learning of scientific experimentation skills over 18 sessions in a 9-week period, and Schlagmüller and Schneider's (2002) study of changes in 9- and 11-year-olds' organization of pictures of objects on a sort-recall task in nine experimental sessions over an 11-week period.

Pressley (1992) criticized these three types of microgenetic designs by arguing that without a control group, they were subject to a variety of sources of experimental invalidity. However, it often is unclear what an appropriate control group would be in such studies, given that the focus is on describing how changes occur under the particular experimental condition, rather than on contrasting how different experimental conditions influence behavior. In addition, the studies have yielded fine-grain data about acquisition of complex skills, concepts, and domains, data that would have been unlikely to have been obtained in any other way and that have contributed a great deal to understanding of learning.

Moreover, despite Pressley's concern that the demands of microgenetic methods inherently preclude use of true experimental designs, increasing numbers of microgenetic studies have employed them (e.g., Chen & Siegler, 2000; Church, 1999; Siegler & Stern, 1998). For example, Alibali (1999) randomly assigned third and fourth graders to one of five experimental groups to compare learning about mathematical equality under varying conditions, and Klahr and Chen (2003) randomly assigned 4- and 5-year-olds to one of two groups to contrast learning about indeterminacy under the alternative conditions.

Although his claim that microgenetic methods preclude true experimental designs proved incorrect, Pressley (1992) did identify a number of tradeoffs that shape microgenetic research—tradeoffs among number of participants, number of sessions, sampling density, and type of task. Some of these tradeoffs are fairly obvious, but others are quite subtle.

One obvious tradeoff is that between number of participants and number of sessions. Microgenetic studies have included from 1 to more than 300 sessions and from 1 to more than 150 participants. In general, the greater the number of sessions, the smaller the number of participants. To cite the extremes, Robinson and Mervis (1998) observed one child for more than 300 sessions, whereas Alibali (1999) observed 178 participants for a single session.

Both number of participants and number of sessions trade off with density of observations. Microgenetic studies have involved within-trial analyses (e.g., Coyle & Bjorklund, 1997; Graham & Perry, 1993), trial-by-trial analyses (e.g., Blöte, Resing, Mazer, & Van Noort, 1999; Siegler & Jenkins, 1989), and session-by-session analyses (Jones, 1998; Shimojo et al., 1986). As a general rule, the higher the rate of change of the phenomenon

under the experimental conditions, the higher the density of observations needs to be. The demands of high-density observation militate toward either a small number of participants, a small number of sessions, or both.

All of these variables also trade off in a rather nonintuitive way with the prevalence of the task in the everyday environment. Some microgenetic studies present everyday tasks that children have encountered but not mastered; other studies present novel tasks. Similarly, some studies present tasks under more typical circumstances than other studies. Although it may seem surprising, changes on familiar tasks presented under quite natural circumstances tend to occur more slowly than changes on novel tasks presented under conditions that are by definition novel. For example, studies of everyday tasks, such as reaching (Thelen & Corbetta, 2002) and arithmetic (Siegler & Jenkins, 1989) have generally reported quite slow rates of change, whereas studies of novel tasks such as Tower of Hanoi (McNamara, Berg, Byrd, & McDonald, 2003) and number conservation (Church & Goldin-Meadow, 1986) have generally reported more rapid changes. Presumably, on familiar tasks most children have already made the easiest discoveries, so that the remaining ones tend to require more time or more facilitative conditions. Thus, although ecologically valid tasks and conditions might be expected to elicit more rapid change than novel tasks and circumstances, the opposite tends to be true.

One way of minimizing these trade-offs is by applying multiple methods, with different sets of advantages and disadvantages, to the same task. This approach has been used to good advantage in the study of semantic organization strategies. By combining cross sectional and longitudinal studies with microgenetic studies, Schneider and his colleagues were able to establish that changes occurred considerably more rapidly than suggested by the cross-sectional data (Schlagmüller & Schneider, 2002; Schneider, Kron, Hünnerkopf, & Krajewski, 2004).

Issues of Strategy Assessment

A second class of methodological issues raised by microgenetic studies involves the reliability and validity of trial-by-trial strategy assessments. Although neither limited to microgenetic studies nor invariably used in them, trial-by-trial assessments are fundamental to many microgenetic studies. Precise analyses of strategy discoveries, of generalization of new strategies beyond their initial context, and of the precursors of discoveries

require identification of when the strategy first emerges. This emergence can be specified most precisely through trial-by-trial assessments.

Before discussing issues of trial-by-trial assessment of strategies, however, it is necessary to define the term *strategy*. The present definition of strategy is one that was first advanced by Siegler and Jenkins (1989, p. 11): a "procedure that is nonobligatory and goal directed." This definition distinguishes strategy from procedure, in that some procedures are obligatory (they are the only way to achieve the goal). The definition also distinguishes strategy from behavior, in that behaviors do not imply any particular goal. Finally, the definition does not imply a rational generation process, conscious choice, or reportability. Including such criteria would exclude many activities that can profitably be conceptualized and analyzed within the present framework, as well as raising truly thorny issues, such as deciding what constitutes a rational generation process.

Returning to issues of assessment, the desirability of assessing strategy use on a trial-by-trial basis has shaped microgenetic research in several ways. Perhaps the most striking influence is that it has led researchers to rely on tasks that involve substantial overt behavior: crawling, walking, reaching, and stepping (e.g., Adolph, 1997; Thelen & Corbetta, 2002); writing and telling stories (Jones, 1998; Jones & Pellegrini, 1996; McKeough & Sanderson, 1996); manipulating physical apparatuses, such as gear systems, bridges, and robots (Dixon & Bangert, 2002; Granott, 1998; Parziale, 2002; Perry & Lewis, 1999; Thornton, 1999); doing mathematics (Blöte et al., 2004; Fletcher, Huffman, Bray, & Grupe, 1998; Goldin-Meadow & Alibali, 2002; Grupe, 1998); organizing to-be-remembered pictures or objects (Blöte et al., 1999; Coyle & Bjorklund, 1997; Schlagmüller & Schneider, 2002); and solving problems collaboratively (Ellis, 1995; Granott, Fischer, & Pariziale, 2002; Wertsch & Hickmann, 1987) among them. The possibilities created by trial-by-trial analysis also have influenced choices of dependent measures. Instead of relying solely on accuracy or solution times, researchers who conduct microgenetic studies also tend to assess the strategy used on each trial through use of videotapes of ongoing behavior, immediately retrospective verbal reports, notebooks that document scientific observations and conclusions, and other external indicators of thinking. This reliance on audible and visible behavior to infer thought processes is atypical of cognitive developmental research (though the reasons for other types of research

not making greater use of these external manifestations of thinking are unclear).

Microgenetic studies of children 4 years and younger have usually relied entirely on overt behavior to assess strategies. This approach has been followed, for example, in studying infant motor development (Adolph, 1997; Vereijken & Thelen, 1997), toddlers' problem solving (Chen & Siegler, 2000), and 3- and 4-year-olds' counting, memory, and attentional strategies (Bjorklund, Coyle, & Gaultney, 1992; Blöte et al., 2004; P. H. Miller & Aloise-Young, 1995).

Some studies of older children also have relied entirely on overt behavior to assess strategies (e.g., Bray, Huffman, & Fletcher, 1999; Lemaire & Siegler, 1995). However, in most recent studies of children 5 years and older, researchers have based strategy assessments on a combination of overt behavior and verbal reports provided during performance or (typically) immediately after. In most studies, the overt behavior is the basis of classification on trials on which it provides unambiguous evidence of which strategy was used; the verbal reports are used on trials on which overt behavior is absent or ambiguous. The combination of overt behavior and verbal reports has proved applicable for assessing strategy use on a wide range of tasks and among diverse populations, for example children with learning disabilities (Ostad, 1997).

Although use of verbal reports to infer strategy use has been widespread, the practice also has been questioned. Concerns have been raised about the veridicality and reactivity of such reports, with some investigators arguing that the need to generate verbal reports affects strategy use and other aspects of performance (Cooney & Ladd, 1992; Russo, Johnson, & Stephens, 1989). The data on which these criticisms were based, however, came from studies that lacked criteria of strategy use independent of the verbal reports (Bray et al., 1999). Results from studies that have included measures of strategy use independent of verbal reports (e.g., solution times, observations of overt behavior) have led to much more optimistic conclusions regarding the value of using verbal reports along with overt behavior.

Veridicality. The most basic issue regarding verbal reports is whether the assessments yielded by using them are accurate. Ericsson and Simon (1984) reviewed the literature on this issue and concluded that retrospective reports generally are veridical when (a) the verbal report is obtained while the trace of processing activity

remains in short-term memory, (b) the processes being described are of sufficient duration (roughly 1 second) that they produce a symbol in working memory, and (c) the processes are relatively easy to describe.

Since the publication of Ericsson's and Simon's seminal book, a great deal of evidence has supported their conclusion (Crutcher, 1994; K. M. Robinson, 2001; Siegler, 1987, 1989). In particular, among 5-year-olds and older individuals, classifying strategy use for each participant on each trial on the basis of both overt behavior and immediately retrospective self-reports has been found to increase the accuracy of classifications relative to that possible through classifying each participant's strategy use solely on the basis of overt behavior (Siegler, 1996).

To illustrate the type of data on which this conclusion is based, consider one study that tested whether examining immediately retrospective verbal reports as well as ongoing overt behavior results in more accurate strategy assessments than relying on the overt behavior alone (McGilly & Siegler, 1990). This study investigated 5- to 9-year-olds' serial recall strategies under verbal-report and no-verbal-report conditions. Children in the verbal-report condition were asked on each trial to describe what, if anything, they had done to help them remember; children in the no-verbal-report condition were not asked about their strategy use but were otherwise treated identically. A variety of measures indicated that the verbal reports added to the validity of the strategy assessments. In particular, the verbal reports revealed considerably more use of repeated rehearsal than was evident without them (74% versus 47% of trials), and did not bias the children's behavior (as indicated by the amount and types of visible strategy use being highly similar in verbal-report and no-verbal-report conditions). Bray et al. (1999), obtained similar findings with mentally retarded children on a different memory task. Thus, for children 5 years and older on tasks that meet the criteria described by Ericsson and Simon (1984), examining verbal reports as well as overt behavior on each trial increases the accuracy of strategy assessments over that possible from examining overt behavior alone.

Reactivity of Self-Reports. The above-cited finding of McGilly and Siegler (1990) that overt strategy use was essentially identical regardless of whether verbal reports were requested provided some evidence that requests for self-reports of strategy use do not alter the strategies that children use. Results of other studies and

from other measures also indicate that immediately retrospective verbal reports are usually nonreactive. For example, Bray et al. (1999) and Robinson (2001) found that requests for such verbal reports had no effect on accuracy and also did not affect the frequency of use of overt strategies on organizational memory and arithmetic tasks.

To minimize the possibility of reactivity, it is essential to avoid instructions that bias participants in favor of one strategy or another; such biased instructions can have large effects on strategy use (Kirk & Ashcraft, 1997). With that caveat, however, it appears that trial-by-trial strategy assessments, based on both observations of ongoing behavior and immediately retrospective verbal reports, can provide veridical and nonreactive strategy assessments for 5-year-olds and older individuals.

Issues of Data Analysis

Investigating change introduces a variety of complex issues regarding data analysis, issues sufficiently difficult that a number of methodologists have argued that no good inferential statistical solution exists for many problems at present (Willett, 1997). These analytic complexities have led to a greater reliance on graphical techniques than is typical in developmental research as a whole and also the use of several inferential statistical techniques that are specialized for analysis of change. Two techniques that have proven particularly useful in microgenetic research are presented here; for more comprehensive discussions see Allison (1984), Singer and Willett (2003), Collins and Sayer (2001), and Moskowitz and Hershberger (2002).

Graphical Techniques. Microgenetic studies often rely heavily on graphical presentation of data. Such graphical analyses have been particularly common in portrayals of discrete aspects of change, for example discovery of new strategies. One graphical technique that has proven especially revealing for examining discrete aspects of change is backward trial graphing. This is a technique in which the event of interest for each participant is aligned with the zero point on the X-axis, regardless of when it occurred in the sequence of trials. In almost all cases, the event of interest occurs for different participants on different trials. Thus, one participant's zero point might occur on the 10th trial of the experiment, another on the 20th, and another on the 30th. All other points on the X-axis are defined relative

to the zero point. The -1 trial or trial block is defined as the one immediately before the event of interest, the -2 trial or trial block is defined as the one immediately before that, the $+1$ trial or trial block is defined as the one immediately after the event of interest, and so on. Thus, backward trial graphs reveal what led up to the event of interest and what happened immediately after it.

The way in which this graphical technique has been used to illuminate change processes within microgenetic studies can be illustrated by describing its use in a study that examined whether unconscious discoveries sometimes precede conscious ones (Siegler & Stern, 1998). Second graders were presented problems of the form, $A + B - B = \underline{\hspace{2cm}}$ (e.g., $18 + 5 - 5 = \underline{\hspace{2cm}}$). These problems were of special interest for investigating unconscious discovery because they could be solved by different strategies that implied very different solution times. The computation strategy, which involved adding the first two numbers and then subtracting the third, implied long solution times, because the computations take young children considerable time. In contrast, the shortcut strategy, which involved reasoning that because $B - B = 0$, the answer must be A , could be executed much more quickly, because no computation was required.

This logic was borne out by the data; the mean reaction time (RT) when children used the computation strategy (as indicated by overt behavior and verbal report) was 16 seconds, whereas the mean RT when they used the shortcut strategy was 3 seconds. Especially important, there was virtually no overlap in solution times; almost all times were either 8 seconds or more, indicating use of computation, or 4 seconds or less, indicating use of the shortcut strategy. This fact, together with the fact that the second graders who participated invariably started out using computation, allowed unusually direct examination of unconscious strategy discovery. In particular, if children's solution times suddenly declined from the computation range to the shortcut range, but the children continued to report using the computation strategy, then it could be inferred that they had discovered the shortcut at an unconscious level (an approach labeled the "unconscious shortcut strategy").

The predicted data pattern was observed. Children's solution times dropped from an average of 12 seconds on the three trials just before their first use of the unconscious shortcut to an average of less than 3 seconds on the first trial on which they used the unconscious shortcut. This finding motivated use of backward trial graphs to examine children's discoveries in more detail.

Figure 11.1 includes two backward trial graphs, which show the patterns of strategy use leading up to the first use of the unconscious shortcut (left) and the first use of the conscious shortcut (right). As shown in the graph on the left, before children's first use of the unconscious shortcut, they consistently used the computation strategy. After the initial use of the unconscious shortcut, most children continued to use the unconscious shortcut over the next three trials. By the fourth trial after the initial use of the unconscious shortcut, half of the children were conscious of using the shortcut (as indicated by their verbal reports).

The graph on the right shows a parallel backward trial graph centered on children's first conscious use of the shortcut. On each of the three trials immediately preceding the first conscious use of the shortcut, roughly 80% of children used the unconscious shortcut (as opposed to less than 10% use of this strategy for the study as a whole). Once children began to report using the shortcut, they continued to use it quite consistently for the rest of that session (though most forgot and needed to rediscover it in the next session a week later). As this example illustrates, backward trial graphing procedures can reveal in considerably detail the events surrounding strategy discovery and other events of interest.

Inferential Statistical Techniques. Inferential statistical techniques for analyzing the type of categorical, repeated measures, nonlinear patterns of data typically yielded by microgenetic studies are not as well developed as techniques based on the general linear model, such as regression and ANOVA. However, some inferential statistical techniques are specifically useful for analyzing microgenetic data. One such class of statistical approaches is collectively labeled "event history analysis" (Allison, 1984; Singer & Willett, 2003). This class of techniques has been used most widely to analyze the type of one-time events that interest epidemiologists (e.g., death). However, the techniques are equally applicable to one-time events of interest to psychologists, such as discovery of a new strategy or walking unaided for the first time. Moreover, event history analysis can also be applied to events that occur multiple times. The technique is particularly useful because it allows examination of time-dependent predictor variables, such as mean solution time on the previous N trials, and because it handles in a nonarbitrary way cases in which the event of interest fails to occur during the study (right censored

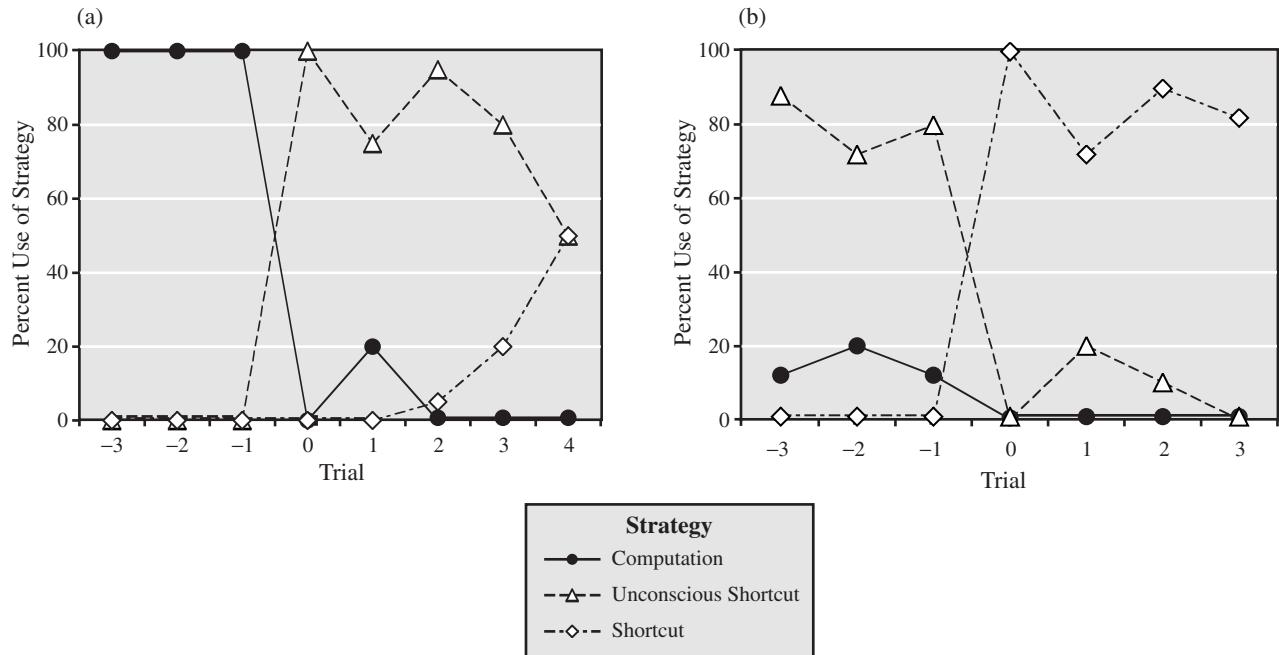

Figure 11.1 (a) Strategy use on trials immediately before and after each child's first use of the unconscious shortcut strategy on A + B - B problems. (b) Strategy use on trials immediately before and after each child's first use of the shortcut strategy on A + B - B problems. *Source:* From “A Microgenetic Analysis of Conscious and Unconscious Strategy Discoveries,” by R. S. Siegler and E. Stern, 1998, *Journal of Experimental Psychology: General*, 127, pp. 377–397. Reprinted with permission.

data). Moreover, it yields results that can be interpreted like the results of standard regression techniques.

In explaining the applicability of event history analysis to microgenetic data, Dixon and Bangert (2002) noted the centrality of two concepts: the risk set and the hazard rate. The risk set includes all participants who have not yet experienced the event of interest, for example those who have not yet generated a strategy. This set decreases over the course of the experiment, as more participants experience the event of interest. The hazard rate is the probability of an event occurring on a given trial; calculation of this probability must reflect the risk set on that trial. For dichotomous variables such as strategy discovery, logistic regression can be used to determine which variables influence the hazard rate.

Dixon and Bangert (2002) used event history analysis to examine discovery of strategies for solving gear movement problems. To determine the relation of prior performance to the likelihood of discovery, they examined speed and accuracy of solutions both on all preceding trials and on a moving window of the immediately preceding five trials. Solution times on the five previous trials, though not on all trials, predicted discovery; the longer the solution times on those recent trials, the more

likely that children would discover a new strategy. This predictive relation held true for two different advanced strategies. The event history analysis also revealed that other aspects of recent past performance, including inaccuracy and low rate of guessing, were positively related to the likelihood of discovery. Thus, techniques such as event history analysis and backward trial graphing are useful for analyzing microgenetic data.

OVERLAPPING WAVES THEORY

Microgenetic studies have consistently indicated that children's thinking is more variable than recognized within most theories of cognitive development. Different children use different strategies; individual children use different strategies on different problems within a single session; individual children often use different strategies to solve the same problem on two occasions close in time; and so on (Siegler, 1996).

To capture these and other findings, Siegler (1996) proposed overlapping waves theory. Perhaps because this theory co-evolved with microgenetic methods, it has

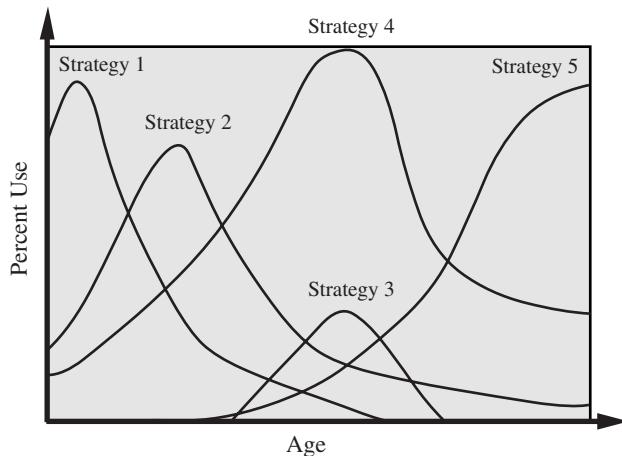

Figure 11.2 The overlapping waves model.

proven particularly useful for integrating findings from such research.

The basic assumption of overlapping waves theory is that development is a process of variability, choice, and change. As illustrated in Figure 11.2, the theory posits that children typically know and use varied strategies for solving a given problem at any one time. With age and experience, the relative frequency of each strategy changes, with some strategies becoming less frequent (Strategy 1), some becoming more frequent (Strategy 5), some becoming more frequent and then less frequent (Strategy 2), and some never becoming very frequent (Strategy 3). In addition to changes in relative use of existing strategies, new strategies are discovered (Strategies 3 and 5), and some older strategies abandoned (Strategy 1).

In many cases, several of these patterns are evident within a single study. Consider a study of number conservation (Siegler, 1995) in which 5-year-olds were given a pretest and four learning sessions. During the learning sessions, children needed to explain the logic underlying the experimenter's answer on each trial. As shown in Figure 11.3, over the course of the experiment, reliance on the relative lengths of the two rows of objects decreased, reliance on the type of transformation that had been performed increased, reliance on counting stayed at a constant low level, and answering "I don't know," first increased and then decreased. Interestingly, roughly half of the 5-year-olds first used the most advanced type of reasoning, reliance on the type of transformation, on a pretest trial. For these children, learning involved increased reliance on transformational reasoning; for the others, it involved discovery of the new approach as well as increasing reliance on it.

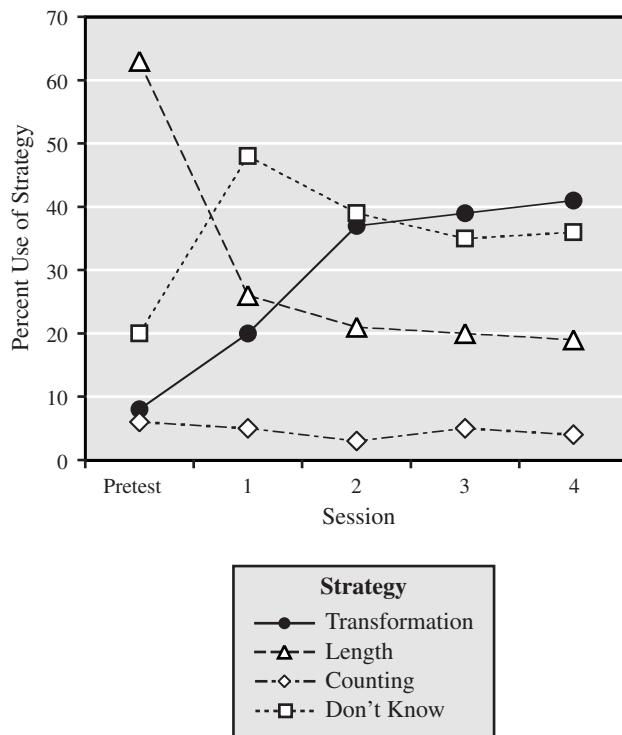

Figure 11.3 Strategy use on number conservation problems. *Source:* From "How Does Change Occur: A Microgenetic Study of Number Conservation," by R. S. Siegler, 1995, *Cognitive Psychology*, 25, pp. 225–273. Reprinted with permission.

As this example illustrates, an important feature of overlapping waves theory is that it provides a means of integrating qualitative and quantitative aspects of learning within a single framework. The approach recognizes that children discover qualitatively novel strategies and concepts; it also recognizes that much of development is due to quantitative shifts in the frequency and efficiency of execution of strategies, and in the adaptiveness of choices among them. Learning clearly involves both qualitative and quantitative changes; there is no reason for developmental theories to focus on one to the exclusion of the other.

Overlapping waves theory also makes several assumptions that are not evident in Figure 11.2. One such assumption is that from early in learning, children usually choose adaptively among strategies; that is, they choose strategies that fit the demands of problems and circumstances, and that yield desirable combinations of speed and accuracy, given the strategies and available knowledge that children possess. A related assumption is that such choices among alternative approaches generally become even more adaptive with experience in the content area. For example, from the beginning of their

experience with ramps, toddlers adjust their descent strategies to the steepness of the ramp (Adolph, 1997). They use quicker but riskier strategies on the shallower ramps and slower but surer strategies on the steeper ones. With age and locomotor experience, their descent strategies become even more finely calibrated to the ramp's slope. A further assumption is that improvements in performance during childhood reflect a combination of generation of superior new approaches; greater reliance on relatively advanced approaches that are already known; increasingly adaptive choices among approaches; and improved execution of all approaches.

Of particular importance for the present discussion, overlapping waves theory suggests that cognitive change can be analyzed along five dimensions: source, path, rate, breadth, and variability. The *source of change* refers to the causes that set the change in motion. The *path of change* is the sequence of knowledge states, representations, or predominant behaviors that children use while gaining competence. The *rate of change* concerns how much time or experience separates initial use of a new approach from consistent use of it. The *breadth of change* involves how widely the new approach is generalized to other problems and contexts. The *variability of change* refers to differences among children in the other dimensions of change, as well as to the changing set of strategies used by individual children.

To see how change can be analyzed in terms of these dimensions, again consider the Siegler (1995) study of number conservation. The source of the most dramatic change in this study was a combination of feedback on the correctness of answers and requests that the 5-year-olds explain why the correct answer (which had been indicated by the experimenter) was correct. This combination led to greater learning than feedback alone. The path of change involved children who were asked to explain the experimenter's reasoning initially relying most often on the relative length of the rows, then going through a period in which they abandoned this approach but did not adopt any consistent alternative, and then usually adopting the correct approach of relying on the type of transformation that the experimenter had performed. The rate of change was moderate; most children required several sessions to progress from initial use to consistent use of the transformational strategy. The breadth of change was relatively narrow; even some of the best learners in the study continued in the final session to often advance length explanations (rather than transformational ones) of the experimenter's reasoning on problems on which the longer row also had more ob-

jects. Finally, there was substantial variability both within and between children. At the level of within-child variability, only 2% of children relied on a single strategy throughout the study; 70% of children used three or more approaches. At the level of between-child variability, individual differences in learning could be predicted by two pretest measures: total number of strategies used by the child and whether the child ever used two different strategies on the same problem. Thus, distinguishing among the source, path, rate, breadth, and variability of change provided a useful framework for analyzing children's learning.

The remainder of this chapter uses the five dimensions of change specified by overlapping waves theory to examine the new field of children's learning and how microgenetic studies have contributed to it. The conclusions are based on 105 studies that met at least one of three criteria for being microgenetic. One criterion was self-description; I attempted to include all studies whose authors used the term microgenetic in the title or abstract (as indicated by a PsychLit search undertaken when I started to write the review) and that focused on children's learning. A second criterion was identification in prior reviews: I attempted to include studies that were described as microgenetic in one of three previous reviews of the literature: Siegler and Crowley (1991), Kuhn (1995), and P. H. Miller and Coyle (1999). A third criterion was meeting the three definitional standards for microgenetic designs, regardless of whether the authors or previous reviewers labeled them "microgenetic."

A few caveats are in order. The boundaries of the category "microgenetic studies" are inherently somewhat subjective, and either narrower or broader criteria could have been adopted. For example, studies that examined pretest-posttest changes, but not the intervening change process, were excluded on the logic that they did not allow detailed, data-based specification of the representations and processes that led to learning. For the same reason, studies that did not present quantitative analyses of changing competence, or that only examined changes in percentage of correct answers rather than also examining changes in strategy use, were excluded. Good arguments certainly could be made for other inclusion criteria that would have resulted in broader, narrower, or overlapping coverage with that in the present review. Even within the present criteria, studies that fit have almost certainly been inadvertently omitted. However, the studies that were examined provide a good sampling of results that have emerged from microgenetic studies of children's learning.

THE NEW FIELD OF CHILDREN'S LEARNING

The findings yielded by microgenetic studies are organized in terms of their implications for the five dimensions of learning described: variability, path, rate, breadth, and source. The discussion of each dimension begins with a summary of basic findings, then examines influences of child and environment on that dimension, and concludes with a discussion of implications and unresolved questions.

Variability

Perhaps the single central phenomenon that has been revealed by microgenetic studies is the great variability of learning (Granott, 2002; Kuhn, 1995; Lee & Karmiloff-Smith, 2002; P. H. Miller & Coyle, 1999; Siegler & Crowley, 1991). Such variability is especially evident in microgenetic studies, because the trial-by-trial assessments characteristic of the approach reveal different processing approaches within as well as between individuals. The variability is evident at every level of analysis. It is present in all domains, not just motor activities and memory where it has long been recognized, but in higher cognitive processes, such as problem solving, reasoning, and conceptual understanding, as well. It is present not only during delimited transitional periods, where it has long been recognized, but in periods where change is less rapid. It is present, moreover, not just at the neural and associative levels, where it has long been recognized, but also at the level of rules, strategies, theories, and other units of higher-level cognition. Finally, the variability is present not only between different people, but also within a single person solving the same problem at two points close in time and even within an individual's actions on a single trial. This section presents evidence for this pervasive variability and for how the variability is related to learning.

Basic Empirical Phenomena

Within-Child Variability

Massive variability of thought and action characterizes people of all ages. It is characteristic of infants; for example, Adolph (1997) found that in descending down ramps, 5- to 15-month-olds sometimes crawled, sometimes slid on their belly, sometimes slid on their behind, sometimes slid head first, sometimes slid feet first, sometimes descended in a sitting position, and some-

times refused to go down at all. It was not the case that one baby used one approach and a different baby another; on relatively shallow slopes, each baby used an average of five distinct strategies, and on relatively steep slopes, each baby used an average of six (Adolph, 1997; Wechsler & Adolph, 1995).

Toddlers' thoughts and actions are similarly variable. Chen and Siegler (2000) found that 18- to 35-month-olds who needed to select an appropriate tool to pull in a desirable toy sometimes used a tool, sometimes reached with their hands, sometimes requested their mother's help, and sometimes just sat and stared at the toy, perhaps hoping that someone would help them. Among the toddlers, 74% used at least three of these strategies during the 13 trials of the experiment, and only 3% used a single strategy throughout.

Comparable variability has been found in microgenetic studies of preschoolers. Most 3- and 4-year-olds use multiple selective attention strategies (P. H. Miller & Aloise-Young, 1995); most 4-year-olds use multiple strategies to solve analogy problems (Tunteler & Resing, 2002); most 4- and 5-year-olds use multiple arithmetic strategies (Siegler & Jenkins, 1989); and so on.

Older children's and adults' strategies are similarly variable. For example, Alibali (1999) found that third and fourth graders used six incorrect strategies and four correct strategies in both speech and gesture while solving mathematical equality problems. Kuhn, Schauble, and Garcia-Mila (1992) found that fifth graders changed their minds about the causal status of features in a scientific reasoning context an average of 10 times; in another study that used a similar task, fifth graders and adults changed their mind about the causal status of features an average of 14 times (Schauble, 1996). Variability of spelling strategies is similarly variable; in Kwong and Varnhagen (2005), each of four strategies was used by a majority of first graders, and each of seven strategies was used by a majority of adults. Thus, thought and action are highly variable within individual infants, toddlers, children, and adults.

This trial-to-trial variability in strategy use is not attributable to people moving in an orderly progression from less adequate strategies to somewhat more adequate strategies to yet more adequate strategies over the course of an experiment. Children often use more-advanced approaches on one trial and then regress to less-advanced ones on the next (Blöte, Van Otterloo, Stevenson, & Veenman, 2004; Coyle & Bjorklund, 1997; Kuhn & Phelps, 1982; Tunteler & Resing, 2002). Illustratively, P. H. Miller and Aloise-Young (1995) found

that 41% of changes in information gathering strategies from one trial to the next were regressions from more advanced to less advanced approaches. These regressions are temporary—the longer trajectory of change was upward in all of these studies—but the progress reflects a back and forth competition rather than a steady march forward.

The trial-to-trial variability cannot be explained in terms of children using different strategies on different problems. The variability is present even when the same problem is presented twice, relatively close in time. These changes, like those on successive trials, often reflect surprisingly even balances between improvements and regressions in situations in which children are not given instruction. Siegler and Shrager (1984) found that 45% of changes of level of basic addition strategies were in a negative direction, and Siegler and McGilly (1989) found that 43% of changes of level of time telling strategies were in a negative direction. In these cases and others, progressions outnumber regressions, but the difference is smaller than might have been expected.

The trial-to-trial variability also is not limited to tasks on which the two strategies differ in efficiency but not in their logical quality. Children have been found to show regressions from logically superior strategies to logically inferior ones surprisingly often. Such regressions have been found on numerous tasks that allow logically superior and inferior strategies, including mathematical equality (Alibali, 1999), matrix completion (Siegler & Svetina, 2002), number conservation (Church & Goldin-Meadow, 1986), control of variables (Schauble, 1990), and logical inference (Kuhn et al., 1992). Adults in the same studies have been found to regress from more advanced to less advanced logic on the last three of these tasks as well. For example, adults as well as children often generate valid inference forms in reasoning about causality and then regress to invalid forms of reasoning (Kuhn et al., 1995). Even Charles Darwin frequently regressed from more to less advanced thinking about evolution, as reflected in the reasoning in his notebooks (Fischer & Yan, 2002).

Cognitive variability also has been demonstrated within a single trial. The most extensive demonstrations of this phenomenon have come from research on gesture-speech mismatches (Alibali & Goldin-Meadow, 1993; Church & Goldin-Meadow, 1986; Graham & Perry, 1993; Perry & Lewis, 1999). On a variety of tasks, including number conservation, mathematical equality, and gear motion, children frequently express one strategy in speech but a different strategy in gesture. For ex-

ample, in Church's (1999) conservation study, 53% of children generated gesture-speech mismatches on at least three of the six problems. When such mismatches occur, children typically express more advanced understanding in gesture than in speech; for example, they might simply cite the height of the liquid columns in explaining their reasoning about liquid quantity conservation, but their hand gestures might include both vertical motions comparing the heights of the two liquid columns and horizontal motions comparing their cross sectional areas.

A variety of other types of within-trial variability have also been documented. On sort/recall memory tasks, children often use multiple strategies on a single trial, such as first organizing the objects into groups and then rehearsing either the names of the groups or the names of the items within each group (Coyle & Bjorklund, 1997; Schlagmüller & Schneider, 2002). On number conservation problems, children sometimes explain their reasoning in terms of both the length of the rows and the type of transformation on items where the two lead to the same answer (Siegler, 1995). On gear problems, children fairly often advance an explanation and follow it with second thoughts, such as, "Wait a minute, I made a mistake" (Perry & Lewis, 1999).

Significance of Within-Child Variability

The fact that substantial within-child variability exists does not necessarily mean that such variability is important. Traditional approaches have recognized the existence of within-subject variability but have treated it as a nuisance to be minimized—error variance (van Geert, 2002). Microgenetic studies, however, have revealed that within-child variability is important—for predicting change, for analyzing change, and for understanding change mechanisms.

Significance for Predicting Change. High initial variability of strategy use often predicts substantial later learning. This relation has been documented with numerous types of variability in numerous content areas. Number of strategies used by each child on a pretest has been found to correlate positively with the child's subsequent learning on number conservation and sort-recall tasks (Coyle & Bjorklund, 1997; Siegler, 1995). Number of strategies used by each adult on a pretest has been found similarly predictive of the adult's subsequent learning on gear problems (Perry & Elder, 1997). In addition, children's use of multiple strategies on a single trial (as opposed to over the entire set of

problems) has been found predictive of their learning on mathematical representation problems (Fujimura, 2001), on taxonomic memory problems (Schlagmüller & Schneider, 2002), and on number conservation problems (Siegler, 1995). The number of different explanations and the number of arguments that a child advances in support of a given explanation on conservation problems also has been found to predict the child's learning (Church, 1999). In addition, progressing through a variable state, in which gestures and speech express different understandings, has been found predictive of generalization to a novel task (Goldin-Meadow & Alibali, 2002).

Positive relations between initial variability and subsequent learning have emerged not only regarding the variability of what children say but also the variability of how they say it. Pauses, vagueness, false starts, talking to oneself, tapping the table, and verbal disfluencies all have been demonstrated to be positive predictors of learning (Bidell & Fischer, 1994; Caron & Caron-Parague, 1976; Hosenfeld, van der Maas, & van den Boom, 1997; Siegler & Engle, 1994; Siegler & Jenkins, 1989). For example, in Graham and Perry (1993), 64% of children who produced vague pretest explanations for answers to mathematical equality problems succeeded on posttest and transfer problems, versus 23% of children who produced more specific explanations.

To specify the influence of different types of verbal variability, Perry and Lewis (1999) presented fifth graders with gear movement problems and obtained independent measures of four types of variability during children's verbal protocols: long pauses, false starts, omissions of nouns or verbs (a form of vagueness), and metacognitive comments about the problem solving process (e.g., "I'm confused here"). They found that children who subsequently mastered the task were higher on all four measures of pretest variability than were other children, that the measures of pretest variability were only modestly related to each other, and that a composite measure of variability predicted learning more effectively than did age, instructional condition, or number of correct pretest answers. Long pauses and frequent metacognitive comments were the types of variability most strongly related to learning. In addition, all measures of variability decreased as children mastered the task.

The decrease in variability with increasing task mastery suggests that the positive relation between initial variability and learning is due to children whose initial

behavior is highly variable being in a state in which they are especially likely to learn, rather than to the high variability being a stable characteristic of good learners. Whether there are in fact consistent individual differences in variability is unknown. A number of investigators have hypothesized that gifted and creative people are especially high in variability (Gardner, 1993; Janos & Robinson, 1985; Stokes, 2001), but some data argue against the hypothesis (Coyle, Read, Gaultney, & Bjorklund, 1998).

Not all types of variability are positively related to learning. Coyle (2001) examined five measures of variability on sort-recall tasks, a type of problem on which multiple strategies can be used within a given trial: number of strategies used at least once during the experiment, mean number of strategies used on each trial, number of pairs of consecutive trials on which different strategies were used, mean number of strategies added and deleted on consecutive trials, and number of strategy combinations used on different trials. A factor analysis of the data on these measures from eight sort-recall experiments indicated two main factors: strategy diversity and strategy change. The first two measures loaded most heavily on the strategy diversity factor, the last three on the strategy change factor. Consistent with past findings, the strategy diversity factor, which corresponded to the kinds of variability described previously in this section, correlated positively with recall. In contrast, strategy changes, the factor on which the last three measures loaded most heavily, correlated negatively with recall. It seems likely that this negative relation was generated by recall failures leading children to shift strategies from one trial to the next or to try new combinations of strategies. More generally, distinguishing among types of variability and determining their relation to learning seems a crucial task for future research.

Significance for Analyzing Change. Accurately assessing within-child variability allows more precise theoretical analyses of how learning occurs than would otherwise be possible. In particular, trial-by-trial assessments allow researchers to analyze the contributions to learning of four component processes: acquisition of new approaches, increasing use of the most advanced existing approaches, increasingly efficient execution of approaches, and improved choices among approaches.

To illustrate how this taxonomy can be used to analyze learning, consider Lemaire and Siegler's (1995) study of the growth of proficiency in single-digit multi-

plication among French second graders. The children's strategy use, accuracy, and speed was observed three times during the year: 1 week, 3 months, and 5 months after the beginning of multiplication instruction. Multiplication skill greatly increased over this period. Contrary to what might have been expected, however, the learning did not reflect addition of new strategies: from the first assessment, which was conducted within a week of the beginning of multiplication instruction, children used the same strategies—retrieval, repeated addition, and guessing—as they did 5 months later. Instead, increased multiplication proficiency reflected the operation of the other three processes. There were large changes in the relative frequency with which the three approaches were used; use of retrieval increased, whereas use of the other two strategies decreased. The adaptiveness of choices among strategies improved; children increasingly focused their use of retrieval on the problems on which retrieval was most likely to yield the correct answer. Finally, efficiency of execution showed large improvements; children executed repeated addition and retrieval far more quickly and accurately at the end of the year than at the beginning.

The finding that improved execution of strategies was a major contributor to learning is not limited to second graders' multiplication. Although contemporary analyses of higher-level cognition have tended to emphasize the contributions of qualitative changes, such as acquisition of new strategies and representations, microgenetic analyses have consistently indicated that quantitative improvements in execution of strategies also play a large role. For example, Schauble (1990, 1996), Kuhn et al. (1995), and Kuhn and Phelps (1982) found that even when children and adults performed ideal experiments for identifying the effects of a given variable, the adults were more likely to learn the effect of the variable, because they more accurately remembered what they did and what happened in the experiment. Chen and Siegler's (2000) examination of toddlers' tool use, P. H. Miller and Aloise-Young's (1995) analysis of preschoolers' selective attention strategies, and Shrager and Callanan's (1991) observations of mothers and preschoolers cooking together are three other cases in which improved execution of strategies contributed substantially to learning.

Another way in which assessment of within-child variability can enhance analyses of learning is through providing sufficiently detailed data to allow investigators to focus on the most informative children and

strategies. Trial-by-trial analyses often indicate that all of the learning shown by a group of children derives from a subgroup of the children; focusing analyses on this subgroup can provide a much sharper focus on how learning occurred than mixing their data with data from children who learned little or nothing (Schlagmüller & Schneider, 2002; Siegler & Svetina, 2002). For example, identifying a subgroup of children who showed substantial learning allowed Gelman, Romo, and Francis (2002) to make more precise statements about changes in ESL students' science notebooks than would otherwise have been possible. Similarly, examining within-child variability allows identification of strategies that do and do not produce learning, which again allows more focused analyses of learning processes than would otherwise be possible. Blöte, Resing, Mazer, and Van Noort (1999), for example, found that on a selective attention task, all of the learning of the 4-year-old participants derived from improved ability to execute one of the three strategies that they used, and Siegler (1995) found that 5-year-olds' learning of number conservation was entirely attributable to increased reliance on one of the five strategies that they used.

Significance for Identifying Change Mechanisms.

Examination of within-child variability also has promoted formulation of mechanisms that specify how such variability leads to cognitive growth. Among these mechanisms are ones for bridging between less and more advanced strategies (Granott et al., 2002), for co-ordinating multiple types of knowledge and procedures through metacognitive understanding (Kuhn, 2002; Lee & Karmiloff-Smith, 2002), for progressively shifting strategy choices toward the more effective approaches (Siegler & Shipley, 1995), and for indicating how gesture-speech mismatch contributes to cognitive growth (Goldin-Meadow & Alibali, 2002).

Findings from microgenetic studies also convey general lessons relevant to a variety of mechanisms. One such lesson involves the existence of conceptual constraints on learning. Contrary to the emphasis of earlier learning theories on blind trial-and-error, microgenetic analyses indicate that children's learning in meaningful domains shows remarkably little trial and error (Bidell & Fischer, 1994; Siegler & Jenkins, 1989). Thus, even untutored 1- and 2-year-olds do not choose randomly among tools when they start to use them; they prefer tools that have the right type of head for pulling in the desired object and that are long enough to reach it (Chen

& Siegler, 2000). As discussed in more detail in the section on learning mechanisms, such findings suggest the existence of mechanisms that constrain children's strategies to those that are conceptually plausible.

Another general lesson of findings regarding within-child variability is that seemingly insignificant variations in children's initial behavior can exert large influences on subsequent strategy discoveries. For example, Thornton (1999) found that 5-year-olds who played the game "20 Questions" typically began by asking whether the answer was a particular object. However, the exact phrasing that they used proved surprisingly predictive of their learning beyond this point. In a game that included several cars as potential answers, only 10% of children who initially asked questions that clearly specified the object of interest (e.g., "Is it the red car?") or who did not name any object characteristics (e.g., "Is it this one?") progressed to asking questions that were informative about multiple objects (e.g., "Is it one of the cars?"). In contrast, 90% of children who initially used a slightly different, ambiguous phrasing (e.g., "Is it the car?") later asked these more informative questions. Thornton hypothesized that the very ambiguity of asking questions such as "Is it the car?" when multiple cars were present made it easier to advance to more informative questions such as "Is it a car?" or "Is it *one of the cars?*" Similarly, Childers and Tomasello (2001) found that 2.5-year-olds who were presented verbs with pronoun frames (e.g., "He kicked it"; "She pushed it") were more likely than peers who heard the same verbs with more specific noun frames (e.g., "Sam kicked the ball"; "Jane pushed the car") to generalize the past tense form to novel verbs (e.g., "She tunned it"; "Jane tunned the car"). The authors hypothesized that the greater consistency of the pronoun frames facilitated learning and generalization of the past tense verbs by making it easier for the children to focus on the verb ending. Thus, subtle differences in the conditions of learning can lead to substantial variation in the learning that occurs.

Influences of Child and Environment

Within-Child Variability

Amount of within-child variability often changes over the course of development, but the changes do not conform to any single pattern. With age and experience, variability can increase (Coyle & Bjorklund, 1997; Dowker, 2003), decrease (Braswell & Rosengren, 2000; Spencer

et al., 2000), increase and then decrease (Gershkoff-Stowe & Smith, 1997; Verijken & Thelen, 1997), stay constant (Flynn et al., 2004; Siegler, 1987), and so on.

Microgenetic studies of children's learning suggest that these disparate patterns may have a common source. Over the course of development, performance often oscillates between less and more variable periods. Therefore, the changes with age and expertise that are observed in any particular study depend on the part of the cycle that is observed. The basic idea that periods of stability (i.e., low variability) alternate with periods of transition (i.e., high variability) was proposed by Piaget (e.g., 1975), and similar ideas have since been suggested by Siegler and Taraban (1986), Goldin-Meadow, Alibali, and Church (1993), Thelen (1994), and van Geert (1997), among others. Microgenetic studies provide considerable support for the idea.

One source of support for the view that variability tends to wax and wane in a cyclical fashion comes from studies of Piagetian problem-solving tasks. On such problems, children often begin with a systematically wrong approach, then move to a variable state in which they oscillate among a variety of strategies, and then move to relatively consistent use of a more advanced approach. This pattern has emerged among children learning about balance scales (Siegler & Chen, 1998), matrix completion (Siegler & Svetina, 2002), and conservation (van der Maas & Molenaar, 1996). The pattern has emerged in microgenetic studies of other reasoning problems as well. For example, Hosenfeld et al. (1997) found that on an analogical reasoning task, children who began the study with a consistently incorrect approach moved over eight sessions toward almost equal use of three different approaches. In contrast, children who began in a more variable state, in which they fairly often used all three approaches, moved toward consistent use of the single most advantageous approach.

Another source of support for the conclusion that variability is cyclical comes from studies of motor development. Many infants, after an early period of bias toward reaching with the right hand, oscillate among varied reaching approaches (e.g., sometimes reaching with both hands, sometimes reaching with one hand, and sometimes reaching with the other) for a prolonged period before eventually returning to consistent right-handed reaching (Corbetta & Thelen, 1999). Similarly, infants' spontaneous kicking oscillates between periods of stability, in which a single form dominates (e.g., kicking one leg only), and periods of instability, in which several forms are used (e.g., kicking one leg re-

peatedly, kicking both legs simultaneously, and alternating between right and left leg kicks) (Thelen & Corbetta, 2002).

The oscillation between periods of lesser and greater variability is also evident in within-trial analyses. When given relevant experience on mathematical equality problems, children who initially produced the same type of incorrect strategy in speech and gesture tended to progress to a more variable state, in which their gestures reflected a correct strategy and their speech did not. In contrast, children who were given the same relevant experience but who began in a variable state, in which their gestures but not their speech expressed a correct strategy, usually progressed to a less variable state, in which gesture and speech expressed the same correct strategy (Alibali & Goldin-Meadow, 1993).

Performance of children in the same experiment who did not receive relevant experience provides a different type of support for the cyclical interpretation. Children who were initially in a variable state, in which their gesture expressed a correct strategy and their speech did not, often regressed to a consistent state, in which both were incorrect. In contrast, as noted in the previous paragraph, children who were initially in the variable state were especially likely to progress to a more advanced stable state if they did receive relevant experience. This finding suggests that high gesture-speech variability may signal "teachable moments" that need to be seized or otherwise be lost. To summarize, findings from microgenetic studies suggest that the disparate observations of age trends in variability are due to the observations tapping different phases of cyclical increases and decreases in variability.

One question raised by this perspective is whether there is a typical pattern of change in within-child variability with increasing age and knowledge. Siegler and Taraban (1986) addressed this question by suggesting the moderate experience hypothesis: that children usually progress from low variability when they have little relevant experience with the task to high variability when they have a moderate amount of experience, to low variability when they have substantial experience with it. The logic is that children often begin with only one or a few ways of solving a problem, then generate a larger variety of ways, and then settle on the best way or ways. Certainly, many examples fit this model: arithmetic, matrix completion, false belief, mathematical equality, and number conservation, to cite five (Alibali & Goldin-Meadow, 1993; Church & Goldin-Meadow, 1986; Flynn et al., 2004; Geary, 1994; Siegler &

Svetina, 2002). Determining whether it is the most common progression, however, is complex. Some questions are definitional: are we talking about variability on a single, narrowly defined type of problem or variability across a whole domain of problems? To illustrate with an everyday example, professional basketball players possess a far greater range of shooting motions than do high school players, but for any single type of shot (e.g., free throws), their motions are far less variable (Gilovich, Vallone, & Tversky, 1985). A second issue is whether we are talking about adaptive or nonadaptive variability. Returning to the basketball example, nonadaptive variability (e.g., variation in the motion of free throws) may decrease with experience, but adaptive variability (e.g., the variety of effective adjustments that can be made when a taller defender unexpectedly comes to block a lay up) may increase. A third issue is whether we are talking about competence or performance. A professional basketball player may know more ways of shooting free throws than a high school player, but may be less variable in her performance in games. Resolving this question is well beyond the limits of this paper, but it certainly is an important and interesting challenge for future research.

Between-Child Variability and Learning

Learning is influenced by between-child as well as within-child variation. Not surprisingly, age is a particularly pervasive influence. Older toddlers learn to use tools more rapidly and consistently than do younger toddlers (Chen & Siegler, 2000). Older preschoolers learn how to bake a cake from watching and interacting with their mothers more effectively than do younger preschoolers (Shrager & Callanan, 1991). Older elementary school students learn more rapidly from experience with Tower of Hanoi problems than do younger students (Bidell & Fischer, 1994). Adults learn more rapidly than 10-year-olds about the effects of variables on unfamiliar scientific reasoning problems and about how to perform controlled experiments (Kuhn et al., 1995; Schauble, 1996).

Between-child variation in initial knowledge also exercises a pervasive influence on learning. Children who use defined rules, as opposed to guessing or not using any systematic rule, show greater learning regarding balance scales (Siegler & Chen, 1998), biological concepts (Opfer & Siegler, 2004), gear problems (Dixon & Bangert, 2002), and scientific experimentation (Kuhn & Phelps, 1982). Similarly, children who can verbalize rules as well as generate responses consistent with them

show greater learning than peers who cannot verbalize the rules but generate similar nonverbal responses (Pine & Messer, 2000). Among children who use systematic rules, those who use more advanced pretest rules learn more about balance scales (Chletsos & De Lisi, 1991). Children with more advanced conceptual knowledge of a domain are superior in learning procedures for solving problems in the domain (Rittle-Johnson & Alibali, 1999; Rittle-Johnson, Siegler, & Alibali, 2001). Knowledge of which features of problems to encode is also positively related to subsequent learning, as indicated by findings on balance scale and mathematical equality tasks (Alibali & Perret, 1996; Siegler & Chen, 1998).

Numerous sources of between-child variability other than age and initial knowledge also influence learning. Children with higher IQs tend to learn more than peers with lower IQs (K. E. Johnson & Mervis, 1994; Siegler & Svetina, 2002). Children who place a greater value on organization are more likely to learn organizational memory strategies than are ones who do not place as great a value on organization (Schlagmüller & Schneider, 2002). Quality of social relationships also influences learning; children learn more about writing when they collaborate with friends than with other classmates (Jones, 1998; Jones & Pellegrini, 1996).

Theoretical Implications and Questions

One implication of research on within-child variability is that typical cross sectional and long-term longitudinal studies systematically exaggerate the changes that occur with age. Sampling at wide intervals makes change appear more abrupt than when sampling is more frequent, because it often eliminates periods of high variability and short-term regressions. In a clever recent demonstration of this point, Robinson, Adolph, and Young (2004) simulated varying sampling intervals by systematically removing observations from a high-density (daily) sampling of infant motor activities. They found that the wider the sampling interval, the more stage-like that development appeared.

A related problem is that classifying children as possessing an ability when they reach some arbitrary criterion (e.g., 75% correct) leads to ignoring the partial understanding manifested earlier. Children who use an advanced strategy on 25% of trials, for example, often are classified as if they had no understanding, when in fact they clearly do have some understanding. Conversely, failures to apply the desired reasoning at the

older age are ignored as long as the child meets the criterion, again leading to the amount and abruptness of change appearing to be greater than they are. Such exaggerated depictions of change may have contributed to the field's traditional weakness in explaining change, by seeming to demand mechanisms that produce larger and more rapid changes than the changes that actually occur.

Another intriguing theoretical issue concerns why within-child variability tends to be positively related to subsequent learning. Several explanations have been advanced. Dynamic systems theory postulates that for a system to change, it must first become unstable (Hosenfeld et al., 1997; Thelen & Corbetta, 2002). Variability in the behavior of interest is one sign of such instability. Another hypothesis is that variability reflects simultaneous activation of conflicting representations, which facilitates the extension of the more advanced representation from one modality to the other (Goldin-Meadow & Alibali, 2002). A third interpretation is that new strategies are often constructed from subroutines of existing approaches, and that assembling subroutines from different strategies is easier if the relevant strategies have been used recently and thus are relatively active (Siegler, 2002).

Although different in their particulars, all of these interpretations have a common core: Learning is most likely when previously dominant approaches weaken. This weakening can come about in varied ways: through the dominant approach failing, as when it results in negative feedback; through the learner being asked to explain why dominant incorrect approaches are incorrect; or through changes in other aspects of the system, as when improved postural control changes infants reaching. The general lesson is that change reflects not only the emergence and strengthening of new variants, but also the weakening of previous approaches.

With regard to differences between children, one issue that has only begun to be addressed concerns the determinants of individual differences in variability. One factor that appears to be important is the conditions under which children first acquire knowledge in the domain. Stokes (1995) demonstrated that if initial learning occurs under conditions that require highly variable responding, the high variability persists, even when the conditions change and high variability is no longer required or advantageous. In contrast, introducing the requirement of high variability later in learning does not produce a similar effect; participants produce high variability while it is rewarded, but return to lower levels of

variability once the requirement is no longer in effect. Personality and cognitive style differences also may contribute to such individual differences (Stokes, 2001).

Path of Change

One of the appealing aspects of the new field of children's learning is that it integrates quantitative and qualitative aspects of change. This is perhaps best exemplified by the new field's depiction of the path of change.

Basic Phenomena

In many tasks and domains, children (and adults) display qualitatively discrete understandings, such as rules, strategies, theories, mental models, and schema. Piagetian, theory-theory, and many information-processing approaches suggest that children progress through a regular developmental sequence of such understandings. Young children show a single, simple understanding; older children a different, more advanced understanding; yet older children a yet more advanced understanding; and so on.

The pervasive within-child variability described in the previous section indicates that such depictions of developmental sequences are too simple. Children cannot progress from one approach to another if at all times they know and use multiple understandings. However, this does not mean that the basic idea of the developmental sequence needs to be abandoned. Instead, the implication is that accurate depictions of the path of change must incorporate not only acquisition of new, qualitatively distinct approaches, but also quantitative changes in the frequency of use of both new and previous approaches.

Even infants progress through regular, age-related sequences of multiple, qualitatively distinct approaches. As noted earlier, infants use a variety of approaches to descend down relatively steep ramps: crawling; walking; sliding head first, sliding feet first, or in a sitting position; or refusing to go down in any way (Adolph, 1997). These approaches emerge in a quite consistent order. Refusing to go down at all is the first response, other than crawling, during the period in which crawling is infants' dominant mode of locomotion. Sliding down head first is typically the next strategy to emerge, followed by sliding down in a sitting position for some infants and sliding down feet first for others. On average, the infants used between three and four distinct descent strategies per session, with the relative frequency of these ap-

proaches changing greatly with age and experience. For example, in infants' first weeks of crawling, they refused to go down the ramp altogether on 100% of trials on which they did not attempt to crawl down. By the time that crawling was about to give way to walking as the main locomotor strategy, infants refused to go down on only 1% of trials on which they did not attempt to crawl down.

The path of change of the 1- and 2-year-olds in Chen and Siegler (2000) showed a similar mix of qualitative and quantitative changes. When the tool use task was introduced, two approaches predominated and were equally frequent: reaching for the goal object and just sitting and looking at it. Next, reaching became the dominant approach, being used on about 65% of trials, though looking, using a tool, and asking for help also continued to be used. With experience on the task and exposure to modeling or a verbal hint, tool use increased in frequency to the point where it was employed on the majority of trials. However, all three other approaches remained as well.

Preschoolers generate similar paths of change in single-digit addition, false belief, selective attention, and other tasks (Amsterlaw & Wellman, 2004; Flynn et al., 2004; P. H. Miller & Aloise-Young, 1995; Siegler & Jenkins, 1989). For example, Siegler and Jenkins (1989) presented 4- and 5-year-olds who knew how to add but did not know the *min strategy* (counting from the larger addend) with 20 to 30 sessions of addition problems. At the outset of the study, the preschoolers counted from one on about 40% of trials, retrieved the answer from memory on about 25%, and used a variety of other approaches (but not the min strategy) on the remaining 35%. By the end of the study, most children had discovered two new strategies (one of which was the min approach), as well as changing their frequency of previous approaches so that retrieval became the single most common strategy. Similarly, the large majority of 3-year-olds studied by Amsterlaw and Wellman (2004) progressed over 12 sessions from never correctly answering false belief problems, to sometimes generating correct false belief reasoning, to consistently answering correctly. None of the 3-year-olds progressed directly from incorrect to consistently correct responding; instead, children required a median of three sessions from the time they first showed correct false belief reasoning to the time when they first generated consistently correct answers. In addition, all children regressed to chance level performance in at least one session after

having responded consistently correctly in a session. Thus, the path of change included a qualitative shift (the first use of correct false belief reasoning) and also a quantitative change (the gradual increase in use of such reasoning).

The broad outlines of the paths of change revealed by microgenetic studies generally have paralleled those observed in cross-sectional and long-term longitudinal studies (Kuhn, 1995; P. H. Miller & Coyle, 1999; Siegler, 2000). Microgenetic studies, however, yield fine-grain as well as broad depictions of paths of change, and thus add invaluable information about them. Some of these types of information about paths of change have already been described: the longer solution times and heightened verbal and nonverbal variability that often immediately precede discovery, for example. However, understanding of paths of change has also been enhanced by numerous other findings from microgenetic studies.

One such contribution is information about short-lived transitional approaches. Certain phenomena that are seen only briefly, and sometimes not very often even then, are nonetheless crucial to understanding the learning process. One example involves naming errors during vocabulary acquisition. When toddlers start to speak, their word learning is extremely slow; it often takes them 6 months to learn their first 50 words. After children use 50 to 100 words, however, vocabulary acquisition greatly accelerates, with children often learning numerous words per day (Dromi, 1987). Gershkoff-Stowe's and Smith's (1997) microgenetic study of word acquisition revealed a surprising feature of this path of change; the acceleration in word learning was accompanied by a short-lived increase in naming errors. Both before and after this time, children rarely chose an incorrect word to name objects, but they frequently did so during the transition period. This transition period was brief and emerged at different ages for different children, probably because it was more a function of vocabulary size than of age; thus, the phenomenon would have been unlikely to be discovered without dense sampling of changing competence.

Numerous other paths of change also have been illuminated by detailed observation of transition periods. One example emerged in Karmiloff-Smith's (1979b) microgenetic study of map drawing. She found that after generating maps that were entirely sufficient for purposes of the task, 6- to 11-year-olds sometimes began to

generate redundant markings that were unnecessary for purposes of solving the problem but that reflected the children's increasing metaprocedural understanding of their own strategies. Chiu, Kessel, Moschkovich, and Munoz-Nunez's (2001) examination of a seventh graders' learning how to graph linear functions provides another example. In response to instruction, the child neither adopted the instructed strategy nor persisted with his original approach. Instead, he merged the two in an unanticipated way, using the instruction to create a refined version of his original approach.

In addition to revealing unsuspected transitional strategies, microgenetic analyses also sometimes reveal that hypothesized transition states do not occur or are not part of the transition. In Siegler's (1995) study of number conservation, no child was observed vacillating between reliance on the length of a row and reliance on its density, the transitional strategy hypothesized by Piaget (1952). In a study of single-digit addition, Siegler and Jenkins (1989) found that a transition state between the sum and min strategies that had been hypothesized by Neches (1987)—counting-on from the first addend—was not used by any child. In a study of categorizations of life status, Opfer and Siegler (2004) observed all three states that had been hypothesized previously (Hatano et al., 1993): the E-Rule (everything is alive), the A-Rule (only animals are alive), and the L-Rule (only plants and animals are alive). However, none of the children followed the hypothesized progression from the E-Rule to the A-Rule to the L-Rule. Instead, all children who used the E-Rule on the pretest progressed directly to the L-Rule.

The trial-by-trial analyses of microgenetic studies yield sufficient data about individual children's learning to examine the consistency of the path of change across individuals. Often, the path has proven to be quite consistent. For example, in Siegler and Stern's (1998) study of discovery of an arithmetic insight strategy, 13 of the 16 children in one group progressed through the same sequence of four strategies (in terms of the order in which they first used each strategy), and 2 of the other 3 children used the same four strategies but reversed the order of the first two approaches.

Deviations from the usual path can also be informative. On mathematical equality problems, for example, some children progress directly from a state in which both gesture and speech express the same incorrect understanding to a state in which both gesture and speech

express the same correct understanding, thus skipping the usual intermediate state of gesture-speech mismatch (Perry, Church, & Goldin-Meadow, 1988). Deviating from the typical path in this way is associated with narrower generalization than following it. Most children who follow the usual sequence generalize their understanding of the equal sign, which they learned in the context of addition, to multiplication, whereas most children who deviate from the usual sequence do not generalize to multiplication (Alibali & Goldin-Meadow, 1993).

By allowing identification of the trial of discovery (the trial on which a child first used a new strategy), microgenetic methods have also made it possible to examine the experience of discovery. Such examinations indicate that even for a single task, experimental procedure, and discovery, the experience varies a great deal among individuals. Of the 4- and 5-year-olds in Siegler and Jenkins' (1989) study of discovery of the min strategy, for example, some children were highly aware of using a novel strategy and commented on it, whereas others showed no awareness of having done anything unusual. Even among those who were aware of using a new approach, some were excited and others not. The experiential aspects of discovery seem to have longer-term consequences; those children who were aware of using a new strategy subsequently generalized it more extensively than those who did not. Excitement at making a discovery seems to have similarly positive effects on adults' generalization of new approaches (Siegler & Engle, 1994).

Influences of Child and Environment

As noted earlier, the path of change tends to be similar among different children of the same age exposed to the same experimental procedure. The commonality in paths of change extends further as well. Children who show similar initial knowledge of a task but who are of different ages tend to progress along the same path. On tool use problems, both 1- and 2-year-olds first either just looked at the goal toy or reached for it; then, reaching became the main strategy with the tool strategy also becoming fairly frequent; then, use of tools became dominant, with increasing focus on the optimal tool (Chen & Siegler, 2000). Similarly, 4- and 5-year-olds progressed through the same set of balance scale rules when both were presented feedback on their answers and asked to explain the reasoning that led to the experimenter's answers (Siegler & Chen, 1998).

Even when both age and initial knowledge differ, the path tends to be similar. For example, Kuhn et al. (1995) found that although adults' scientific reasoning started at a more advanced level than that of 10-year-olds, the children and adults progressed along a common path of theory-evidence coordination. The path involved first noting that evidence from experiments is relevant to beliefs about the causal status of variables; then supporting prior beliefs that a variable matters by citing a result from a single experiment that is consistent with the prior belief; and then supporting prior beliefs that a variable does not matter by citing single instances consistent with that belief. Next comes citation of multiple observations to justify prior beliefs, followed by the development of controlled experimentation and a gradual increase in the frequency of valid inferences on the basis of the experimental evidence. Adults tended to start further along this path and to progress further along it than the 10-year-olds, but the progression was the same.

The path of change also tends to be similar for children with and without mental retardation. For a task on which external memory aids could be used to help remember the location of objects, children with and without mental retardation who were matched for mental age showed the same path of change. Both groups initially did not use the external memory aids, then manipulated individual tokens but did not place them in ways that would help in recalling the target locations, and then arranged the objects so that they provided straightforward cues to the locations that needed to be remembered (Fletcher & Bray, 1995). Similarly, Fletcher et al. (1998) reported that 8-year-olds with mild mental retardation showed a path of change in basic arithmetic similar to that of the typical preschoolers in Siegler and Jenkins (1989).

This consistency of the path of change across individuals is not perfect. In most studies, people vary somewhat in their paths of change. This is true even in the studies cited above as illustrations of the consistency of change across individuals. For example, in Siegler and Jenkins (1989), discovery of the shortcut sum strategy usually was followed quickly by discovery of the min strategy, but one child in the study discovered the min strategy without ever using the shortcut sum, and another child used the shortcut sum many times over a protracted period before discovering the min approach. Sometimes there are two common paths of change. In one such case, Lavelli and Fogel (2002) examined

amount of infant-mother communication on a weekly basis over the infants' first 14 weeks. They found that for roughly half of infant-mother dyads, face-to-face communication increased steadily over the period, whereas for the other half, the amount of communication increased until about 8 weeks and then steadily decreased. Another example of inter-child variability in the path of change comes from the area of motor development. Spencer et al. (2000) observed babies' reaching each week between 3 and 30 weeks and every other week between 30 and 52 weeks. The components involved in development of stable reaching were similar across infants—improved control of the head and upper torso, independent sitting, ability to extend the hand to a distant target, and ability to touch and grasp nearby objects—but different infants mastered the components in different orders.

Theoretical Questions and Implications

These results indicate that the traditional view of developmental sequences is outdated; children rarely progress directly from one consistent understanding to a different consistent understanding to a third consistent understanding. Both the amount of within-child variability—children using multiple approaches over protracted time periods—and the amount of between-child variability—different children showing different paths of change—indicate that the traditional conception is too simple.

These findings raise the issue of whether it makes sense to talk at all about developmental sequences in a post-Piagetian world. I think that it does, because it calls attention to a central developmental phenomenon: that children generate increasingly adequate, qualitatively distinct, strategies and understandings prior to mastering concepts and problem solving skills. These partially correct strategies and understandings frequently reflect broadly applicable ways of thinking that children apply when they lack superior alternatives, for example 5-year-olds focusing exclusively on the single most salient dimension on liquid quantity conservation, balance scale, shadow projection, and other problems.

The challenge, then, is to refine the concept of developmental sequences so that it is consistent with current data on paths of change yet also as parsimonious as possible given those data. One promising approach would be to recognize that developmental sequences are multifaceted and therefore need to be characterized in multiple ways. For example, the path of change might be charac-

terized in terms of the order in which strategies are first used, also in terms of the order in which different strategies become the single most common approach, and also in terms of the mixture of strategies used at various points. In some cases, the first and second of these characterizations will coincide, as they did in Siegler and Stern (1998). In other cases, each approach will yield a unique perspective, as when some early developing strategies never become common (as in Siegler & Jenkins, 1989). Together, these multiple depictions of paths of change may contribute to an accurate and nuanced understanding of developmental sequences.

Rate of Change

Both scientific and everyday theories about strategy discovery vary greatly in the rate of change they envision. Theories that emphasize trial and error suggest that discovery of new approaches will be a slow process; theories that depict discoveries as arising from flashes of insight, as in the tale of Archimedes in the bathtub, suggest a rapid if not instantaneous rate of change.

The concept *rate of change* can be usefully divided into two components: amount of time/experience before the first use of a new approach (here labeled the *rate of discovery*, and amount of time/experience before frequency of the new approach reaches its asymptotic level (here labeled the *rate of uptake*). Distinguishing between the two types of information is essential, because the relation between them varies considerably. Sometimes, discovery is quite rapid but uptake takes a long time. For example, second graders in Siegler and Stern (1998) took an average of only seven trials to discover an arithmetic insight strategy, but did not use the strategy on the majority of trials in any session until five sessions (100 trials) later. In contrast, kindergartners in Siegler and Svetina (2002) required an average of about 50 trials before they discovered a correct strategy for solving matrix completion problems, but required only about 12 trials beyond that point to use it consistently.

Experimental conditions also affect the two rates of change differently. For example, in Opfer and Siegler's (2004) study of categorization of life status, the teleology condition led to slower discoveries than did the two other experimental conditions, but once the discovery was made, its uptake was much faster in the teleology condition. In Blöte et al. (2004), discoveries occurred most often on easy problems, but uptake of the new strategy was comparable on easy and difficult problems.

In Siegler and Jenkins (1989), introducing challenge problems did not influence the rate of discovering the min strategy, but it greatly increased the uptake of the strategy among children who already had discovered it. Thus, a comprehensive description of the rate of change requires information regarding both the rate of discovery and the rate of uptake.

Basic Phenomena

Perhaps the most basic question regarding the rate of discovery is whether discoveries tend to be made quickly or slowly. Phrased in terms of models of discovery, a good answer might be "Faster than connectionist models imply, slower than symbolic models imply." Connectionist models tend to discover new approaches extremely slowly (to the extent they discover them at all). For example, McClelland's (1995) model of balance scale learning requires thousands of trials to learn each new rule. Clearly, children discover new rules much faster than that. On the other hand, children rarely discover new rules in a single trial, as symbolic approaches such as Newell's (1990) model of balance scale learning do. Instead, results from microgenetic studies suggest that when feedback is given (as presupposed in both connectionist and symbolic models), discoveries usually take anywhere from a handful of trials to a few hundred trials. We might label this *human-scale learning*.

The difference between human scale learning and that of connectionist and symbolic models is evident in the difference between Siegler and Chen's (1998) empirical data on 5-year-olds' discovery of balance scale rules and the discovery of the same rules by McClelland's (1995) and Newell's (1990) simulation models. Over the course of 16 problems, two-thirds of the 5-year-olds in Siegler and Chen (1998) who initially used no identifiable rule discovered Rule I. Over the same number of problems, one-third of 5-year-olds who initially used Rule I discovered Rule II. Sixteen trials is reasonably representative of human scale strategy discovery, but it is far different from either a single trial or thousands of trials. Rates of strategy discovery vary considerably across studies, depending on characteristics of the children, experimental situation, and relation between old and new strategies. However, as the Siegler and Chen results indicate, discovery is rarely as fast as symbolic models suggest or as slow as connectionist models imply.

Children's learning tends to differ from that of the simulation models not only in the rate of discovery but

also in the rate of uptake. Both symbolic and connectionist models tend to use a superior new strategy consistently on a given problem once the strategy has been discovered and used on that problem. Children, however, often extend newly discovered strategies surprisingly slowly. The relatively slow extension of advanced thinking extends even to problems that are viewed as reflecting fundamental developmental advances that have broad ramifications for a wide range of thought. For example, 43% of children who were just beginning to use transformational reasoning on number conservation problems used that reasoning again when the same problem was presented two sessions (24 trials) later, and 76% used it when the same problem was presented four sessions (48 trials) later (Siegler, 1995). The same relatively slow uptake is usually evident when new problems are structurally identical but differ in their particulars from earlier ones. Thus, in three microgenetic studies of acquisition of understanding of false belief (Amsterlaw & Wellman, 2004; Flynn, 2005; Flynn et al., 2004), uptake was quite gradual. Only 4 of 13 3-year-olds who acquired understanding of false belief in Flynn et al. (2004) consistently displayed such understanding thereafter. Similarly, all children in Amsterlaw and Wellman (2004) who improved their false belief understanding regressed from one session to the next at least once during the study, though the overall trend was toward improved performance.

Slow uptake of new ways of thinking has been documented with a wide variety of other tasks and age groups as well. For example, 4-year-olds who spontaneously used rather sophisticated analogical reasoning strategies in one session often regressed to less sophisticated strategies for several sessions thereafter (Tunteler & Resing, 2002). Regressions have also been found to be common in the quality of 4-year-olds' storytelling (McKeough & Sanderson, 1996), in 8-year-olds' use of organizational memory strategies (Coyle & Bjorklund, 1997), in 11-year-olds' solving of gear problems (Perry & Lewis, 1999), and in adults' use of scientific reasoning strategies (Kuhn et al., 1995).

Uptake of new strategies tends to be slow even when children can explain why the new approach is superior to the old. For example, in Siegler and Jenkins (1989), one child, on her trial of discovery of the min strategy, explained why she didn't count from one by saying, "Cause then you have to count all those numbers" (p. 66). Another child in the same study commented on her first use of the min strategy by saying, "Yeah—smart answer"

(p. 80). Yet, both of these children, like others in the study, generalized use of the new strategy quite slowly (though faster than children whose visible behavior indicated that they had used the min strategy but who claimed that they had counted from one).

Although uptake of newly discovered strategies is generally quite slow, this is not always the case. For example, Schlagmüller and Schneider (2002) found that 8- to 12-year-olds adopted an organizational strategy for remembering groups of objects quite rapidly once they began to use it, and Thornton (1999) observed similarly rapid uptake of an efficient strategy for playing “20 Questions” in a 5-year-old. A number of factors that have been found to influence the rate of discovery and uptake of new strategies are considered in the next section.

Influences of Child and Environment

Rates of both discovery and uptake increase with age. Toddlers between 27- and 35-months discover effective tool use strategies more rapidly than 18- to 26-month-olds and their uptake of the strategy is also quicker (Chen & Siegler, 2000). Among preschoolers, 5-year-olds are faster than 4-year-olds to learn that certain relations are indeterminate (Klahr & Chen, 2003). The trend continues with older children; 13-year-olds are quicker than 10-year-olds to discover and generalize an organizational strategy to enhance memory (Bjorklund, 1988), and adults are more likely than 10-year-olds to discover and generalize effective scientific experimentation and inference strategies (Kuhn et al., 1995; Schauble, 1996). To illustrate the magnitude of the differences among age groups that sometimes emerges, in Thornton (1999)’s study of how children build toy bridges, 5-year-olds required more than three times as many trials as 7-year-olds to discover an insightful strategy. In addition, younger children sometimes fail to maintain learning under circumstances in which older peers do so. For example, 4-year-olds who received training in understanding indeterminate relations frequently regressed when their understanding was assessed 7 months later, though all 5-year-olds maintained their original learning (Klahr & Chen, 2003).

Other characteristics with which children enter studies also influence their rate of learning. Rates of discovery and uptake of new approaches tend to be greater for children with higher IQs (K. E. Johnson & Mervis, 1994; Siegler & Svetina, 2002). Similarly, children who start with more advanced rules tend to progress to yet more advanced approaches more rapidly than children whose initial rules are less advanced (Fujimura, 2001;

Siegler & Chen, 1998). Relatively advanced encoding and conceptual understanding are also associated with rapid discovery and uptake of new approaches (Rittle-Johnson et al., 2001; Siegler & Chen, 1998).

In addition to these influences of child variables, a variety of experiential variables also influence rates of discovery and uptake. Direct instruction in problem solving produces faster discovery and uptake of new approaches, through narrower generalization, than does instruction in underlying principles (Alibali, 1999; Opfer & Siegler, 2004). Exposure to a model who both selects the most appropriate tool and demonstrates how to use it to obtain the goal leads to faster discovery and uptake of the new approach than does a verbal hint that identifies which tool to use but does not demonstrate its use (Chen & Siegler, 2000). Encountering problems that are moderately beyond current understanding produces faster discovery than encountering ones that are far beyond it (Siegler & Chen, 1998).

Relations between new and existing approaches also exert a large influence on the rate of uptake of new approaches. Strategies that offer large advantages in accuracy and speed on the problems being presented have a faster rate of uptake than strategies that offer smaller advantages. Evidence for this point can be found in Siegler and Jenkins’ (1989) 11-week study of discovery of the min strategy. The first 7 weeks of this period were spent on problems with addends 1 to 5. Exposure to such problems led most children to discover the min strategy, but only to very gradual uptake of it. Therefore, in Week 8, Siegler and Jenkins presented children with challenge problems, problems such as $22 + 3$, on which counting from 1 would work badly but on which the min strategy would work well. Encountering the challenge problems led children who had already discovered the min strategy to greatly increase their use of it, not only on those problems but on subsequent small addend problems as well.

Between-experiment evidence is consistent with this conclusion that uptake (but not necessarily discovery) is faster when the new strategy has large advantages over previously discovered alternatives for solving the types of problems being presented. Problems on which the new strategy leads to consistently correct performance, and on which older strategies lead to systematically incorrect or chance performance, evoke the fastest uptake of new strategies. Thus, uptake of new strategies has been relatively rapid on mathematical equality, number conservation, matrix completion, Tower of Hanoi, and balance scale tasks (Alibali & Goldin-Meadow, 1993; Bidell &

Fischer, 1994; Church & Goldin-Meadow, 1986; Siegler & Chen, 1998; Siegler & Svetina, 2002). Uptake is slower when the new strategy produces smaller improvement in accuracy and when its main advantage is speed. Examples include use of the arithmetic shortcut strategy rather than addition and subtraction to solve $A + B - B$ problems (Siegler & Stern, 1998), use of systematic experimental design strategies rather than unsystematic comparisons to learn about the causal influence of variables (Kuhn & Phelps, 1982; Kuhn et al., 1995; Schauble, 1996), use of organizational strategies for remembering objects that can be organized into a few categories (Coyle & Bjorklund, 1997; Fletcher et al., 1998), and use of bridging, a strategy of envisioning a rough outline of a strategy prior to formulation of the strategy, in construction of robots and bridges (Granott, 1998; Parziale, 2002).

Even strategies that bring large benefits sometimes have relatively slow uptakes. One reason is that newly discovered strategies are subject to forgetting (i.e., to their strength diminishing below the point at which they would be chosen) and therefore sometimes need to be rediscovered. One type of evidence for the role of forgetting is that extension of new strategies tends to be more gradual in multisession microgenetic studies than in single session ones. Children fairly often continue to use a newly discovered strategy quite consistently in the session in which it is discovered (e.g., Alibali, 1999; Siegler & Chen, 1998). However, when children return a few days or a week later, they often have forgotten the strategy, thus necessitating rediscovery. This phenomenon was particularly dramatic in Siegler and Stern's (1998) study of discovery of the shortcut strategy for solving problems of the form $A + B - B = \underline{\hspace{2cm}}$. After discovering the shortcut strategy, children used it on between 70% and 90% of the remaining trials in the session. However, 0 of the 15 children who discovered the shortcut approach used it on the first trial of the next session, a week later; not until the sixth trial of the new session did a majority of children again use it. By the end of that session, all 15 children were again using the shortcut strategy. However, the "off again, on again" pattern continued; even five sessions after the initial discovery, most children began the session by using the standard computation strategy (adding A and B and then subtracting C), though the rediscoveries of the shortcut strategy were made increasingly quickly in later sessions.

Forgetting plagues not only everyday discoveries but also profound ones. Wegener (1915/1966), the father of plate tectonic theory, claimed that he generated the

basic idea in 1910 or 1911, shortly before his classic 1915 publication describing it. A friend, however, recalled Wegener describing the idea to him in 1903 when they were both graduate students (Giere, 1988). Thus, the cycle of discovering, forgetting, and rediscovering characterize even the most profound insights.

Theoretical Implications and Questions

Probably the most intriguing question raised by findings regarding the rate of change is why the uptake of effective new strategies is so often slow. After discovering a strategy that is both more accurate and logically superior to prior approaches, why not use it all the time? Several contributing factors have already been cited: forgetting of newly discovered approaches; the omnipresence and generally adaptive value of within-child variability; and associations between frequently used strategies and the types of problems on which they have been used, which must be weakened for the new approach to be chosen consistently. However, other factors almost certainly contribute as well.

One likely contributing factor is the benefits and costs of using newly discovered strategies. When children first use a strategy, they often execute it less effectively, and at a greater cost in mental resources, than will be the case after greater use (Guttentag, 1984). Such utilization deficiencies have frequently been observed in microgenetic research; indeed, because microgenetic studies allow examination of newly discovered strategies, they provide the ideal situation for observing utilization deficiencies. In one example of a utilization deficiency arising within a microgenetic study, 3- and 4-year-olds' discovery of a potentially effective selective attention strategy did not initially improve their accuracy (P. H. Miller & Aloise-Young, 1995). In another example, 4- and 5-year-olds' initial uses of the min strategy did not improve their accuracy or solution times relative to counting from one on small number problems (Siegler & Jenkins, 1989). In a third example, 9-year-olds' initial use of an organizational strategy did not improve their memory of the objects that had been organized (Bjorklund et al., 1992). And in a fourth particularly striking case, the first two uses of an organizational strategy led to below chance accuracy, whereas the last few uses of the same strategy produced almost perfect accuracy (Blöte et al., 1999). Thus, part of the reason for the slow uptake of seemingly useful new strategies is that the strategies at first are less useful than they later will be.

A second question regarding the rate of change (and also its path and variability) concerns the sources of within-condition variability that cannot be traced to children's demographic characteristics or initial knowledge. Even when age and knowledge are comparable, children within any given experimental condition vary greatly in the rate of discovery and uptake of new strategies. Consider the extent of such variation in Siegler and Jenkins (1989). Among the seven children who discovered the min strategy, the first discovery occurred in the 2nd session, the last in the 22nd. Despite this substantial variation, neither age nor prior knowledge of addition nor other relevant types of numerical knowledge predicted the rate of discovery.

Similar within-condition variations due to unknown causes in rate of discovery and uptake of new approaches have arisen among other age groups and on other tasks. For example, 33% of 3- and 4-year-olds in Flynn et al. (2004) showed abrupt change over seven sessions of presentation of a seven-task theory of mind test. Abrupt change was defined as children at least once during the study passing at least three more tasks than in the previous session. The other 67% of children showed gradual change. Similarly, 24% of the third and fourth graders in Alibali (1999) showed abrupt change (as defined by use of a nonoverlapping set of strategies on the pretest and posttest), whereas the other 76% did not. In P. H. Miller and Aloise-Young's (1995) similar analysis of 3- and 4-year-olds' acquisition of a selective attention strategy, the corresponding percentage of abrupt and gradual changes was 37% and 63%. Kuhn and Phelps (1982) and Siegler (1995) also found that although the majority of children showed gradual change, a minority showed abrupt change. Thus, although a variety of child and environmental variables have been found to influence the rate of discovery and generalization, much variance remains to be explained.

Breadth of Change

In general, learning is neither as narrow nor as broad as could be imagined. It almost always generalizes beyond the item on which a new approach was generated, and it rarely is instantly extended to all items and tasks on which the discovery is relevant. Thus, just as there seems to be a human-scale *rate* of learning, there also seems to be a human-scale *breadth* of learning.

This similarity between findings regarding the breadth and the rate of change is not coincidental. Except in cases in which the same item is presented re-

peatedly, the uptake of new strategies always involves problems that differ in some way from the item on which the discovery occurred. In all such instances, whether the uptake of new strategies is viewed as an issue of the rate of change or the breadth of change is to some degree a matter of definition. For purposes of this chapter, extensions of new approaches to different problems on the same task were discussed under the rate of change heading; the discussion of breadth of change in this section is limited to cases in which new approaches are extended to a different task (though even that distinction winds up being somewhat subjective, as will become evident later).

Basic Phenomena

Many volumes have been written lamenting children's lack of transfer and the narrowness of their learning (e.g., Bransford, Brown, & Cocking, 1999; Cognition and Technology Group at Vanderbilt, 1997; Lave, 1988). Much less has been written about the fact that learning also tends to be far from literal. Indeed, there may be a tendency to define "transfer problems" as problems on which useful known strategies tend not to be spontaneously applied, and to define problems on which children spontaneously extend appropriate strategies as not requiring transfer.

Another reason why learning often seems narrower than our intuitions suggest it ought to be is that new strategies and capabilities can transform a familiar task into a novel one. The transition from crawling to walking provides a revealing example. As infants who could crawl but not walk gained experience with crawling, they adjusted their descent strategies increasingly precisely to their physical limits. In particular, they increasingly used descent strategies safer than crawling (e.g., sliding in a prone position) when the slope was too steep for them to crawl down safely (Adolph, 1997). When the same children began walking, however, their descent strategies became less well calibrated to their capabilities; they often tried to walk down steep slopes and fell. Thus, the new capability of walking converted a familiar task, on which children chose appropriate strategies, into a novel task that initially elicited riskier choices.

This example also illustrates another reason why learning is often narrower than seems ideal. New learners invariably face two challenges: extending their learning to the cases in which it is useful, and not extending it to the cases in which it is not useful. Accomplishing these goals requires knowing when the strategy will be useful and also often requires knowing how to

adapt the strategy to a novel context. Each of these difficulties is evident in children's learning about mathematical equality. When third and fourth graders learn how to solve addition problems of the form $A + B + C = + C$, many fail to transfer their learning to multiplication problems of the form $A \times B \times C = \underline{\hspace{2cm}} \times C$ (Alibali, 1999; Alibali & Goldin-Meadow, 1993). However, learners often overextend new mathematical equality strategies to superficially similar problems on which the new strategy is not applicable. For example, after correctly solving several problems of the form $A + B + C = + C$ by adding A and B , third and fourth graders often add A and B to answer similar looking problems on which that strategy produces incorrect answers, such as $A + B + C = \underline{\hspace{2cm}} + D$ (Siegler, 2002). In this regard, older learners are no different than 2-year-olds, who sometimes both overextend and underextend the same newly learned word (Bowerman, 1982).

Despite the difficulty posed by these twin pitfalls, learners within microgenetic studies sometimes do show impressive transfer. One context in which this has been found repeatedly is acquisition of the control of variables strategy for scientific experimentation. Second, third, and fourth graders who were provided explicit instruction in the control of variables scheme on one problem (e.g., factors influencing extension of springs) showed almost complete transfer of the scheme to superficially unrelated but structurally parallel problems (e.g., factors influencing speed of objects sinking in water). Even more impressive, the children maintained the gains over a 7-month period with no further experimental intervention (Chen & Klahr, 1999).

In this study, the transfer was to different physical reasoning tasks. Broad transfer of the control of variables scheme also has been demonstrated between physical and social reasoning. When fifth graders and adults were first presented reasoning problems in one domain (physical or social), and then presented problems from the other domain, their proportion of valid experiments and inferences in the new domain did not even temporarily diminish relative to the highest level reached in the initial domain (Kuhn et al., 1995).

An intriguing feature of this relatively broad learning of the control of variables scheme is that it can emerge as a by-product of trying to learn specific content. The children and adults in Kuhn's and Schauble's studies of this scheme (Kuhn, Amsel, & O'Laughlin, 1988; Kuhn & Phelps, 1982; Kuhn et al., 1992, 1995; Schauble, 1990, 1996) were not instructed in the control of variables scheme, nor did the instructions they re-

ceived call attention to it. They were simply asked to find out which variables mattered on the particular tasks that they were presented. The learners made considerable progress in inferring which variables were, in fact, influential, but along the way, they also learned how to conduct experiments. Thus, relatively broad learning at times arises out of problem-solving activity aimed at meeting other goals.

Influence of Child and Environment

Consistent with findings regarding the other components of change, the breadth of learning increases with age. Older preschoolers show broader learning than younger toddlers (Chen & Siegler, 2000), older school age children show broader learning than younger ones (Bjorklund, 1988; Dixon & Bangert, 2002), and adults show broader learning than do school age children (Schauble, 1996). When initial learning is equated, however, this relation fairly often disappears; younger preschoolers who learned an initial problem to the same extent as older ones showed comparable transfer (Brown, Kane, & Echols, 1986), as did younger elementary school and middle school children who learned balance scale and tic tac toe problems as well as older peers (Chletsos & De Lisi, 1991; Crowley & Siegler, 1999).

A variety of other variables also have been found to influence the breadth of learning. Recognizing the value of new strategies influences extension of them to new problems (Paris, Newman, & McVey, 1982). Learning a strategy on problems on which the strategy is always applicable leads both to more correct extensions and to more overextensions than does learning the strategy on problems on which it sometimes applies and sometimes does not (Siegler & Stern, 1998). To the extent that the influence of variables violates learners' expectations, they tend to perform fewer experiments about the effects of the variables and to learn less about them (Schauble, 1996).

Theoretical Implications and Questions

One implication of these findings from microgenetic studies is that what is often taken as lack of transfer actually reflects a lack of stability in the initial learning. Particularly direct evidence for this view came from Opfer and Siegler's (2004) study of 5-year-olds learning about biological categories. On the posttest of this study, children were asked to categorize the life status of the specific plants, animals, and inanimate objects about which they earlier received feedback and also to categorize novel plants, animals, and inanimate objects.

The posttest classifications were far from perfect, but they were equally imperfect on familiar and novel items; the percent correct categorization was almost identical on the two. Given the diversity of objects within the experiment (the plants included flowers, trees, grass, beans, and clover; the animals included cats, crocodiles, bees, worms, and octopi), the breadth of learning was more impressive than would have been evident without data on use of the new categorization scheme on repetitions of the original entities. Similar evidence came from Siegler's (1995) number conservation study, in which use of transformational reasoning on repetitions of the same problem was no higher than generalization of the reasoning to problems on which the reasoning was not used earlier. Thus, the general high variability of use of new strategies may underlie many apparent failures to transfer learning to different types of problems; distinguishing between the two interpretations requires presenting examples identical to those originally learned as well as novel examples.

A second theoretical implication concerns the crucial role of encoding of categories in determining the breadth of learning. The heterogeneity of members of each superordinate category in Opfer and Siegler (2004) provided little reason to expect broad transfer. However, children appeared to encode "living" as a property that applies to all objects or to no object within each superordinate category. Thus, they thought that either all plants or no plants are alive. Children did not show similar consistent categorization for two other biological properties—capacity for growth and need for water—when asked whether the same objects possessed those properties. Why properties are encoded as applying more or less broadly to classes of objects is an important question for future studies on the breadth of children's learning.

Sources of Change

Microgenetic studies have demonstrated that a wide variety of experiences can evoke change: practice, feedback, direct instruction, social collaboration, requests to explain observations, and so on. In this respect, they are like training studies. Where microgenetic studies go beyond training studies is in the depth of their portrayal of how the particular sources of change produce learning.

Basic Phenomena

Physical maturation and general experience produce substantial changes in many capabilities, even without

any specifically relevant experience with the experimental situation (e.g., Shimojo et al., 1986; Spencer et al., 2000; Thelen & Ulrich, 1991). At times, these general changes are as sizeable as those that occur over the same age range among children given directly relevant experience. Thus, in Adolph (1997), control group infants who never had descended down ramps generated strategies and strategy choices equivalent to those of age peers who had encountered the ramps on a weekly basis for several months. Amount of experience at home going up and down stairs and climbing on to and off of furniture (as measured by parental report) appeared to be a crucial factor. Such experience at home was related, above and beyond the effect of age, to individual differences in the infants' ability to discriminate safe from risky ramps.

Although the practice and feedback obtained by the infants in Adolph (1997) did not enhance their ramp descent skills, problem-solving experience often does produce learning. This is unsurprising when children receive feedback or instruction that guides them toward improved solutions. More surprising, problem-solving experience in the absence of feedback or instruction also often helps children learn. Even when children receive feedback, learning frequently occurs following success rather than failure of existing strategies, a phenomenon first noted by Karmiloff-Smith (1979b) in the context of map drawing and language learning and replicated in many other contexts since then. Learning without negative feedback has been shown for theory of mind inferences (Flynn, 2005), scientific reasoning (Kuhn et al., 1992, 1995; Schable, 1996), analogical reasoning (Hosenfeld, van den Boom, & van der Maas, 1997; Tunteler & Resing, 2002), memory strategies (Bjorklund, 1988; Coyle & Bjorklund, 1997), and other problem-solving skills. Learning without feedback or instruction often involves generation of new strategies, as well as improved execution of existing strategies. Regardless of whether the activity is a game of 20 questions (Thornton, 1999), a set of mathematical equality problems (Alibali, 1999), a map-drawing task (Karmiloff-Smith, 1979b), or rediscovery of the decimal system following brain injury (Siegler & Engle, 1994), people generate new approaches even without specially designed instruction or failure of existing approaches. Thus, problem solving *per se* can be a source of change.

Another source of change that has received considerable attention in microgenetic research is social collaborative problem solving. Microgenetic analyses of collaboration have been applied to mother-infant inter-

action (Wertsch & Hickmann, 1987), pairs of 5- to 9-year-olds learning about balance scales (Tudge, 1992; Tudge, Winterhoff, & Hogan, 1996), pairs of first graders learning to write narratives (Jones, 1998; Jones & Pellegrini, 1996), small groups of fourth graders solving mathematical word problems via reciprocal instruction (Taylor & Cox, 1997), pairs of fifth graders learning about decimal fractions (Ellis, Klahr, & Siegler, 1993), pairs of fifth and seventh graders building bridges (Parziale, 2002), pairs of sixth, seventh, and eighth graders solving science reasoning problems (Kuhn & Pearsall, 2000), a classroom of ninth-grade ESL students learning a science curriculum (Gelman et al., 2002), and small groups of adults designing robotic devices (Granott, 1998; Granott et al., 2002). The large amount of overt behavior, both conversations and actions, generated by collaborative problem solving makes such situations ideal for microgenetic analysis.

A particularly interesting finding that has emerged from these studies is that the degree of engagement of the partners is crucial to the effectiveness of learning (Ellis et al., 1993; Forman & MacPhail, 1993; Glachen & Light, 1982; Perret-Clermont, Perret, & Bell, 1991; Tudge, 1992; Tudge et al., 1996). Listening intently to partners' explanations, requesting clarification of them, and reaching shared understanding strongly influence how much learning occurs.

A number of factors probably contribute to the effects of engagement on learning. Engagement seems likely to reflect interest in the subject matter, general motivation to learn, and the quality of the relationship between or among collaborators.

Engagement also seems likely to be related to a learning process that is powerful—in both collaborative and noncollaborative situations—extracting causal relations. Listening intently, requesting clarifications, and reaching shared understandings may help learners probe deeply enough to understand underlying causal relations within the problems, and such understanding of causal relations may be crucial to learning.

Evidence from studies of individual as well as collaborative learning attests to the crucial role of causal understanding in all kinds of understanding.

Ability to form causal connections among events starts in the 1st year of life (e.g., Kotovsky & Bailargeon, 1994). Even 1-year-olds find it easier to learn to reproduce causally coherent sequences of actions than arbitrary sequences (Bauer, Chapter 9, this *Handbook*, this volume). Thus, ability to explain the causes of events seems to be a basic property of human beings.

Despite this early development, even older children and adults fail to grasp causal relations in many situations in which doing so would be useful. This poses an especially large problem for understanding mathematics and science. Even among adults at elite universities, causal understanding of physical and biological phenomena tends to be extremely shallow (Rozenblit & Keil, 2002).

Somewhat surprisingly, given this poor understanding of causality underlying physical and biological phenomena, microgenetic studies have revealed that people are highly motivated to learn about causal relations. When children expect some physical or biological variables to be causal and others not to be, they generate more experiments regarding the effects of the variables that they expect to be causal (Kuhn et al., 1988, 1992). Both 10-year-olds and adults more effectively learn that particular physical variables are causally related than that they are not related (Schauble, 1996). Children also are reluctant to abandon a belief that a variable exerts a causal influence in favor of the conclusion that the variable is not causal (Kuhn & Pearsall, 1998).

Understanding causal relations is also crucial to learning. Children learn more when actively testing causal hypotheses through self-generated experiments than they do from watching the same experiments generated by other children, where they do not know the hypothesized cause being tested (Kuhn & Ho, 1980). Understanding why a given memory strategy exerts a positive effect is closely related to whether children choose to use the strategy when not required to do so (Paris et al., 1982). In addition, among older children and adults, individual differences in efforts to explain the causal hows and whys in science and math textbooks are closely related to the amount learned (Chi, Bassok, Lewis, Reimann, & Glaser, 1989; Chi, de Leeuw, Chi, & LaVancher, 1994; Nathan, Mertz, & Ryan, 1994).

How does causal understanding enhance learning? One path is through avoiding trial and error and limiting searches for new approaches to plausible alternatives. For example, understanding how counterbalancing produces stable physical structures allows school age children to construct superior new bridges if their initial attempts collapse (Thornton, 1999). Similarly, understanding the goals that successful addition strategies must meet allows preschoolers to discover effective addition strategies without any trial-and-error (Siegler & Crowley, 1994). Conversely, misunderstanding causal relations often produces distorted recollections of experiments and results, which impedes learning (Kuhn

et al., 1995). And as noted earlier, causal relations, once learned, are more memorable than arbitrary relations (Bauer, Chapter 9, this *Handbook*, this volume). Thus, causal understanding motivates, guides, and maintains learning.

Influences of Child and Environment

Although infants and toddlers sometimes identify causal relations, and although adults fairly often fail to identify such relations, the frequency with which people identify causal connections on any given task generally increases with age. In scientific reasoning contexts, adults consistently are superior to older children, and older children are superior to younger ones, in learning which variables exert a causal influence (Chen & Klahr, 1999; Kuhn et al., 1992, 1995; Schauble, 1996). The same age trends are apparent on other types of problem-solving tasks; for example, on the previously mentioned bridge building task that required understanding of the causal role of counterbalancing, 10% of 5-year-olds, 40% of 7-year-olds, and 70% of 9-year-olds succeeded (Thornton, 1999).

The pervasive positive effect of understanding causal relations raises the issue of whether encouraging children to seek causal understanding improves their learning. Numerous experiments indicate that the answer is "yes." Asking 5-year-olds to explain why an experimenter advanced the number conservation answer that she did leads to greater learning than does asking peers to explain their own answers or simply providing feedback (Siegler, 1995). Asking 7-year-olds to explain why some representations are better than others leads to their subsequently generating better representations themselves (Triano, 2004). Asking 5- to 9-year-olds to explain why a balance scale rotated as it did leads to greater learning than just having them observe the movements (Pine & Messer, 2000). Asking 12-year-olds to explain statements within eighth-grade biology textbooks enhances their learning, even relative to having them read the textbook twice (Chi et al., 1994). Asking first through fourth graders to explain both why correct answers are correct and why incorrect answers are incorrect leads to greater learning of mathematical equality and sinking objects problems than does asking peers to explain the correct answer alone or to explain their own reasoning (Siegler, 2002; Siegler & Chen, in preparation). The same has been found in classroom settings; asking children to explain why wrong answers are wrong as well as why right answers are right is more ef-

fective instructionally than just modeling the correct answer. The difference is particularly large on problems fairly far removed from the original problem (Taylor & Cox, 1997). This tendency for understanding of causal relations to be especially important on transfer problems has also appeared in laboratory studies of other tasks (Alibali, 1999; Crowley & Siegler, 1999; Rittle-Johnson & Alibali, 1999; Siegler, 2002).

Theoretical Implications and Questions

Why does being asked to explain observations enhance learning, and why does being asked to also explain why wrong answers are wrong enhance learning further? The phenomena are not attributable to time on task; encouragement to explain observations heightens learning even when time on task is controlled (Aleven & Koedinger, 2002; Chi et al., 1994; Renkl, 1997).

At a general level, self-explanation seems to work by increasing learners' depth of processing. One way in which it does this is to increase the likelihood of learners generating any explanation. People often accept observations without asking "why." However, when people are explicitly asked, "Why do you think that happened?" they are more likely to think about the observation deeply enough to generate an explanation or, in Chi's (2000) formulation, to repair their mental model. Constructing such an explanation is often harder than it might appear; learners who generate incorrect answers and who then are asked to explain the correct answer often initially respond by saying, "I don't know" (Flynn, submitted; Siegler, 1995). However, in these same studies, increasing numbers of children eventually did generate the correct explanation, and it became the most frequent approach.

A related process through which encouragement to explain may enhance learning is by increasing the persistence of explanatory efforts. In Siegler's (2002) study of mathematical equality, the third- and fourth-grade participants took around 11 seconds on Trial 1 to generate an answer to the $A + B + C = \underline{\hspace{2cm}} + C$ problem that they were presented. After being asked to explain both why the right answer was right and why the wrong answer was wrong, children in that condition took much longer to generate answers to the same type of problems on the next few trials; the mean solution time rose to 22 seconds on Trial 2 and 25 seconds on Trial 3. This extra time was not attributable to the correct strategy that they eventually learned inherently taking longer; after two more trials, their times returned to

the original level of around 11 seconds. Peers who received feedback on the same problems but who were not asked to generate explanations did not show this pattern of increasing and then decreasing solution times; their mean times remained around 11 seconds on all trials. Instead, the extra time taken by children who were asked to explain correct and incorrect answers seemed to reflect a deeper search for a strategy that could generate correct answers.

Consistent with this explanation, although children in both feedback and self-explanation groups of Siegler (2002) generated ways of solving the problems correctly by the end of the training session, the discoveries differed in quality. Most children in the feedback group generated a strategy that yielded correct answers on the problems that were presented ($A + B + C = \underline{\hspace{2cm}} + C$ problems); they simply added $A + B$. This strategy worked on these problems, but it did not generalize beyond them. In contrast, most children who were asked to explain both correct and incorrect answers relied on one of two more advanced and general approaches: these children either computed what they needed to add to C to equalize the values on the two sides of the equal sign or subtracted C from both sides. The result was that on the posttest, the percent correct on problems of the type presented during training did not differ for the two groups, but there were substantial differences on transfer problems such as $A + B + C = \underline{\hspace{2cm}} + D$, on which the more sophisticated strategies would work and the less sophisticated one would not. Thus, the effectiveness of encouragement to explain observations also is probably due in part to such encouragement producing deeper searches of existing knowledge.

A third mechanism through which self-explanation may exercise its effects is by decreasing the strength of existing, incorrect ways of thinking. Evidence for such a weakening process again was found in Siegler (2002). The frequency of children's predominant incorrect strategy, adding $A + B + C$, fell much more rapidly in the group asked to explain both why wrong answers were wrong and why right answers were right than in a group asked only to explain why right answers were right. On the initial trial, before feedback or requests for explanations, 80% of children in both groups used the $A + B + C$ approach. On the next trial, 50% of children in the feedback group continued to use this approach, but only 25% of children in the self-explanation group did. As emphasized throughout this chapter, incorrect approaches often persist for substantial periods of time, even after

superior approaches are also known; instructional approaches that undermine the incorrect approaches, in this case by having children explain why they are incorrect, can speed learning by undermining the logic that supports them and thus decreasing their appeal.

RELATIONS BETWEEN LEARNING AND DEVELOPMENT

The relation between short-term and long-term change (aka learning and development; microdevelopment and macrodevelopment; change at short and long time scales) is among the enduring issues in developmental psychology. Classical theorists have taken sharply conflicting stances regarding the issue. Werner (1948, 1957) and Vygotsky (1934/1962) viewed short-term change as a miniature version of long-term change, generated by similar underlying processes and characterized by identical sequences of qualitatively distinct stages. Learning theorists such as Kendler and Kendler (1962) also viewed the two as fundamentally similar, but unlike Werner and Vygotsky, they viewed both short-term and long-term change as proceeding through gradual incremental processes with no qualitatively distinct stages. Piaget (e.g., 1964, 1970) expressed a third perspective; he viewed the two types of change, which he referred to as learning and development, as fundamentally dissimilar. In his view, development created new cognitive structures; learning merely filled-in specific content.

The relation of short-term to long-term change continues to be discussed by contemporary theorists: dynamic systems (e.g., van Geert, 1998), neo-Piagetian (e.g., Case, 1998), and information processing (e.g., Elman et al., 1996). There appears to be a broad consensus that changes over short and long time periods resemble each other, but much less agreement as to the level of detail at which the resemblance holds. Some investigators have concluded that the similarity is a deep one; for example, Thelen and Corbetta (2002) wrote:

We study microdevelopment because we believe that the processes that cause change in a matter of minutes or hours are the same as those working over months or years. In other words, the principles underlying behavioral change work at multiple time scales. (p. 60)

Other investigators (e.g., P. H. Miller & Coyle, 1999; Pressley, 1992) have concluded that the degree of similarity between microgenetic and age-related change is

uncertain, both at the level of the descriptive course of change and at the level of underlying mechanisms. They also have noted that the conditions used to elicit change in microgenetic studies often differ from those that elicit it in the everyday environment. Even when the eliciting events are basically similar, the higher density of relevant experiences and the more consistent feedback in the laboratory setting could result in the changes being quite different in their specifics. These issues led P. H. Miller and Coyle (1999) to conclude: "Although the microgenetic method reveals how behavior *can* change, it is less clear whether behavior typically *does* change in this way in natural settings" (p. 212).

After noting this uncertainty regarding the precision of the resemblance between microgenetic and age-related change, Fischer and Granott (1995) and Kuhn (1995) suggested a solution: Set up direct comparisons with identical populations, methods, and measures of the changes observed in microgenetic studies and those observed in cross-sectional and long-term longitudinal studies. To provide such a direct comparison, Siegler and Svetina (2002) combined cross-sectional and microgenetic designs within a single experiment. In the cross-sectional part, they presented 6-, 7-, and 8-year-olds with standard matrix completion and conservation problems of the type used by Inhelder and Piaget (1964) and Piaget (1952). Then, a randomly chosen half of 6-year-olds were presented four sessions of feedback and self-explanation prompts on matrix completion problems, followed 2 months later by a posttest on matrix completion and conservation. The other half of the 6-year-olds did not receive the four feedback-and-self-explanation sessions, and thus served as a control group.

The overall magnitude of change among children in the microgenetic condition, as indicated by the percent correct answers, proved comparable to the magnitude of the change between ages 6-years and 7-years among children in the cross-sectional part of the study. This comparability of overall change allowed a reasonable comparison to be made of the detailed patterning of changes on 11 measures of performance.

Microgenetic and age-related changes were similar on 10 of the 11 measures. On five of these measures, both groups showed significant changes, and on another five, neither group did. The specificity of many of the matches was quite striking. For example, there were changes over both sessions and years in number of answers correct on the size dimension, but no changes over sessions or years in the number of explanations that

mentioned size. Qualitative aspects of change were also similar. For example, children in both groups produced the same predominant error; in both cases, it accounted for about 70% of total errors. The learning of children in the microgenetic condition also was highly stable over time and generalized to the conservation tasks, qualities that Piaget identified as defining characteristics of developmental change. Thus, at least in this case, microgenetic change proved extremely similar to age-related changes that occurred without any experimental manipulation.

Similar broad parallels in the path of microgenetic and age-related change have been found on balance scale, sort-recall, mathematical equality, addition, language development, map drawing, false belief, and many other problems (Alibali & Goldin-Meadow, 1993; Chletos & De Lisi, 1991; Flynn et al., 2004; Grupe, 1998; Karmiloff-Smith, 1979a; Schlagmüller & Schneider, 2002). To cite one example, experience performing a selective attention task produced the same inverted U-shaped function in amount of private speech as emerged between ages 3 and 5 years without such experience (Winsler, Diaz, & Montero, 1997). To cite another example, the same type of balance scale rule progressions that emerged in cross-sectional studies between ages 5 and 8 years emerged over trials within a single session when 5-year-olds were given feedback and asked to explain their observations (Siegler & Chen, 1998).

Clearly, microgenetic and age-related change will not always be so similar. When direct instruction is provided, people may often follow paths different than the ones they would otherwise have followed. To illustrate, children who produce gesture-speech mismatches while solving mathematical equality problems usually progress toward correct gesture and speech if given direct instruction; however, they usually regress toward incorrect gesture and speech in the absence of instruction (Goldin-Meadow & Alibali, 2002). Highly directive instruction also can alter the path of change in another way; it at times produces immediate consistent use of the correct approach and thus eliminates intermediate approaches that would otherwise have appeared (Opfer & Siegler, 2004). Nonetheless, when microgenetic studies do not involve directive instruction, microgenetic and age-related changes tend to be highly similar. As Kuhn (2002) noted:

Microgenetic analysis achieves a reintegration of learning and development as processes that have fewer differences

than they do commonalities. . . . Rather than standing in opposition to the study of development, fine-grained studies of learning illuminate, indeed are essential to understanding, the more macro-level phenomena of development. (p. 111)

CHANGE MECHANISMS

Deeply understanding how change occurs is the holy grail of developmental psychology: a profound goal, never fully attained, probably not attainable, but worth pursuing nonetheless. One reason for the impossibility of fully succeeding is that change processes are inherently unobservable; they can only be inferred from behavioral observations at different points in time. Another reason is that such mechanisms can be described at multiple levels that vary in specificity (maturation, improved working memory, automatization), time gain (years, seconds, milliseconds), and system (behavioral, computational, neural). Progress in understanding mechanisms at each level of specificity, time gain, and system inevitably raises questions about the other levels.

Despite these inherent limits on understanding change processes, the detailed descriptions of change yielded by microgenetic analyses can move us toward the goal, both by suggesting candidate mechanisms that are consistent with the wide range of data yielded by such studies and by ruling out alternatives that are inconsistent with them. One good example comes from studies of gesture-speech mismatches. Alibali and Goldin-Meadow (1993) hypothesized on the basis of microgenetic data that gesture-speech mismatches reflected competition between representations, and that simultaneous activation of competing representations would require more cognitive resources than would activating a single idea. To test this hypothesis, Goldin-Meadow, Nusbaum, Garber, and Church (1993) asked children to remember a set of unrelated words while they solved mathematical equality problems. All of the children generated incorrect mathematical equality strategies in speech, but some generated correct strategies in gesture. Strikingly, the children who generated correct strategies in gesture, and who thus were more knowledgeable about mathematical equality, did less well on the concurrent task of remembering words. This evidence strongly suggested that simultaneous activation of competing representations is one mechanism underlying gesture-speech mismatches.

Microgenetic studies also can illuminate neural mechanisms that underlie learning. For example, Haier et al. (1992) found that as college students learned to play the video game Tetris, they reduced their overall glucose metabolism, with the decrease being greatest in brain areas that did not seem essential for playing the game. The largest changes in glucose metabolism were seen among the participants who showed the largest improvements in game playing skill.

The detailed data yielded by microgenetic studies also constrain mechanistic accounts and raise process-level issues that otherwise would not arise. One such case involves learning in the face of success. Microgenetic studies of map drawing, counting, balance scales, arithmetic, sort-recall, and selective attention tasks have shown that strategy discoveries follow success as well as failure (Blöte et al., 1999, 2004; Karmiloff-Smith, 1979b; P. H. Miller & Aloise-Young, 1995; Siegler & Jenkins, 1989). The observation has created a need for models that, unlike connectionist and many symbolic models, generate new approaches without error detection.

Another way in which microgenetic data can help specify mechanisms is by revealing relations among multiple changes. In one illustrative study, Robinson and Mervis (1998) sampled a single child's language development on a daily basis between the ages of 11 and 25 months. Of particular interest were their findings concerning the relation between vocabulary size and grammatical development. They found that the precursor mechanism proposed by van Geert (1991) fit their data. This mechanism links two asynchronously developing capabilities: a predecessor (earlier developing) capability and a successor (later developing) capability. The predecessor (in this case, vocabulary) needs to reach a critical value before the successor (in this case, use of plurals) begins to emerge. The emergence of the successor capability initially increases the rate of development of the predecessor. Over time, however, the successor becomes a competitor for resources with the predecessor, and development of the predecessor slows. Finally, the successor reaches an asymptotic level and stops competing for resources, and the rate of development of the predecessor again increases. As in the other examples in this section, the microgenetic data were critical for linking this mechanism to the change being explained.

Microgenetic studies can be particularly useful for enhancing understanding of change mechanisms when they are part of a back-and-forth process involving them,

formal modeling, and traditional cross-sectional and longitudinal empirical studies. Research on the development of basic arithmetic illustrates this process.

A number of early cross-sectional studies indicated that preschoolers and young elementary school children use varied strategies to solve simple addition problems (e.g., Fuson, 1982). As noted earlier, preschoolers' most common approach is the sum strategy, which involves putting up fingers on one hand to represent the first addend, putting up fingers on the other hand to represent the second addend, and then counting all of the fingers. First and second graders' most common approach is the min strategy, which involves counting up from the larger addend.

This information provided the basis for Siegler and Jenkins' (1989) microgenetic study of discovery of the min strategy. Children of the age just prior to when the discovery would usually be made (4- and 5-year-olds) were presented 20 to 30 brief sessions of experience with addition. The study yielded eight main findings, which also could be viewed as eight main constraints that a satisfactory model of discovery of the min strategy would need to meet: (1) Almost all children discovered the min strategy; (2) all children used varied strategies both before and after the discovery; (3) the shortcut sum strategy, which incorporated some aspects of the sum strategy and some aspects of the min strategy, usually was generated shortly before discovery of the min strategy; (4) discoveries often occurred in the context of success rather than failure; (5) generalization of the min strategy was slow; (6) presenting challenge problems on which the min strategy was particularly advantageous hastened generalization; (7) strategy choices were at all times responsive to problem characteristics; and (8) children discovered the min strategy without any trial and error.

This last finding was particularly intriguing. Despite solving between 140 and 210 problems and generating a number of novel addition strategies, none of the children ever generated an illegal strategy. It was not that no illegal strategies were possible; for example, children could have added the first addend twice and ignored the second one, or added the first addend to the second one and then added the second one again. This raised the question of how children were able to invent legal strategies without any trial and error with illegal strategies.

To address the question, Siegler and Jenkins hypothesized that even before children discover the min strategy,

they possess a goal sketch, a conceptual structure that indicates the goals that a legal strategy must meet. The goal sketch for addition indicates that legal strategies must include procedures for quantifying each addend and combining the two addends into a single answer.

This hypothesis motivated Siegler and Crowley (1994) to perform a new empirical study to test whether children possess such a goal sketch even before they discover the min strategy. They asked 5-year-olds, some who already used the min strategy and some who did not, to judge the smartness of three addition procedures that a puppet executed: the sum strategy, which all of the children already used in their own problem solving; the min strategy, which some children used and some did not; and counting the first addend twice, which none of the children used. The question was whether children who did not yet use the min strategy would view it as smarter than counting the first addend twice, which they also did not use. It turned out that they viewed the min strategy as much smarter than counting the first addend twice; in fact, they viewed the min strategy as being slightly smarter than the strategy they used most often, the sum strategy. This finding led to the conclusion that children possess conceptual understanding of addition akin to the goal sketch before they discover the min strategy and that this understanding helps them avoid trial and error in the discovery process.

These data from Siegler and Crowley (1994), together with the prior cross-sectional and microgenetic findings, provided crucial constraints on a computer simulation of discovery of the min strategy (Shrager & Siegler, 1998). The model began with two strategies—retrieval and the sum strategy—and was presented addition problems like those in Siegler and Jenkins (1989). Through solving these problems, the model learned which types of strategies work best in general and on particular types of problems. The mechanisms that produced learning and discovery within this model are illustrated schematically in Figure 11.4.

As shown at the top of Figure 11.4, within this model when strategies are used to solve problems, the process yields information about the answers to the problems, as well as the speeds and accuracies characteristic of the strategies and the problems. The model learns which strategies are most effective in general and which work best on problems with specific features, as well as which work best on particular problems. Each problem-solving effort also yields a trace of the processing per-

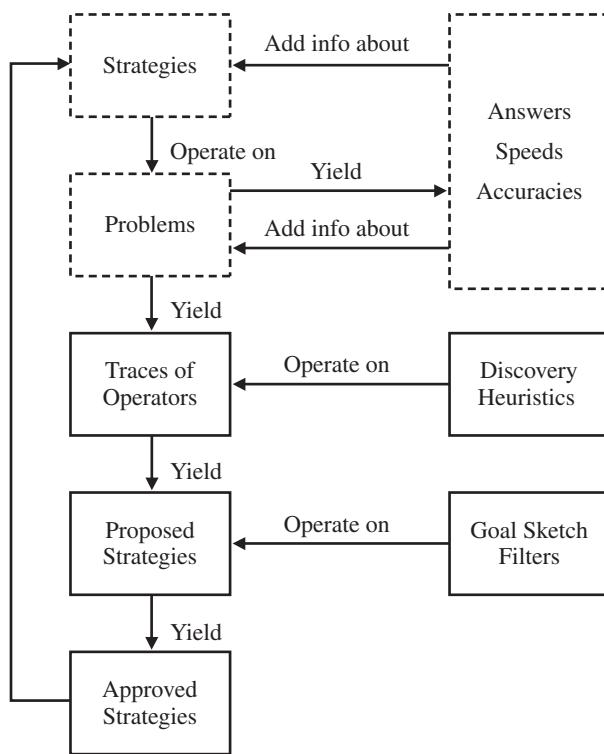

Figure 11.4 SCADS model of strategy choice and strategy discovery. The way in which children choose among strategies and learn about the characteristics of problems, strategies, and their interaction is schematically represented at the top of the diagram; the way in which they generate appropriate new strategies and avoid generating inappropriate ones is schematically represented in the bottom part. *Source:* From “SCADS: A Model of Children’s Strategy Choices and Strategy Discoveries,” by J. Shrager and R. S. Siegler, 1998, *Psychological Science*, 9, pp. 405–410. Reprinted with permission.

formed on that trial. As problem solving became increasingly automatized, working memory resources are freed, which allows discovery heuristics to examine these traces to see if more efficient processing is possible. If so, the model proposes a new, potentially more efficient strategy, and compares it to goal sketch filters, which test whether the proposed strategy satisfies the basic goals of addition. This mechanism eliminates potential illegal strategies before they lead to behavior, and at the same time allows legal strategies to be tried. The overall result was that the simulation generated behavior that matched all eight key characteristics of children in the microgenetic study and that generated numerous other phenomena that had been observed in prior cross-sectional studies.

Siegler and Araya (2005) recently expanded the model to simulate Siegler and Stern’s (1998) findings regarding how children generate an arithmetic insight. That model produces variations in performance under different experimental conditions, regressions between sessions, learning within sessions, patterns of overgeneralization and undergeneralization, and both conscious and unconscious strategy discoveries. Of particular interest, the model indicates that what looked at a behavioral level to be five distinct strategies is at a mechanistic level only two strategies combined in different ways and with different levels of activation. As these examples suggest, combining microgenetic data, data on changes with age, and formal modeling techniques offers considerable promise for enhancing understanding of how children learn.

CONCLUSION

The research summarized in this chapter supports the view that children’s learning is inherently a process of variability, choice, and change. This characterization is not unique to children’s learning; indeed, mechanisms that generate variability, choice, and change are essential to all adaptive systems, from plants and animals to cultures and corporations. The specific mechanisms that produce these characteristics vary greatly, but the characteristics themselves are invariant.

Microgenetic studies have revealed numerous aspects of how variability, choice, and change operate in the context of children’s learning. Such studies have revealed that children are constantly generating new variants, not just during delimited transition periods and not just when existing approaches fail, but at all times. They also have revealed that the varying approaches that children generate are constrained by conceptual understanding, rather than being a process of trial and error. They also have revealed that choices among variants are surprisingly adaptive from the beginning of learning, that this is true even in infancy, and that the choices become yet more adaptive with experience in the specific domain. And the research also has revealed that the uptake of even the best new approaches often is slow and halting, and that this is true even when children can explain why the new approach is superior to alternatives.

All of these characteristics seem to be true of what has traditionally been called “development” as well as what has traditionally been called “learning.” Indeed,

the distinction between development and learning seems increasingly artificial, given that both are processes of variability, choice, and change, and that studies of age-related changes and learning reveal so many empirical commonalities. However, this may only be how things appear at present. Detailed analysis of the mechanisms that operate over shorter and longer time periods may reveal more substantial differences than are currently evident. Mechanistic models of short-term change, guided by and constrained by microgenetic data, are being created in increasing number. Testing whether the mechanisms that produce changes within these models can also account for long-term changes—and determining how, if at all, they need to be changed to do so—promises to be a particularly exciting frontier for the new field of children's learning.

REFERENCES	547

This chapter is about intentional and strategic processes that children can use to perform cognitive tasks. Five overarching conclusions follow from this wide-ranging review:

1. Often children do not use strategies to perform cognitive tasks, ones they are capable of using, with such nonuse traditionally labeled a production deficiency (Flavell, 1970; Waters, 2000). Production deficiency

can be due to a number of causes: (a) not knowing a strategy that could be used in the present situation, (b) not knowing that it is appropriate to use a known strategy or strategies in this situation, (c) not understanding how to adapt known strategies to the present situation, (d) using an approach that is not overtly strategic (e.g., relying on the first idea that comes to mind to solve a problem presented rather than carefully reflecting and trying alternatives), or (e) simply

not being motivated to exert the effort to carry out known strategies (e.g., Pressley, Borkowski, & Schneider, 1987, 1989). Production deficiencies are common in children, with many situations where adults also are production deficient.

2. Sometimes even very young children are strategic, most prominently, when asked to carry out familiar tasks in familiar situations.
3. Children sometimes use strategies that are less efficient and/or effective than ones they could use (Kuhn, 2002a, 2002b; Siegler, 1996).
4. Children who do not use strategies (or the most effective strategies) on their own often can be taught to use effective strategies with clear benefits in performance that can motivate future use of the strategies (Borkowski, Carr, Rellinger, & Pressley, 1990). This conclusion has been substantiated in many investigations.
5. In the absence of strategies instruction, children often discover strategies just from performing a task repeatedly, although leaving strategic competence to discovery does not always result in children acquiring strategies quickly or acquiring the most effective strategies.

DEFINITION OF STRATEGY

What is a strategy as research psychologists understand it? On the positive side, strategy means about the same to psychologists as it does to laymen. Thus, one definition of strategy is: “A *strategy* is a general plan or set of plans intended to achieve something” (Sinclair, 2001, p. 1540). All of the elements of strategy considered important by psychologists are in that simple definition. A strategic learner plans in advance, with the plan motivated by some goal, a desire to achieve some end. So, a savvy adult confronting the task of memorizing the driver’s license test book has a goal—passing the written driving exam. To do so requires some preparation, which can be tedious, for example, if the reader decides simply to read the booklet over and over until it is memorized. Alternatively, the strategic reader will identify the sections she or he does not know and focus on those. Perhaps for especially detailed points that might be on the written driving test, the reader will use a classic mnemonic (e.g., remembering to park at least 10 feet from a fire plug by forming an image of a basketball player shooting a basketball at the fire plug as if it were the basket, recognizing that the basketball rim is 10 feet high).

There is one tricky aspect to the notion of strategy, however (see Schneider & Pressley, 1997, chap. 5 for a review of this issue). When people are first learning to use strategies, their employment of them seems more deliberate, conscious, and intentional than is the case when they have had experience with the task and used the strategy many times. That is, with increasing experience, strategy use becomes more automated and effortless. To be considered a strategy, however, the process has to be controllable. That is, the user can interrupt the automatic cognition and take charge of the cognitive processes, performing them consciously and intentionally. Thus, Pressley, Forrest-Pressley, Elliot-Faust, and Miller (1985) offered the following definition of strategy, “A strategy is composed of cognitive operations over and above the processes that are natural consequences of carrying out the task, ranging from one such operation to a sequence of interdependent operations. Strategies achieve cognitive purposes (e.g., comprehending, memorizing) and are potentially conscious and controllable activities” (p. 4). In this definition they captured that the strategy user does not always have to be conscious of and in control of strategic processes, but there must be potential for this to occur in order to be considered strategic.

Some of the most historically prominent research on strategies was carried out with respect to children’s memory and memorizing, and, thus, there will be substantial attention in this chapter to memory strategy development. Strategies can be classified as either memory encoding or memory retrieval strategies. For example, a task may require a learner to remember pairs of words or pictures presented to them. An encoding strategy is to construct a mental image that includes the paired items when the pairs are presented (e.g., if given the pair, *cow* and *rock*, perhaps imagining a *cow* eating the grass around a *rock* that is in the pasture). The ability to use such imagery encoding strategies increases with age between 5 and 11 years of age (see Pressley, 1977). Later, on the test, when the item *cow* is presented, if the learner thinks back to the image of the *cow* nibbling grass around a *rock*, that would be using a retrieval strategy (i.e., remembering the interactive image to remember the pair-mate). The use of such a retrieval strategy develops during the early elementary years (Pressley & MacFadyen, 1983). Because there has been much more research on encoding than retrieval strategies, most of the memory strategic work considered in this chapter focuses on encoding strategies.

Because consciousness is at least always possible when strategies are functioning, researchers in memory

strategy development have typically studied explicit memory. Explicit memory contrasts with implicit memory, in that the latter does not depend on conscious mediation (Graf & Schacter, 1985; Jacoby, 1991). In general, explicit memory improves with development, largely because of strategy use and the development of metacognitive understandings (i.e., cognitive regulative understandings, such as knowing when, where, and how to apply particular strategies), which also will be considered in this chapter. Increasing such metacognitive understandings increases the likelihood that children will use the strategies they know appropriately (Murphy, McKone, & Slee, 2003).

One advantage of the definition offered by Pressley and colleagues (Pressley, Forest-Pressley, et al., 1985) is that it includes potential consciousness rather than fully conscious use as necessary for cognitive processes to be considered strategic. Alternative definitions that require the thinker being in conscious control would not be consistent with some of the strategies reviewed in this chapter. When a reader automatically relates what is being read to prior knowledge, that strategy is covered by the Pressley, Forest-Pressley, et al. (1985) definition, but would not be included if conscious planfulness was part of the definition.

CLASSICAL RESEARCH ON DEVELOPMENT OF MEMORY STRATEGIES

Much of the early work on strategic processes in children was conducted with reference to children's memory and memory development. Thus, both the fourth and fifth editions of the *Handbook of Child Psychology* included long chapters devoted to the topic of memory development (Brown, Bransford, Ferrara, & Campione, 1983; Schneider & Bjorkland, 1998), with both of these chapters including substantial information about children's memory strategies and active attempts to remember. This reflected substantial research activity during the concluding third of the twentieth century to determine what strategies children use to remember and how their memory strategies develop.

Since the last edition of the *Handbook of Child Development*, however, the cognitive developmental literature has included very little work on the development of memory strategies in children. The last major wave of memory strategies work was with preschoolers. A cadre of researchers, in fact, succeeded in identifying situations where even 2- and 3-year-old children are strate-

gic, quite intentionally engaging in cognitive acts intended to improve memory and other performances. Such work, which was conducted in the late 1970s and 1980s, will be covered in this chapter as well.

Due to a lack of recent research on memory strategies, at least one observer asked in print whether memory development belongs on the endangered topic list in developmental psychology (Kuhn, 2000a). This question makes a lot of sense with respect to study of memory strategies, but probably not children's memory more generally, for at least some of the memory developmentalists have turned their attention in recent years to other problems of memory development. Eyewitness memory is one such area that has received much recent attention (for a review, see Gordon, Baker-Ward, & Ornstein, 2001). For the most part, researchers interested in children's eyewitness memory have focused on situations where children were not trying to memorize (i.e., people rarely were trying to memorize when they see an activity that is the focus of court testimony). Thus, more attention has been paid to studying how factors out of children's control that can distort their memories rather than studying what children might do intentionally to remember events (Ceci, Fitneva, & Gilstrap, 2003). This movement toward understanding children's eyewitness memory was fueled, in part, by many important findings in the 1970s and 1980s about adult eyewitness memory (see Thompson et al., 1998).

Basic theory and research on strategies development and instruction, especially in the area of memory, proceeded in an orderly way for several decades, however, the history of strategies development has been a history of attempting to explain individual differences in development that went beyond mere developmental differences indexed by age. Thus, the early memory development researchers became aware that there were large differences in memory within developmental levels, differences that often could be explained by the strategies used by children as they tackled memory tasks. The insights from this work now inspire researchers who are trying to close the gap between normally achieving students and those who fail to learn to read, write, and problem solve in school. Although there has rarely been a complete closing of such gaps, there has often been vast improvement in the functioning of struggling learners who have been taught strategies. That there has been a progression from basic to applied work over the years requires that this chapter be organized both historically, beginning with the work of the 1960s and 1970s,

with simultaneous movement toward contemporary work and more applied research.

One researcher did more than anyone else to inspire the body of research on strategies. Work on cognitive strategies was launched when Flavell and his colleagues (Flavell, Beach, & Chinsky, 1966) asked children to remember a list of pictures so that they could recall them after they were removed from sight. The researchers especially watched the lips of the children after the items had been presented but before recall occurred. Among 5-year-olds, only 2 of 20 children rehearsed the labels for the pictures that were to be remembered. In contrast, 17 of the 20 10-year-olds in the study did so. In addition, they found a strong relationship between whether a child verbally rehearsed and performance on the memory recall test. Children who rehearsed more recalled more. This was the beginning of a program of research and writing for Flavell on children's use of rehearsal strategies. Many followed Flavell's lead to memory strategy development as a topic deserving of scientific study.

Many also followed his lead when he and another group of student colleagues (Kreutzer, Leonard, & Flavell, 1975) began to study children's metamemory, or what they knew about their memories. This first investigation was an interview study in which children were asked questions to determine if they understood factors effecting memory, including strategic factors. Thus, one question asked children to think of ways that they could remember to take a pair of ice skates to a party they would be attending. Six- and 7-year-olds did not think of as many ways to remember the skates, as did the 9- and 11-year-old children. Flavell and his colleagues hypothesized that before children would use a strategy, they needed to know about it, that such metamemory was critical for strategies to be used. This first study of metamemory would become one of the most cited studies in the cognitive development literature. The field of metacognition, which includes metamemory and many other metas (e.g., meta-attention, meta-communication, meta-perception), requires volumes to summarize (e.g., Metcalfe & Shimamura, 1996).

For almost 30 years, studies about the development of memory strategies were prominent in the field. Then, suddenly in the early to middle 1990s, the work on memory strategy development stopped. In fact, Pressley recalls vividly a Society for the Research of Child Development meeting in the mid-1990s where some of those who had been players in the work on memory

strategies assembled for dinner. The topic of conversation was, "What happened?"

We think that what happened was the following: Much had been discovered by those studying intentional memory and memory strategies, so much that the sub-field had entered a period of incrementalism, where new studies did not add much. The very visible scientists who had carried out most of the work on memory strategy development followed Flavell's lead in another way. He liked to do work that defined new fields. He moved on to other work once the research on memory strategies and metacognition was launched. Most of those sitting at that dinner, and others who would have been like-minded company, were now off studying other problems, defining new areas, doing what Flavell had done. Many went on to study use of strategies in other task situations, including reading and writing (e.g., the present authors are immersed in the study of children's use of comprehension strategies during reading; see Pressley, 2000). In particular, there has been considerable interest in studying meaningful strategies instruction in content areas such as reading and writing directed at children with learning difficulties, who often benefit substantially from such instruction (Swanson, 1999, 2000). Such studies lead us to believe that research on strategies instruction has great relevance to education (Pressley, 1995).

Even so, it is simply undeniable that the work on intentional memory strategies development that was conducted in the 1960s, 1970s, 1980s, and 1990s was a monumental contribution to cognitive development and developmental psychology more generally. Much of what is known about how mind functions and how mental functioning shifts with development is known because of this body of research. Thus, this chapter is a summary of what was found by those studying intentional, strategic memory, about the model of cognitive development that resulted from their efforts.

The early work in basic cognitive development that advanced the idea that strategy production deficiencies can be overcome through instruction has inspired contemporary applied developmental psychologists. Such researchers have shown that strategies matter in academic cognition and children can be taught strategies that improve their academic cognition. Before discussing those contributions, however, we open the chapter with a summary of the general information-processing perspective on memory, and begin with the basics that framed many of the ques-

tions posed by memory development researchers in the 1960s and 1970s. We conclude this discussion with a much more complete model of information processing that includes constructivist, sociocognitive, and motivational perspectives. We emphasize elaborations and shifts from the original model. Then, we turn our attention to how the information-processing model has informed understanding of individual differences in children's cognitive competencies, including gifted children, children with mental retardation, and children with learning disabilities. We stress the point that some of the researchers who were interested in memory development simultaneously contributed to understanding cognition in special populations. Then we turn the discussion to how scientists interested in improving children's reading, writing, and mathematical problem solving are teaching strategies in ways that are very well informed by the basic research and theory of the 1960s through 1990s. By the conclusion of the chapter, we hope that readers will come away with the understanding that while memory development is not as active an area of research as it was in the last portion of the twentieth century, the understandings of children's information processing produced by memory developmental researchers remain exceptionally important in the new century, and, if anything, their impact is expanding.

INFORMATION-PROCESSING THEORY IN THE 1960S AND STUDIES OF THE DEVELOPMENT OF CHILDREN'S VERBAL LIST LEARNING STRATEGIES

At the time Flavell and associates (1966) conducted their study, there was much discussion in the emerging cognitive psychology literature about two-store models of memory (Atkinson & Shiffrin, 1968; Broadbent, 1958; Waugh & Norman, 1965). A small amount of information (i.e., seven or so items) could be held in short-term memory for a short period of time, remaining there only so long as it was actively processed (e.g., rehearsed if it was a list of picture labels; Miller, 1956). If the participant rehearsed the labels sufficiently, the labels would transfer into long-term memory and could be recalled later. Thus, someone going to the store to buy "eggs, milk, butter, and mayonnaise" can remember the list by repeating the list over and over, but after awhile can stop, for the list will have been stored in long-term memory.

The new two-store models were replacing associative learning models, which had predominated in memory research in the 1950s. Even so, the associationists still influenced Flavell's thinking about memory as he began his work. W. A. Bousfield (1953) observed that when adults studied lists with words that belonged to several mutually exclusive categories, they tended to cluster categorically related items together in their recall, even if the items had been presented randomly during study. This finding prompted much work on how learners organize and reorganize material to be learned based on their associative knowledge base.

The framework of the 1960s on memory inspired developmentalists to conduct studies on memory similar in style to those conducted by researchers studying adults, only with children as the participants. Thus, many studies were carried out in which children were asked to learn verbal materials in classic or close to classic verbal learning paradigms (i.e., the classic approaches used to study the memories of students enrolled in introductory psychology courses in the 1950s and 1960s), which involved learning lists of various sorts. These studies proved to be very informative about children's rehearsal, organizational, and elaborative strategies. The work of William Rohwer (1973), serves as one such example. He studied paired-associate learning in children and adolescents. Rohwer demonstrated that when children embedded to-be-learned paired-associates into meaningful sentences (e.g., when asked to learn the pair *bear-blanket*, constructing a phrase such as, "The *bear* grabbed the *blanket* with its paw"), recall of the pairings increased dramatically (e.g., when given *bear* on a text, recall that *blanket* went with it). Rohwer also established that adolescents were more likely to use this strategy on their own than were children, although children could construct such sentences with great benefits for memory when they were instructed to do so.

Rehearsal Strategies

Given this intellectual backdrop, the time seemed right for studies of children's rehearsal strategies during list learning. What was established over a number of studies was that children did rehearse. If an item was presented early in a list, it was especially likely to be remembered because there were more opportunities to rehearse it (i.e., the strategic child would say the word when presented, then say it again along with the second word presented, and then with the second and third word). The

finding that items presented first were recalled better later became known as the primacy effect, with the primacy effect increasing during childhood. Although 5- to 6-year-olds did not evidence much primacy, older children did, reflecting that the younger children did not rehearse as actively or completely as the older children (e.g., the younger children would say the names of the items one time, when they were presented, with the older children continuing to say the name as long as they could and then cumulatively rehearsing all of the items previously presented as each new item was presented). There were consistent and strong correlations between observations of cumulative rehearsal in children and memory of the early items in a list (e.g., Belmont & Butterfield, 1977; Cuvo, 1975; Hagen & Stanovich, 1977; Kellas, Ashcraft, & Johnson, 1973; Naus, Ornstein, & Aivano, 1977; Ornstein, Naus, & Liberty, 1975). Additional support for the conclusion that use of the cumulative rehearsal produced primacy effects was produced in experiments in which primacy varied depending on whether the operations in the experiment encouraged rehearsal (i.e., participants were instructed to rehearse; for example, Gruenenfelder & Borkowski, 1975; Hagen, Hargrave, & Ross, 1973; Hagen & Kingsley, 1968; Keeney, Cannizzo, & Flavell, 1967; Kingsley & Hagen, 1969) or prevented it (e.g., did not permit enough time for rehearsal to occur; Allik & Siegel, 1976; Hagen & Kail, 1973).

The finding that instruction positively affected young children's abilities to rehearse, and thereby remember more, was especially influential. The researchers who conducted these studies established that the children's memory problem was that they were not using the rehearsal strategy. If the children used the rehearsal strategy, their memory improved. All that was required for them to use the strategy was for someone to instruct them to do so. Flavell (1970) referred to the young children's problem as a production deficiency; they failed to produce a strategy that permitted them to accomplish the intellectual task they were to accomplish. That children could benefit from instruction in strategy use was a hugely important finding that resulted in the flood of research on strategies instruction. This is an area of basic research that would link directly to real world instructional applications, some of which is discussed later in this chapter.

Those studying rehearsal also established that use of less than maximally efficient strategies was not just a childhood phenomenon. The best way to learn a list of

items is to rehearse the items cumulatively as they are presented up to the presentation of the last few items. As those are presented, speed up the cumulative rehearsal and finish the list quickly. Then, on the recall test, recall the last few items first. This improves recall because the last few items on the list will still be in short-term memory at the time of the test. Once those are recalled, the person can then retrieve from long-term memory the items from the beginning of the list that received so many cumulative rehearsals (Barclay, 1979). This cumulative rehearsal, fast finish strategy is used by college students, but not by children. The development of efficient list-learning strategies extends into early adulthood.

Organizational Strategies

Memory development researchers also asked children to study and remember lists consisting of items that can be semantically related to one another (e.g., a list containing some fruit items, names of several pieces of furniture, and various types of vehicles). In general, when children in the primary grades recall such lists, the order of recall is fairly random. By 10 to 11 years of age, children tend to recall the related items together, with the interpretation of this recall pattern being that the students made use of the categorical relationships in the list to study and learn items (e.g., Cole, Frankel, & Sharp, 1971; Moely, Olson, Halwes, & Flavell, 1969; Neimark, Slotnick, & Ulrich, 1971). Even so, if the lists are composed of saliently associated items, even preschool children produce recall organized around the categories in the to-be-learned list (e.g., Myers & Perlmutter, 1978; Rossi & Wittrock, 1971; Sodian, Schneider, & Perlmutter, 1986). It also helps if participants are instructed to notice the inter-relationships within to-be-learned lists, for example, by being asked to place like-category items in piles during study. Such strategy instruction can increase recall, even in young elementary grade children (Black & Rollins, 1982; Kee & Bell, 1981; Lange & Griffith, 1977; Moely et al., 1969; Schneider, Borkowski, Kurtz, & Kerwin, 1986).

In general, with increasing age during the elementary school years, children's recall of categorizable lists increases, with increased organization of the output (i.e., items from the same category are more likely to be recalled together by older than younger children). A variety of analyses were carried out to determine whether this increased organization at recall reflected increas-

ing deliberate and strategic use of the categorical information in the lists. In other words, the learner mindfully noted that the items were categorizable and he or she deliberately thought about the list items in categories. The alternative was that, because the learner's knowledge of categories was expanding with development, the categorical nature of the list was noticed and used automatically as the learner read the list (i.e., with advancing age, the learner automatically notices there are animals on the list and associates the animals without thinking about it, with the same happening for pieces of furniture or types of vehicles). Because the learner does not exert intentional effort to use the categories, this is considered a knowledge base effect (i.e., the learner's prior knowledge enables automatic recognition and use of the categorical structure of the list, resulting in improved memory and organization at recall). In fact, both strategic and knowledge base effects probably mediate the increasing recall (e.g., Bjorklund, Muir-Broaddus, & Schneider, 1990; Ornstein, Baker-Ward, & Naus, 1988; Ornstein & Naus, 1985; Rabinowitz & Chi, 1987; Schneider, 1993), with the particular mix of conscious strategy use of automatic knowledge-base mediation depending somewhat on the child (e.g., a child with a great deal of knowledge of a category is more likely to use categorical information automatically, without thinking; Gaultney, Bjorklund, & Schneider, 1992; Schneider & Bjorklund, 1992; Schneider, Bjorklund, & Maier-Brückner, 1996).

Elaboration

For the most part, researchers studied elaboration strategies with paired-associate learning. Typically, investigators presented participants with pairs of items (e.g., shoe and balloon, car and candy, dog and sandwich), with the task of remembering the pairs. At testing, the participant was presented one of the paired items and had to recall the pair mate. This is a very challenging task, unless participants use an elaboration strategy. Verbal elaboration involves creating a meaningful verbal context that includes the paired items. "The *balloon* popped when the *shoe* stepped on it," "The *candy* melted in the hot *car*," and "The *dog* ate the *sandwich*" would be verbal elaborations that could mediate (improve) recall of the sample pairs. Alternatively, participants could be asked to construct mental images embedding the items (e.g., the participant sees a shoe kicking a balloon in his or her mind). Rohwer, Levin,

Kee, and Pressley, in particular, did much work on the development of elaboration strategies abilities in children. Basically, children rarely used such strategies on their own. However, even preschool children benefit from instructions to use verbal elaborations, instructions to use imagery strategies proved increasingly helpful as children advanced through the elementary school years (see Pressley, 1982, for a review).

Conclusions

The verbal learning and information-processing traditions of the 1950s and 1960s set the stage for the field of memory development, which emerged in the 1960s. A great deal was discovered by conducting studies with children, using traditional paradigms used with adults such as free recall of lists of items, serial recall of lists of items (i.e., recall of the items in order), and associative recall of lists of items. As a general rule, there were many production deficiencies discovered. Often children did not use strategies on their own.

Even so, children often proved to be able to carry out strategies if instructed in their operations. This was observed with respect to rehearsal, organizational, and verbal elaborative strategies. This work was foundational with respect to what would become the field of cognitive strategies instruction, providing demonstration that often children could be taught to do what they would not do on their own. That said, once taught, children did not always continue to use the instructed strategies. They did not maintain use of strategies learned or transfer them to other situations where they could be useful. (This is a topic that we discuss in more detail as the chapter unfolds.)

We close this section noting that other deficiencies besides production deficiencies were proposed over the decades of study of basic memory development. For example, Reese (1970) coined the term "mediational deficiency." Mediational deficiencies occur when a child produces a strategy but the strategy fails to improve memory. There has been little evidence of such deficiency in the memory development literature, however (Waters, 2000). A slight variant of this is a *utilization deficiency*, when a younger child would carry out a strategic procedure as completely as an older child but not receive the same amount of benefit from use of the strategy (Bjorklund, Miller, Coyle, & Slawinski, 1997; Miller & Seier, 1994), or a learning disabled student would carry out a strategic procedures as completely as

a normally achieving student and fail to obtain as much benefit (Gaultney, 1998). Again, there is little evidence of such a deficiency (Waters, 2000), with evidence for utilization deficiency even less compelling when longitudinal analyses are employed rather than cross-sectional analyses (Schneider & Sodian, 1997). That said, there will be enough mentions of utilization deficiency in what follows to conclude that there are situations where children seem to carry out strategies but do not benefit from them. However, why this is the case is not understood at present. The possibility that a child might construct a cognitive mediator during study by using a strategy and fail to use the strategy when testing also has received support (i.e., there is support for the construct of retrieval deficiency; Kobasigawa, 1977; Pressley & Levin, 1980; Pressley & MacFadyen, 1983). Despite some attention to mediation, utilization, and retrieval deficiencies, work on these problems is not nearly as extensive as on production deficiencies. Throughout this chapter, we will provide massive evidence that children often do not produce strategies that they could execute profitably.

What may be surprising to many readers is that so little mention of preschoolers has been made until this point. One reason is that preschool was definitely not a focus of research on strategies for a very long time. The conclusion that was implicit in the early studies was that children were strategies production deficient until elementary school, with little strategic behavior inferred from the performances of kindergarten or first-grade students in the early studies of rehearsal, organization, and elaboration. Brown and her colleagues (Brown & DeLoache, 1978; DeLoache, 1980), however, alerted us to one reason that 5- and 6-year-olds might have seemed so nonstrategic in memory studies. Verbal recall and associative memory tasks probably seemed pretty strange and unfamiliar to them. While these activities bear some resemblance to school tasks encountered during the primary years, they do not resemble demands put on kindergarten children before they enter school. In fact, when preschoolers were studied in familiar situations, they often proved to be quite strategic.

THE STRATEGIES PRODUCTIVE PRESCHOOLER (AT LEAST SOME OF THE TIME)

Because early childhood does include memory demands, conceptually it made sense to study memory from ages 0

to 5 as a complement to the work conducted with older children and reviewed thus far in the chapter. A great deal of memory research was conducted with infants in the 1970s and 1980s (e.g., Rovee-Collier & Gerhardstein, 1997). As a result, researchers interested in the development of strategic memory in the preschool years (i.e., ages 2 to 5) began to modify tasks that had been used in infancy studies (Daehler & Greco, 1985). In fact, preschoolers proved to be strategic when given memory tasks that were similar to ones encountered in the real world of early childhood.

Retrieving Hidden Objects

Studying how preschoolers respond to hiding and finding games proved to be a good way to learn about strategic behaviors in preschoolers, revealing that, at least some of the time, preschoolers can be strategic (although strategic retrieval is anything but certain in other situations). Ritter (1978) carried out the first study to assess whether preschoolers would use a retrieval cue strategy when they were in a situation where using retrieval cues was essential for adequate performance. Participants were placed in front of a turntable with six covered cups. Their task was to find a piece of candy that would be hidden in one of the cups, with the turntable then spun quickly enough that it would not be possible to visually track the cup with the piece of candy. There were paper clips and gold stars readily available that could be used to mark the cup with the piece of candy, if the participants thought to do so when the experimenter used a nondirective question, "Is there something you can do to help you find the candy right away?" If the child did not do so with this question, increasingly explicit prompts were given to the child, from pointing to the clips and stars and saying, "Can these help you find the candy right away?" to "Do you want to leave the marker there or put it some other place?"

All of the third-grade participants in the study used the markers with the most nondirective prompt. None of the preschoolers responded to this least directive prompt, although most of preschoolers did respond to more directive prompts. In general, the younger the preschooler, the more directive the prompt that was required for the children to use the markers. More than one-third of children between 3 and 4.5 years of age, however, did not use the retrieval cues even with the most explicit prompting, however. Other investigators using similar setups obtained results very much consistent with Ritter's (1978) outcomes. They confirmed that

strategic use of retrieval cues must be prompted during the preschool years, when use of such cues is observed at all (Beal & Fleisig, 1987; Whittaker, McShane, & Dunn, 1985).

DeLoache, Cassidy, and Brown (1985) studied a retrieval situation that was even more familiar to young children than Ritter's (1978) hiding game. The study took place in a living room setting, with the experimenter hiding a Big Bird doll right in front of the child (the child saw the experimenter put the doll under a pillow on a couch in the living room). When the 18- to 24-month-old participants knew that they would later have to find the doll, they literally kept their eyes on it! Even though the experimenter provided attractive toys to occupy the participants as they waited to retrieve the object, the children kept looking back at the pillow. The researchers controlled the study enough to infer that the children used a memory strategy. Thus, when the doll was placed on the couch in full view with the child knowing they would have to retrieve it later, the child did not keep looking back. There was no need to do so, since there was no memory requirement (i.e., the doll was in full view). The DeLoache et al. (1985) study provided clear evidence that, at least some of the time, even 2-year-olds can be highly strategic: They can be strategic when given a familiar task in a familiar setting. Anyone who has raised a preschooler knows that finding toys around the house is a daily routine for 2-year-olds. In fact, during the 1980s, researchers produced a number of demonstrations that children 3-years-old and older can be very strategic when it comes to remembering where objects have been hidden (Haake, Somerville, & Wellman, 1980; Wellman & Somerville, 1982; Wellman, Somerville, & Haake, 1979).

Remembering Instructions

If a child does something different when told to remember material currently being presented versus when material is presented without memory instruction, one can make the inference that the child is doing something intentionally strategic. Baker-Ward, Ornstein, and Holden (1984) provided a compelling demonstration that preschoolers are more likely to use memory strategies when asked to remember. Specifically, Baker and colleagues (1984) presented toys to 4-, 5-, and 6-year-olds, with them instructed to play with the toys. In the memorization condition of the study, however, participants were also asked to remember a subset of the toys forever. The participants in the remember condition played less

with the toys and more frequently verbalized the names of the to-be-remembered toys. That is, the researchers observed memory strategy use by preschoolers in this study. Actual memory of items was better in the memorization condition only for 6-year-olds, suggesting a utilization deficiency in the preschoolers. Even though they used a memory strategy, it did not benefit their memory (Miller & Seier, 1994). Subsequent studies would constructively replicate the Baker-Ward et al. (1984) results, providing support for the position that preschool-age children can be strategic when learning lists of objects but that the strategies they carry out are not always effective in improving memory (e.g., Lange, MacKinnon, & Nida, 1989; Newman, 1990).

Summary

Memory development researchers established that preschoolers do evidence some strategies use when involved with familiar tasks such as playing with toys. As is the case for research on memory strategies use in the elementary years, there has been relatively little research on preschoolers' use of memory strategies. That does not mean there has not been study of memory. In fact, there has been an impressive amount of study of preschoolers' memory development, as will be evident in the next section documenting the developmental study of the many components of memory. Once these components are reviewed, a more complete and contextualized model of strategy use and development is possible.

AN INFORMATION-PROCESSING MODEL OF INTENTIONAL, STRATEGIC MEMORY: ESSENTIAL COMPONENTS TO UNDERSTAND STRATEGY USE AND STRATEGY INSTRUCTION

As a result, of the research that investigated the development of memory strategies with age, much was learned about the factors affecting use and utility of intentional memory strategies. This work was foundational in understanding children's information processing more generally but also how strategies instruction can stimulate the complex information processing required for real academic achievement.

Working/Short-Term Memory

A fundamental question in human cognition is how much information the mind can manage at once. This is

a critical question because human thinking skill very much depends on being able to manipulate information in consciousness. Although all theories of human information processing include a short-term capacity construct, the functioning of the construct is construed differently in the various models. Some view short-term capacity as a passive container (e.g., Atkinson & Shiffrin, 1968), others portray short-term capacity as attentional capacity, which hints at greater activity than storage (e.g., Cowan, 1995; Kahneman, 1973), while still others emphasize mental activity even more, referring to the short-term capacity as working memory (e.g., Baddeley, 1987). In the more complex of models, working memory can be subdivided into subcomponents. For instance, working memory may consist of separate components, verbal and visuospatial working memory, which permit juggling of both verbal and nonverbal chunks of information (e.g., Logie, 1995).

Researchers often test short-term capacity by asking participants to remember pieces of information presented as a list at a rate of one item per second. Researchers present participants with lists until they can no longer recall all of the items. Usually, adults can recall between five and nine items on such tasks, with seven items as the average (Miller, 1956). While even young preschoolers can remember an item or two, the capacity to remember increases with development during childhood (Dempster, 1981). Developmental psychologists have expended considerable effort to understand why short-term memory capacity increases with age, and whether the observed performance increase represents a fundamental increase in underlying mental capacity or something else. For example, one viable possibility is that performance on short-term capacity tasks depends on an individual's speed of information processing, with slower processing individuals less able to attend to (operate on, mentally juggle) as many pieces of information as individuals who process information more rapidly (Cowan, 2002). From this perspective, the fact that processing speed increases with age, explains the developmental increase in observed performances on tasks that measure short-term memory capacity (e.g., Kail, 1995, 1997a, 2000; Kail & Hall, 2001). However, to date, there is no resolution about what exactly accounts for developmental increases in short-term memory tasks (see Schneider & Pressley, 1997, chap. 3, for a review of the possibilities).

Although performance on short-term capacity demanding tasks increases with age during childhood, individual differences exist at any given age in the ability

to do these tasks, with some children seeming to be able to deal with more information than other children. Given these individual differences and developmental shifts in short-term capacity, children with greater short-term capacity relative to age-mates and older children, when compared to younger children, can more effectively implement memory strategies that require considerable mental effort (Guttentag, 1989; Kee, 1994). That is, at least some developmental differences in ability to use memory strategies might be explained by short-term capacity differences in children. This possibility has been assessed with respect to imagery strategies.

For instance, children in the upper-elementary grades benefit more from instructions to use imagery strategies to learn verbal materials than do children in the primary grades (for a review, see Pressley, 1977). Pressley, Cariglia-Bull, Deane, and Schneider (1987) evaluated whether this developmental shift could be explained by short-term capacity differences among elementary-age children. They asked 6- to 13-year-old children to learn sentences that depicted vivid, easily imagined actions. For example, the participants studied sentences like, "The angry bird shouted at the white dog," and "The fat boy ran with the grey balloon." Participants in the imagery condition were instructed to construct vivid images representing the meanings of the sentences in order to remember them. Control participants were simply urged to try hard to remember the sentences. Consistent with previous research, the imagery instruction was effective with older children in the study but not with younger children. They found that memory of the sentences was better in the imagery compared to the control condition for the older participants in the investigation but not for the younger participants. More importantly, short-term capacity differences explained performance in the imagery condition but not in the control condition. In the imagery condition, participants with greater short-term capacity outperformed participants who had relatively less short-term capacity. In the control condition, there was no relationship between short-term capacity and performance. Cariglia-Bull and Pressley (1990) replicated this finding, thereby increased confidence in the earlier finding that at least some of the developmental differences in improved performance under imagery instructions can be explained by short-term capacity differences in children.

Kail (1997b) provided an analysis linking information-processing speed, children's imagery skills, and performance on short-term memory tasks requiring im-

agery. This analysis bolstered the case that short-term capacity matters in children's memory when mediated by capacity-demanding processes, such as imagery generation. Similarly, Woody-Dorning and Miller (2001) constructed an analysis of selective study procedures with kindergarten and grade-1 students. Thus, they demonstrated that a short-term memory capacity deficiency could explain the utilization deficiency observed in some children. (Some students produced the selective strategy but did not seem to benefit from it.)

Strategy Knowledge as Procedural Knowledge

When strategies are first learned, they are executed very mindfully. Anyone who has watched a child in the primary grades participate in a memory strategy instruction experiment knows that for many children, it takes all the mental capacity they can muster to be able to complete tasks such as rehearsing long lists of words, using an organizational strategy to put to-be-learned content into memorable piles, or constructing meaningful semantic relationships between pairs of items that are not obviously related. Of course, this is no different than learning any skill. Experimental psychologists over more than a century of research have repeatedly demonstrated that practice makes faster, and easier. And as a result, less working memory is required to carry out the procedure (Johnson, 2003).

Those who teach children strategies have to keep in mind that their acquisition is going to be like any other skill acquisition. At first, the strategy will only be carried out very consciously, requiring a great deal of attention on the part of the child. With practice, the child will automatize execution of the strategy, and will require much less effort to carry out the strategy (J. R. Anderson, 1980, 1983). In fact, as this chapter proceeds, we provide many examples of cognitive strategies instruction which includes a great deal of practice of the strategies being taught. This reflects the work of contemporary applied researchers who have found that efficient execution of strategies that are taught takes practice.

Metacognition

Metacognition is knowledge and awareness of one's thinking and thinking processes (e.g., Flavell, 1981). This awareness is important in self-regulation of thinking (McCormick, 2003). Therefore, one type of metacognition is knowing when and how to use the various strategies and how to apply them to newly encountered

situations (Flavell, 1979; Paris & Winograd, 1990; Pressley et al., 1987, 1989). With respect to memory strategies, metacognitively competent individuals might know to apply organizational strategies whenever they are presented information to learn that can be divided into categories (Pressley et al., 1987, 1989). That is, transfer very much depends on a learner knowing when and where a strategy can be used, as well as how the strategy can be adapted to new tasks, points that can be made during strategy instruction (e.g., O'Sullivan & Pressley, 1984; Pressley et al., 1987, 1989). A learner is more likely to understand and successfully apply a strategy to a new situation if he or she has been encouraged to think about why the strategy works and has received instruction about why it works (Crowley & Siegler, 1999). With increasing age, there is greater transfer of strategies taught, although transfer is rarely as complete as it could be (for an illustration about how to determine the difference between actual transfer and potential transfer, see Pressley & Dennis-Rounds, 1979). Again, good strategies instruction results in learners who can and will transfer the strategies they are learning. It typically includes information about the effects produced by a strategy, as well as information about when and where to use the strategy being acquired (Pressley, Borkowski, & O'Sullivan, 1984, 1985).

Another important form of metacognition that is critical to effective strategies use is awareness of how one is doing on a task (e.g., recognizing that one has not studied enough to do well on an upcoming test or recognizing that the text being read is not understood). We refer to such awareness as monitoring. Being aware that learning or comprehension is not complete can serve as a cue for using strategies (e.g., deciding to study some more, deciding to reread a text). Thus, monitoring is a key to self-regulated use of cognitive strategies (e.g., Markman, 1985). A very consistent finding is that people often mis-monitor. This phenomenon that has been found again and again across a variety of populations, using a number of procedures (e.g., Dunning, Johnson, Ehrlinger, & Kruger, 2003). For example, children in the primary grades often believe they are more ready for a test than they really are (Kelly, Scholnick, Travers, & Johnston, 1976; Levin, Yussen, DeRose, & Pressley, 1977; Monroe & Lange, 1977; Worden & Sladewski-Awig, 1982). Sometimes children think they understand a text when they do not (Markman, 1985). When children mis-monitor they should be encouraged to pay attention to cues that alert them to the fact that they do not understand. Furthermore, children need to interpret

these cues as signals for applying more effort rather than signals to give up, believing the task is too difficult (e.g., Meichenbaum, 1977; Weiner, 1979).

Some strategies have a built-in monitoring component. If a child is using a cumulative rehearsal strategy and cannot remember the items on the list to rehearse them, that is a clear signal the material has not been learned. Also, if a child cannot retell a story just read, that provides powerful cuing that the story was not understood well enough (e.g., Thiede & Anderson, 2003; Thiede, Anderson, & Therriault, 2003). A very important finding in the monitoring literature was that practice tests provide tremendously powerful information about whether one is ready. Often, in advance of a practice test, people will believe they are going to succeed. If they experience difficulties on the practice test, they realize that their preferred strategies are not working, which motivates them to use other strategies (Pressley & Ghatala, 1990; Pressley, Levin, & Ghatala, 1984). Students should be encouraged to test themselves as they are trying to learn or understand content, given that their monitoring is often very poor, and that practice tests can inform them when their learning and understanding are incomplete.

A learner who can transfer the cognitive strategies they know broadly and appropriately is sometimes thought of as meta-strategic (Kuhn, 1999, 2000a, 2000b). Kuhn (e.g., 2001, 2002) currently leads the way in theorizing about how generalized use of strategies occurs. First of all, unlike the conception of memory strategy instruction in the 1960s and 1970s, Kuhn recognizes that a child often has several different strategies she or he could employ in a task situation. This is consistent with Siegler's view that learners typically have several strategies that they can apply to a task, with some more likely than others to be used at particular points in development (Siegler, 1996, 2000). Thus, for simple free recall list learning, the child could simply listen, say the name of the just revealed object one time, say it multiple times, could cumulatively rehearse the items on the list (i.e., saying over and over the names of all the objects revealed so far), or could create a mental image or invent a story incorporating all the list items. At any point in development, some of the strategies are more likely to be used than others.

For example, 5-year-olds often verbally name objects one time, right after the object is presented. On some trials, however, they might use rudimentary cumulative rehearsal, perhaps naming the most recently presented

object and the object that preceded it. After the researcher presents all the objects on a list, the child's recall is tested. The occurrence of the test might increase awareness (i.e., metacognition), making clearer to the participant child that the goal of this exercise is to remember the items on the list. As the child recalls the list, she or he may notice that some items are remembered better than others, for example, the cumulatively rehearsed items are remembered better. With some reflection on that task, the child's understanding of the utility and potency of the various strategies available to him or her changes in ways that can effect subsequent strategy use. Thus, if given a similar list learning task a day later, the child might be more likely to use cumulative rehearsal, recognizing its benefits from the previous experience. Eventually, as successful recall attempts occur and the child recognizes that cumulative rehearsal helped, the child's understanding that cumulative rehearsal is potent in list learning increases. The result is that cumulative rehearsal becomes the most likely strategy used during such list learning for the child. In short, a child has theories about how to do well in list learning, theories about strategies that work for these tasks. These theories drive strategy use, but as a strategy is used and list learning tested, the child has opportunities to reflect on the strategies used and change his or her understanding about what works in list learning. These new understandings affect subsequent strategy use. Thus, this growing awareness leads to greater use of little implemented, but effective strategies and reduces use of previously deployed but less effective strategic procedures.

Kuhn's (2001, 2002a, 2002b) emphasis on meta-strategic understandings as driving forces in strategy choice is consistent with classical conceptions of the role of metacognition in mediating strategy choice (e.g., Borkowski et al., 1990). Kuhn has reported some investigations where she has mapped strategy shifts as a function of experience with strategies and tasks, consequent development of understanding of tasks, and understanding of the strategies that can be used to accomplish tasks (for a review see Kuhn, 2001, 2002a). Understanding of this process can be accomplished using a microgenetic approach (Siegler, Chapter 11, this *Handbook*, this volume). This methodology involves observing how participants use and change strategies over many attempts to accomplish similar tasks, as well as documenting their shifts in understanding of the strategies being used (i.e., changes in metacognition that drive future applica-

tion of the strategies the learner knows that can be applied to the task).

Some of the most important information a learner can acquire about strategies is that they improve performance in certain situations. Such metacognitive understanding increases the motivation to transfer effective strategies from previously encountered tasks to new, similar tasks. (This is a point we elaborate on in the next subsection). In fact, one of the most reliable findings in the strategies instruction literature is that providing information about a strategy's benefits greatly increases the likelihood that the learner will continue to use a strategy being taught (see Pressley et al., 1984, 1985; Schunk & Zimmerman, 2003). Also, learners are more likely to continue to use a strategy if they can successfully carry out the strategy well enough that it works (i.e., does produce benefit). That is, they must possess self-efficacy with respect to use of the strategies being learned (Schunk & Zimmerman, 2003).

World Knowledge

Many strategies cannot be carried out by a learner unless she or he has substantial world knowledge. Consider an elaborative strategy for learning facts. Suppose a person is asked to learn the following facts about Canada: Baseball was first played in the province of Ontario. There are more teamsters in British Columbia than any other province. The first museum was in Ontario. As it turns out, when many facts are presented, this is a difficult task, even for students from Canada. However, a Canadian can make it an easier task by asking her- or himself a question as each fact is processed, such as why does it make sense that this happened in this particular province? This strategy dramatically increases learning only for people with a lot of background knowledge about Canada. When Germans are asked to use this strategy to learn content about Canada, there is no improvement in their learning (Woloshyn, Pressley, & Schneider, 1992). Likewise, if Germans are asked to learn facts about German states, they benefit from the strategy, whereas Canadians do not (Woloshyn et al., 1992). Martin and Pressley (1991) evaluated a number of possible explanations of the effects of such why-questioning. Why-questioning works by encouraging learners to relate what they are learning to relevant prior knowledge. This does not seem to occur automatically in the absence of why questions. Thus, encouraging students to ask why facts they are learning make sense produces a

large increase in learning. However, that is only possible if learners possess prior knowledge that permits them to answer the why questions they are asking.

Many strategies depend on prior knowledge. Organizational strategies cannot be applied to list learning if learners do not know the categorical information required to organize the material in the list. A common reading strategy, which we will discuss later in the chapter, is to make predictions about what is going to be covered in a text based on the title and pictures. Such predictions are possible only if the learner possesses prior knowledge about the text topic. Similarly, readers are often taught to associate ideas encountered in text to what they know already. Again, this strategy can only be carried out if learners possess relevant prior knowledge.

In addition to enabling strategy use, development of knowledge can replace strategy use, with the work of Siegler and his colleagues especially informative on this point (see Siegler, 1996, for a review). Consider the specific case of spelling. Suppose that you ask children in first and second grade to spell some first-grade words (e.g., moon, fish, bug). There are two ways that this task can be done. One way is to sound out each word. The other way is simply to retrieve the proper spelling from long-term memory. The latter is only possible if the child knows the word. Rittle-Johnson and Siegler (1999), found that first graders rely more on the sounding out strategy, whereas second graders are more likely simply to retrieve such words from their prior knowledge. Retrieving is easier and faster than sounding out! Apparent in the Rittle-Johnson and Siegler (1999) data as well as in Siegler's other investigations of strategy use is the fact that children do not consistently use just one strategy in any task situation. Thus, for spelling, sometimes they sound out and sometimes they retrieve the spelling from memory. Similarly, when asked answers to arithmetic fact problems (e.g., $5 + 4 + ?$, $7 - 3 = ?$), children sometimes will use a counting strategy and sometimes they will just know the answer based on prior knowledge (e.g., Steel & Funnell, 2001). Barrouillet and Fayol (1998) confirmed that an increase in retrieval of answers from memory, when combined with advancing age, occurred when there has been increasing experience with an arithmetic task. In basic memory situations, even some children who use a very efficient strategy some of the time (e.g., some form of elaboration to learn paired associates) will use a less efficient and less certain strategy (e.g., repeating paired associates over and over) some of the time (Pressley & Levin,

1977). Mixed strategy use is very much the norm, a point made clearly in the next subsection. However, occasions certainly exist when trial-to-trial variability in strategy use involves moving from a less effective to a more effective strategy. For example, Schlagmueller and Schneider (2002) showed that 8- to 12-year-olds who first attempted to learn categorizable lists without using a categorizing, clustering strategy, would suddenly shift to employing such a strategy, and then sticking with it from that point on. Also, there are some data consistent with the conclusion that high ability learners are more likely to use effective strategies consistently to the exclusion of less effective strategies (e.g., Coyle, Read, Gaultney, & Bjorklund, 1998).

In general, however, an important lesson from this body of work is that as the prior knowledge base expands, learners rely more and more on what they know rather than working it out using strategies, although they may occasionally revert to strategy use just to make sure (e.g., Steel & Funnell, 2001). Even mature thinkers shift their thinking as they learn more. Thus, early in a course of study (e.g., a law school course), students are more likely to use strategies as they read that do not depend much on prior knowledge. As a course progresses, however, they are increasingly likely to relate what they are encountering in text to other knowledge of the law, more likely to elaborate new information by thinking about other information they have acquired (Stromso, Braten, & Samuelstuen, 2003).

We emphasize that world knowledge develops early in life. We do so, because, for the first half of the twentieth century, the assumption was that very young children (i.e., during the first 1.5 to 2 years of life) did not form memories, or, if they did, their memories were quickly forgotten. Piaget (e.g., 1952, 1962) conceived of infancy as a buzz of perceptual confusion, a period of time when children had not yet developed symbolic competencies essential for memory. Freud (e.g., 1963) claimed that anything that was encoded during childhood was eventually repressed.

At mid-century, Fantz (1956) demonstrated that infants prefer novel visual stimuli. That could only occur if babies remembered something about stimulation they had experienced previously. As the century proceeded, the finding that infants had visual pattern memory had received substantial research support (Fantz, 1956). De-Casper and Spence (1986), when studying attentional preferences, found that children remembered sounds

they heard while in the womb. Thus, infants seem to have some memory even before they are born.

By the end of the 1st year of life, babies begin to be able to recall sequences of events such as a sequence of events required to make a simple toy operate (Carver & Bauer, 1999, 2001). This rapidly improves during early childhood. Bauer, Wenner, Dropik, and Wewerka (2000) observed that about 67% of their 32-month-old participants could recall a sequence they had experienced a year earlier. There are many contextual factors that effect recall of sequences (see Bauer, 2003, Chapter 9, this *Handbook*, this volume, for a review). Children are more likely to recall logically ordered sequences than arbitrary sequences. Also, memory is better if exposure to sequences is repeated. Active participation in the event sequence also improves memory of the sequence. Finally, memory is better if the child is provided some hints at testing.

By 2 years of age, children remember much about the events in their life. Ask a 2.5-year-old about a visit to the emergency room that occurred 6 months earlier and the child can recall quite a bit (Peterson & Rideout, 1998). In fact, 3-year-olds can recall many types of events that they have participated in, from making cookies to visiting Disney World. Moreover, they have very detailed knowledge about frequently repeated events, such as birthday parties and going to McDonalds (see Fivush, 1997, for a review). Children can remember events that happened in kindergarten years later (Hudson & Fivush, 1991). Such data make clear that the experiences a preschooler has go far in determining what the child knows. Children largely know what they experience.

Beyond the experiences, however, opportunities to talk about what has been experienced also effect young children's memories, or at the very least, their abilities to access and talk about their memories of the past. Children who have mothers who talk with them a great deal about their experiences, who ask their children questions and elaborate on their children's answers, have children who are much better able to talk about their past experiences than mothers who do not so completely engage their children in conversations about life events (P. J. Bauer, 2003; Fivush, 1994, 1997; Nelson, 1993a, 1993b). Children remember what they talk about with others. Interpersonal communications are tremendously important in building a knowledge base.

One indication of extensive knowledge of the world is vocabulary. A child's vocabulary knowledge provides a

good indication of their ability to comprehend new events that occur in their world, for example, understanding of new texts that are encountered (e.g., Venezky, 1984). An analysis by Hart and Risley (1995) concerning the development of vocabulary during the preschool years, powerfully suggested that experience determines the development of preschoolers' world knowledge. Hart and Risley observed preschoolers and their families in their homes over a 2.5-year period, beginning when children uttered their first words. The most striking difference over 1,300 hours of observations in 42 homes was that children living in professional families (i.e., mom and dad were educated) heard more than 2,000 words an hour, with many of the words occurring in conversations involving the child. In contrast, in working class families, children heard about 1,200 words per hour, with less parent-child conversation in general. In families receiving welfare, children heard about 600 words per hour, with much less parent-child conversation. With respect to the quality of the verbal interactions, professional families were more likely to respond to what their children said than did working class families, who were more responsive than the families receiving public assistance. The latter disproportionately talked to their children about what they should not do compared to more socioeconomically advantaged families.

By 3 years of age, there were clear differences in the amount of vocabulary possessed by the children in Hart and Risley's study. For example, the child in the professional family with the least vocabulary development knew more words than the child in a family on welfare with the most extensive vocabulary. The authors studied the children again when they were 9 and 10 years old, and observed a strong relationship between vocabulary development during the preschool years and success in reading. These data have received a great deal of attention in recent years as evidence that interactive language experiences during the preschool years go far in determining knowledge development that effects later intellectual competence. These data are complemented by an extensive experimental literature establishing that when parents of preschoolers are taught how to interact with their children over books (i.e., how to ask questions of their children during a reading and respond to children's remarks and questions) the children's language development improves, especially as indexed by increased vocabulary (e.g., Whitehurst et al., 1988, 1994). In short,

there is converging evidence that world knowledge is a critical component in children's memory and intellectual performance in general, and depends, in part, on linguistic interactions during early childhood.

Conclusions

In the decade following the first research on children's use of strategies to mediate and improve memory, researchers conducted studies to determine whether preschoolers are strategic in memory situations. They are, at least when given simple memory tasks in familiar settings. However, when given the types of verbal learning tasks that proved revealing about memory strategy use by school-age children, there was little to no evidence of preschoolers using strategies to impact their memory performance. A conclusion about preschoolers' memory that emerged from the work on strategies was that memory during this period of time was fragile, and that children were only successful in using strategies in specific contexts.

The problem with this conclusion is apparent to anyone who has ever raised a child. Preschoolers seem to remember quite a bit. Bauer (Chapter 9, this *Handbook*, this volume) and her colleagues have demonstrated that before children can speak, they are learning about complex sequences they experience in their worlds. Indeed, when Bauer's analyses are combined with work in perceptual recognition, it is clear that the knowledge base of children is developing even before they are born.

Researchers such as Nelson (1993) and Fivush (1994, 1997) have analyzed in detail just how complete such memories are, and have completed detailed analyses about how interactions between parents and their children at home serve to consolidate and refine memories of important experiences. Hart and Risley (1995) also carefully observed preschoolers in their home settings. They established clear linkages between the richness of children's verbal interactions with their parents and the development of world knowledge as indexed by vocabulary knowledge.

Whitehurst and associates (1988, 1994) complemented this work with experimental studies in which there was a causal relationship between verbal interactions with parents and language and knowledge development. Whitehurst's work provides a different way of thinking about strategy instruction and children's development. He taught parents strategies for interacting with

their preschoolers over picturebooks. This instruction led to changes in parent-child interactions that translated into differences in children's vocabulary knowledge. An examination of exemplary preschool environments that have improved children's intellectual functioning (for a review, see Eckenrode, Izzo, & Campa-Muller, 2003), such as the Perry Preschool Project (Hohmann & Weikart, 2002) and the Carolina Abecedarian approach (Martin-Johnson, Attermeier, & Hacker, 1996), reveals that a centerpiece in their interventions is teaching adults to interact with children in ways that will enrich adult-child interactions and encourage children to engage in mind expanding activities intended to increase children's knowledge of the world.

It is important to distinguish between intentional memory and incidental memory (Bauer, Chapter 9, this *Handbook*, this volume). Although preschoolers are sometimes very intentional in forming memories (e.g., making certain they remember where Big Bird is hidden), more often whatever memories are formed are incidental to their real goal at the moment. Thus, as children converse, their goal is to communicate, but in doing so, they incidentally remember some of the verbal labels that parents supply about the objects being discussed (e.g., Bloom, 2000). There is no doubt at this point that preschoolers acquire massive amounts of information incidentally.

In summary, a major discovery about children's memory during the last third of the twentieth century was that preschoolers can develop extensive world knowledge if they experience a conceptually rich world. These analyses make clear that extensive and meaningful interactions with others make a huge difference in the preparedness of children to cope with the demands made on them later, for example, in school. The child who arrives at the kindergarten classroom door with extensive vocabulary is more likely to thrive in school than the child who does not. Such a child is better prepared for school. This includes being better prepared to use the strategies taught in school in a self-regulated way.

STRATEGY USE AS THE COORDINATION OF INFORMATION-PROCESSING COMPONENTS

Self-regulated use of all types of strategies, including memory strategies (e.g., J. Alexander & Schwanenflugel, 1994; DeMarie & Ferron, 2003), depends on coordination of the information-processing components

reviewed in this section such as strategies, metacognition, motivation, and prior (i.e., world) knowledge. Although interest in basic memory in children waned in the past decade, interest in strategy use in other problem areas soared. We will discuss several important directions in the second half of this chapter. Among these directions will be text processing, or how people attempt to understand and remember what they read. Skilled, adult readers are unambiguously strategic as they process text. Much of the convincing evidence for this conclusion has emerged from verbal protocols of reading. Researchers employing verbal protocol methodology ask readers to think aloud as they read, and report whatever they are thinking as they read (Pressley & Afflerbach, 1995). Good readers coordinate their use of a variety of strategies in order to make sense of challenging texts. In other words, competent readers are very meta-strategic. The interaction between the reader's prior knowledge and strategies use is also apparent.

Thus, what do skilled readers do to comprehend a text? Often, they have a goal for reading (e.g., to learn information to prepare for a talk on the subject of the text). They may skim the text, perhaps identifying parts that deserve to be read quickly versus more carefully. They might activate prior knowledge (e.g., if it is an article about the comforts of a new type of jet airliner, perhaps remembering how uncomfortable she or he has been on airliners in the past). By the end of the skim, many readers will have made predictions about what will be in the text on the basis of reading the title, looking at headings and pictures, and prior knowledge about the topic of the text.

Then comes the reading itself, which is often done selectively (i.e., skimming some parts, skipping others, reading what are perceived as the most novel or most important points with special care). As reading proceeds, the reader might make notes or try to summarize large sections of the text, pausing to reflect upon parts of the text that are particularly relevant to the reading goal. The prereading predictions might be reconsidered in light of the reading, with new predictions made about what might be next. As reading proceeds, the reader increasingly refines understanding of the messages in the text. He or she might jump back and forth while doing this, to understand the facts in the text, with the intent of specifically remembering the parts that are most novel. Flipping back and forth through a text may also aid a skilled reader's attempt to integrate the ideas in the text.

There often is a great deal of conscious inference making. This means going beyond the information given in the text, based both on attention to ideas that are in the text and relevant prior knowledge. Thus, the meanings of unfamiliar words sometimes are inferred. Sometimes the reader relates the information in text to their personal experiences (e.g., when reading that the new plane has only aisle and window seats, the reader recalls how uncomfortable it had been to be in a middle seat on other airliners). The reader might make inferences about the author (e.g., this writer must work for the plane manufacturer, given how positive and uncritical he is about the new plane). Also, the reader often comes up with questions (e.g., How can flying such a small airliner be profitable?) and is especially attentive to subsequent sections of text that answer the questions that surface.

Much of the meaning is in the text, but much of it also emanates from the reader's prior knowledge. That is, readers interpret what they read, with any given text permitting a large number of interpretations. After reading, the reader might reflect additionally on the text, making certain she or he knows the most important points of the text, perhaps reflecting on whether these ideas are consistent with the reader's own perspectives, and perhaps considering updating or changing one's views depending on whether the text was persuasive or not.

While reading, skilled readers monitor their understanding of text and pay attention to points that are confusing or inconsistent within text. They are aware of whether the ideas in the text were known to them previously as well as whether they agree with the ideas in the text. When confused, capable readers often will go back and re-read and, or reduce their reading speed in an effort to understand better. Good readers monitor whether they are paying enough attention or being distracted. They especially monitor whether their efforts are paying off. That is, if they perceive that the text is not informing their reading goal, they might decide to speed up reading, or skim, or stop reading a text altogether. If the text is full of ideas advancing their thought, they may increase their strategy use by reading more slowly, deliberately reflecting on the text, and taking notes.

Excellent readers pay attention to individual words in the text that they do not know. If they sense that understanding a particular word is critical to understanding the text, they may analyze the text for cues to its meaning or even look up the word. If they decide that they do not need to know the word in order to understand the text, the reader often will just continue reading.

All of the skilled reading behaviors that we have just summarized take place in working memory. Although knowledge about strategies is stored in long-term memory, when strategies are activated, they operate in working memory. Likewise, prior knowledge is stored in long-term memory, when knowledge is activated and consciously thought about, the activation occurs in working memory. Similarly, motivational thought (e.g., I can do this task if I exert effort.) also occurs in working memory. In order for all of the information-processing components to function, strategy execution and knowledge access must be fairly automatic, so as not to exceed the capacity limits of working memory.

In summary, skilled reading is massively strategic, involving metacognitive processes (i.e., knowing when to use which strategies), and relating ideas in a current text to prior knowledge. The complicated information processing that is the skilled reading just described is decidedly more complicated than children's approaches to understanding a text, which often boils down to little more than straightforward reading of the words in the text from beginning to end (e.g., Kucan, 1993; Lytle, 1982; Meyers, Lytle, Palladino, Devenpeck, & Green, 1990; Phillips, 1988). That is, children readers are generally production deficient with respect to the reading strategies and processes used by skilled, adult readers. Consistent with the second overarching conclusion of this chapter, however, later we review the evidence that children can be taught the comprehension strategies that are at the heart of skilled, adult reading. Such instruction can result in children who are active, metacognitive, and motivated enough to continue using the strategies when reading in a self-regulated fashion. Before doing that, however, we take up discussion of strategies instruction with exceptional child populations.

BASIC RESEARCH ANALYSES OF EXCEPTIONAL CHILDREN WHO BENEFIT FROM STRATEGIES INSTRUCTION

As research on strategies use by normal students proceeded, basic researchers also turned their attention to atypical students, including children with mental retardation, students with learning disabilities, and children suffering from attention deficit and hyperactivity. This work informed and inspired many who were searching for ways to improve the intellectual lives of disadvantaged children. In this section, we review the basic work

with atypical populations that convinced many that struggling students should be taught strategies.

Meichenbaum's Analyses of Attention Deficit Hyperactivity

Donald Meichenbaum's (1977) text, *Cognitive Behavior Modification*, summarized a body of work that stimulated others to follow suit. Meichenbaum and Goodman (1969) involved second graders with attention deficit and hyperactivity, who were asked to do a matching task that required careful comparison of several similar geometric figures. The researchers asked the students to select from a set of similar figures one that matched the test figure exactly. This is a very difficult task for young students with attention deficit-hyperactivity because they characteristically fail to consider task details carefully, and respond to a task before reflecting on it.

Meichenbaum and Goodman (1969) taught the participants in the experimental condition a strategy for accomplishing such a difficult task. Basically, they taught the students to tell themselves to slow down when doing such a task and to reflect before responding, and look carefully at each feature on the test stimulus and the choices (i.e., to self-instruct themselves to be careful and reflective). At first, a teacher modeled and explained the strategy, then provided support as students tried the approach on their own. Performance on this difficult task improved because of this strategy training. There were many follow-up studies by a number of researchers (see Meichenbaum, 1977; Pressley, 1979), who concluded that teaching the self-instruction strategy to hyperactive learners improved their ability to do tasks that required slow and careful processing.

Over the years, Meichenbaum and his colleagues have spent much time with educators to encourage them to teach their students to use the self-instruction strategy. They paid attention to how instruction can be delivered in a way that facilitates students' continued strategies use. The conclusions (e.g., Meichenbaum & Biemiller, 1998, chap. 10) that follow from their clinical-classroom work (and that of others) are very consonant with some of the conclusions from the basic memory development literature. Their recommendations include the following:

- Students should be taught to transfer, with teachers letting them know from the beginning that transfer is the goal.

- When students are in a situation where they might apply a strategy they know (but seem not to be doing so), teachers should give them a hint to reflect on the situation and use a strategy they know.
- Teachers should discuss with students different contexts that are appropriate for a particular strategy.
- Students should have practice opportunities with diverse situations where strategies they are learning could be applied. Such practice should occur as part of long-term instruction that permits students to become more proficient in strategy use as they become more aware of when strategy use is helpful.
- Students should practice using a strategy with diverse tasks and diverse settings because this increases awareness of when to use a strategy.
- Students should think aloud as they do tasks. This provides a window for the instructor documenting whether the student is attempting to transfer the strategies being taught.

In short, the main message from Meichenbaum's work and the clinical practice inspired by his work is that students can be taught to use strategies. A broad application of strategies is most likely to occur if the teaching is long term, varied, and complete, and continues until there is evidence that students are transferring what they are learning. This perspective is reflected in much of the strategy instruction that will be considered subsequently.

Strategy Instruction with Students with Mental Retardation

Many of the researchers who were concerned with memory development in children with normal intelligence also studied memory development in children with mental retardation, especially children who are considered to be educable (i.e., they can learn, although typically more slowly than normal students, achieving less, and are not as capable of taking on tasks as difficult as normal age mates). One major finding was that children with mental retardation are much less likely to develop memory strategies than are normally achieving children (Ellis, 1979). More positively, when children with retardation are instructed to use memory strategies, often they can do so with improved performance. They can rehearse list items, use categories to organize clusterable lists, and construct verbal elaborations of paired associates. However, their performances rarely approach the levels of

normal children using these strategies (Blackman & Lin, 1984; Brown, 1978; Taylor & Turnure, 1979). Even so, like normal children, after being taught memory strategies, children with mental retardation rarely continued to use the strategies, even in situations almost identical to the training situation (Borkowski & Cavanaugh, 1979; Brown, 1974; Brown & Campione, 1978; Campione & Brown, 1977). To use Flavell's (1970) term, these children were production deficient with respect to memory strategies with simple instruction of strategies not resulting in long-term use of them.

Belmont, Butterfield, and Ferretti (1982) offered a critical analysis that illuminated conditions when memory strategies instruction is more effective for children with mental retardation. They evaluated more than 100 studies of strategy instruction directed at children with mental retardation. They found little evidence of continued use of strategies, especially in situations that differed even a small amount from the training situation (i.e., failure to transfer the strategies taught). A few studies did produce longer-term use of the strategies taught. Of the seven studies that resulted in some evidence of transfer, six of them shared a common characteristic. Instruction was especially complete with respect to the components that Meichenbaum (1977, chap. 7) has identified as important in promoting self-regulated use of strategies in children with attention deficit and hyperactivity. In the studies in which students produced some evidence of transfer, students were taught to formulate a goal (e.g., remember the list items), make a plan to attain the goal, and monitor whether the plan was working as it was being carried out (e.g., asking themselves, "Did the plan work?"). If the children did not successfully learn the material they were taught to cope, by deciding whether they used their plan, trying to use the plan again, or trying to come up with a new plan.

Why might this teaching work? An important problem for students with mental retardation is that they do not self-regulate. The type of instruction advocated by Meichenbaum (1977) is intended to increase self-regulation, especially using language, which is something that students with mental retardation fail to do (Whitman, 1990). In addition, such instruction encourages students to monitor, to appraise whether they are making progress on the task, and to be aware that there is a connection between the strategies they are learning and their performance outcomes (see Borkowski & Kurtz, 1987).

The demonstrations of improved performance for students with mental retardation as a result of self-regulated strategy instruction greatly impacted educators of special populations. Additionally, these studies greatly motivated much of the work covered in the remainder of this chapter, and contributed to the hypothesis that children's performance will improve if they are taught to use strategies that are well matched to task demands. And while students with mental retardation may not persist in their strategy use as long as other students, there was reason to believe that instruction emphasizing self-regulated use of strategies might produce enduring strategy instructional effects (Belmont et al., 1982; Campione, Brown, Ferrara, Jones, & Steinberg, 1985; Meichenbaum, 1977).

Strategy Instruction with Students with Learning Disabilities

The defining characteristics of students with learning disabilities is that they have difficulty learning some type of academic content, despite being otherwise normally intelligent. Because failure to learn to read has such negative consequences tied to it, learning disabilities in reading have received much attention (e.g., Siegel, 2003; Vellutino, 1979). Math learning disabilities have also captured the attention of a number of researchers, again, because failing to learn math is obviously problematic, for learning arithmetic and more advanced mathematical skills are foundational in western education (Geary, 2003).

While a plethora of theories of learning disability exist, the potential biological bases of learning disabilities have received the most attention in recent years. Thus, behavioral genetics studies of the heritability of learning disabilities have provided substantial evidence that difficulties in learning particular skills often pass from parents to children following patterns most consistent with genetic mediation (for a brief review, see Thomson & Raskind, 2003). The most visible biologically oriented work in learning disabilities, however, is concerned with determining whether there are neurobiological differences between students with learning disabilities and normally achieving students (Shaywitz & Shaywitz, 2003). Researchers generating neuro-images as students perform academic tasks (e.g., basic reading tasks) have identified some differences in the neuro-imagery patterns between students with learning disabilities and normal students.

Since the concept of learning disabilities became prominent in the early 1970s, much research has established that there are neurobiological correlates of learning disabilities (C. J. Miller, Sanchez, & Hynd, 2003). As this work proceeded, both basic and applied cognitively oriented researchers explored the hypothesis that students with learning disabilities could be taught strategies to improve their learning. This work was informed by basic research involving the same memory tasks that had been used to understand memory strategy development in normal students. In general, on basic verbal memory tasks, students with learning disabilities typically performed more poorly than normally achieving students. Converging evidence points to one contributing factor that may explain this gap. Students with learning disabilities were less likely than normally achieving students to use effective memory strategies (e.g., Bauer, 1977a, 1977b; Dallago & Moely, 1980; Kastner & Rickards, 1974; Tarver, Hallahan, Cohen, & Kauffman, 1977; Tarver, Hallahan, Kaufmann, & Ball, 1976; Torgesen, 1977; Torgesen & Goldman, 1977). That is, students with learning disabilities often were production deficient in comparison to same-age normally achieving students who had discovered and were using strategies to perform basic list-learning tasks. More positively, students with learning disabilities can be taught basic memory strategies, and as a result can improve their memory (e.g., Bauer, 1977b; Tarver, Hallahan, Cohen, et al., 1977; Tarver, Hallahan, Kauffman, et al., 1976; Torgesen, 1977). However, this improvement generally never completely closes the gap between their performance and that of normally achieving students (see Swanson & Saez, 2003).

This basic memory strategies work with students with learning disabilities likely inspired Deshler and his colleagues (e.g., Deshler & Schumaker, 1988, 1993) to begin work on a variety of strategies that students with learning disabilities might use to improve their academic performances, including their memory of academic material. The clinical work of Deshler and his associates led to a set of insights about how to teach cognitive strategies to students with learning disabilities so that long-term use of the strategies was accomplished. They recommend that instruction should begin with teacher modeling and explanation of strategies (preferably provided by several different teachers in several different settings), followed by guided practice of students as they attempt to apply strategies. Teachers

can emphasize that strategies can be transferred by making clear where and when it makes sense to use particular strategies. As students learn to use strategies, they are taught to give themselves pep talks by self-verbalizing ("I am doing well here," or, "I can handle this"). Teachers can encourage their students to monitor their performances by assuring their students note the co-variation between strategy use and academic success (see also Swanson & Saez, 2003; Wong, Harris, Graham, & Butler, 2003). That is, there is an emphasis during instruction and practice of strategies that use of strategies pays off in performance gains. As students increasingly learn to use strategies on their own, and apply the strategies to a diverse range of materials, teacher support fades, because the goal is for the students to use the strategies in a self-regulated fashion.

Strategies Use by Gifted Students

Although there has been little study of strategies use and instruction with gifted students compared to average and low-ability students, the research that exists supports the conclusion that gifted individuals are more strategic, and tend to use more advanced strategies in a more coordinated and orderly fashion than age mates (Coyle et al., 1998; Feldman, 1982; Gaultney, Bjorklund, & Goldstein, 1996; Geary & Brown, 1991; Jackson & Butterfield, 1986; MacKinnon, 1978; Robinson & Kingsley, 1977; Zimmerman & Martinez-Pons, 1990). An assumption from the very earliest modern studies of strategies instruction is that gifted students benefit less from strategies instruction because such students are likely to use strategies spontaneously (Rohwer, 1973).

Conclusions

Shortly after memory development researchers established that strategies instruction often benefits normal children, researchers interested in intellectual disabilities analyzed the strategies used by children with attention deficit-hyperactivity syndrome, mental retardation, and verbal learning disabilities. In all cases, they found that these populations did not use strategies to accomplish basic information-processing and memory tasks as extensively, or as successfully as normally achieving children. However, these children did benefit from strategies instruction. Although performance typically did not reach the level of normally achieving students, it

was better following strategies instruction. A consensus emerged that for students with mental disabilities to generalize the strategies they were learning, instruction had to be extensive, and include a great deal of teacher support as students practiced the strategies they were learning. During this instruction, students learned when and where to apply the strategies as well as to monitor the effects of using strategies and use them on their own. Despite the reduced interest in memory strategy development and instruction among researchers studying normal development, there continues to be memory strategy development and instructional research with populations of children with attention deficit and hyperactivity disorder (Cornoldi, Barbieri, Gaiani, & Zocchi, 1999; French, Zentall, & Bennett, 2001; Shallice et al., 2002), retardation (e.g., Fletcher, Huffman, & Bray, 2003; Fletcher, Huffman, Bray, & Grupe, 1998), learning disabilities (Mastropieri, Sweda, & Scruggs, 2000), language impairment (Gill, Klecan-Aker, Roberts, & Fredenburg, 2003), autism (Bebko & Ricciuti, 2000), prefrontal dysfunction due to phenylketonuria (White, Nortz, Mandernach, Huntington, & Steiner, 2001), deafness (Bebko, Bell, Metcalfe-Hagget, & McKinnon, 1998; Bebko, Lacasse, Turk, & Oyen, 1992; Bebko & McKinnon, 1990; Bebko & Metcalfe-Haggert, 1997), and low birth weight due to premature birth (Luciana, Lindeke, Georgieff, Mills, & Nelson, 1999).

The insights gained from basic memory and cognitive instructional studies inspired and informed educators who are concerned with teaching potentially at-risk students to use strategies as they read words, attempt to comprehend ideas in text, compose, and problem solve. In the next section, we briefly review notable strategies instruction research for each of these important academic tasks, emphasizing research on students at risk for academic difficulties.

APPLIED STRATEGIES INSTRUCTIONAL RESEARCH

Strategy instructional approaches for a variety of academic tasks are being developed and evaluated, especially for at-risk students, including students with learning disabilities of various sorts. Much of this work was informed by the basic research on strategies use and instruction that has been considered thus far in this chapter. In the following section, we highlight

some of the most visible and promising applied strategies instructional work. This research makes obvious that production deficiencies can be overcome with strategies instruction that is metacognitively rich, and encourages self-regulated use of the strategies being taught.

Word Recognition

The most common problem that beginning elementary students have with respect to reading is learning to recognize the words. Students who experience difficulties in learning to read words in first grade are at high risk of becoming poor readers in the later elementary grades (e.g., Juel, 1988) and beyond (Cunningham & Stanovich, 1997; Rayner, Foorman, Perfetti, Pesetsky, & Seidenberg, 2001).

Researchers have conducted numerous, well-controlled experiments that evaluate various ways to teach beginning, struggling readers how to sound out words (i.e., studies of phonics instruction; see Pressley, 2002, chap. 5, for a review). Although some debate exists about how great an impact such instruction has, in general, it does seem to have a discernible impact on children's abilities to read words (Camilli, Vargas, & Yurecko, 2003; National Reading Panel, 2000). Such instruction, however, tends to have a focused impact. Thus, while this instruction typically increases beginning readers' recognition of words, it does not increase their fluent, automatic recognition of words (Torgesen, Rashotte, & Alexander, 2001). Moreover, students' reading comprehension rarely improves as a result of phonics instruction (Lovett, Barron, & Benson, 2003; National Reading Panel, 2000).

Evaluations of phonics have focused on a several types of phonics instruction. Thus, there are studies of synthetic phonics, when students are taught to sound out words by blending the letter combinations in a word, and their associated sounds (e.g., sounding out *cat* as /k/ /short a/ /t/). Proponents of other approaches encourage readers to focus on chunks of words. Thus, the words *bat*, *cat*, *sat*, and *mat* all contain the chunk *-at*, so that once a student knows one of the words (e.g., *cat*), she or he can decode the other *-at* words by analogy to *cat*. In research to date, none of the particular approaches to phonics instruction has proven to be better than the others (National Reading Panel, 2000). However, based on an Chall's early analysis (1967), it had been assumed for

a long time that synthetic phonics had more impact than other forms of phonics instruction.

Lovett and her associates at the Hospital for Sick Children in Toronto have led the way in evaluating the benefits of asking students to learn and use a repertoire of phonics strategies, rather than just one (Lovett et al., 2000). The participants in this study were 6- to 13-year-olds with severe reading difficulties. Everyone received 70 hours of intervention. Some received both instruction in sounding out of words and a form of decoding by analogy instruction, which had them learn keywords, each representing one of the 120 key spelling patterns in English (e.g., *cat* as a keyword for the pattern *-at*). Other participants were taught only to sound out words, while others only received decoding by analogy instruction. Control participants experienced math tutoring with some classroom survival skills training. At the end of instruction, participants receiving the combined sounding-out and decoding by analogy training demonstrated significantly better word recognition.

Much more work needs to be done on the effects produced by teaching struggling readers both to use sounding-out strategies and analogy approaches. Such flexibility in decoding instruction may be especially important for students who experience difficulties either with analyzing and blending or with decoding analogically using word chunks. For students experiencing the former problem, instruction should focus more on the word chunks and use of analogies to decode words. For students experiencing the latter problem, downplaying word families and word chunks in favor of analyzing and blending would make sense. In short, what is needed might be decoding instruction that accommodates individual differences in students rather than being one-size-fits-all instruction. Working out the specifics of such instruction is going to be challenging, however.

Again, Lovett, Barron, and Benson (2003) are currently evaluating an intervention that involves teaching struggling beginning readers to use five strategies as a repertoire: (1) sounding out words, (2) decoding by analogy to known words (i.e., a rhyming strategy), (3) peeling off prefixes and suffixes and isolating a smaller root word, (4) trying each of the sounds a word's vowels could make, and (5) looking for smaller, known words in a longer unknown word. They seem to have been influenced by Meichenbaum's (1977) thinking, since their intervention includes instructing students to self-instruct their use of strategies. For example, if trying to

decode the word *unstacking*, a student would self-regulate strategy use through four steps (Lovett et al., 2003, p. 285, table 17.1): (1) They would choose a strategy, saying to themselves something like the following: "My game plan is first to use peeling off. Then I am going to use the rhyming strategy and look for the spelling patterns I know." (2) The students would use these strategies, self-verbalizing as they do so: "I am peeling off *un* and *ing*. My next game plan is rhyming. I see the spelling pattern *-ack*. The key word is *pack*. If I know *pack*, then I know *stack*." (3) The reader would then check: "I have to stop and think about whether I am using the strategies properly. Is it working? Yes, I'll keep on going. I will put all the parts together—*un-stack-ing*." (4) The student self-reinforces by declaring she or he "scored," if the word seems correct. If not, the student would start the sequence again, choosing, using, and checking strategy use: "The word is *unstacking*. I scored. I used peeling off and rhyming to help me figure out this word and they worked." Evaluations of this self-instruction approach are underway as this chapter is being written, consistent with a great deal of ongoing research on a variety of word recognition strategies.

Comprehension Strategies Instruction

Although instructing students to use a repertoire of word recognition strategies in a self-regulated fashion is a recent trend, researchers have been teaching students to use comprehension strategies in a self-regulated fashion for more than a quarter of a century. The first such study was carried out by Meichenbaum and Bommarito (reported in Meichenbaum & Asarnow, 1979). Those investigators taught comprehension strategies to middle-school students who could decode but were experiencing difficulties understanding what they read. Instruction began with an adult modeling self-verbalized regulation of comprehension strategies such as, looking for the main idea, attending to the sequence of important events in a story, and attending to how characters in a story feel and why they feel the way they do, as well as some other strategies helpful during reading.

The students saw the adult read as they heard the following verbalizations by the adult:

Well, I've learned three big things to keep in mind before I read a story and while I read it. One is to ask myself what the main idea of the story is. What is the story about? A

second is to learn important details of the story as I go along. The order of the main events or their sequence is an especially important detail. A third is to know how the characters feel and why. So, get the main idea. Watch sequences. And learn how the characters feel and why.

While I'm reading I should pause now and then. I should think of what I'm doing. And I should listen to what I'm saying to myself. Am I saying the right things?

Remember, don't worry about mistakes. Just try again. Keep cool, calm, and relaxed. Be proud of yourself when you succeed. Have a blast. (pp. 17–18)

By the end of six training sessions, the students were self-verbalizing covertly, with control gradually transferred to the students over the course of six sessions. There was greater pretest-to-posttest gain on a standardized comprehension test for students receiving instruction than for control condition participants. This was the first demonstration that teaching students to use a small repertoire of comprehension strategies in a self-regulated fashion makes a difference in the understanding of text.

During the 1970s and 1980s, however, most research on comprehension strategies was not about teaching their self-regulated use or even teaching students to use several strategies in combination. Rather, researchers typically employed true experiments to demonstrate that many individual comprehension strategies (e.g., creating mental images representing the meanings in text, asking questions about text content, summarization) improved elementary students' comprehension and memory of text (for reviews, see National Reading Panel, 2000; Pressley, Johnson, Symons, McGoldrick, & Kurita, 1989). This work made clear that elementary students were production deficient with respect to these strategies, but they could execute them, if instructed to do so, and thereby improve their comprehension and memory of text.

A major problem with respect to the experiments on individual strategies was that good readers never employ a single strategic process. Rather they flexibly articulate a variety of strategies as they attempt to make sense of text (Pressley & Afflerbach, 1995). Moreover, professional educators who taught study skills to students had recognized for years that tasks such as reading and learning from text required integrated use of a variety of strategies (e.g., the SQ3R approach encouraged students to survey a text before reading, ask questions about the text based on headers and pictures, read the text, recall

and review it; Robinson, 1961). Thus, reading research had plenty of inspiration to explore the possibility of teaching students to use repertoires of individual comprehension strategies that had been validated in the experiments of the 1970s and 1980s.

Reciprocal Teaching

Palincsar and Brown (1984) developed a comprehension strategies technique that amalgamated tactics emphasized in the study skills literature and strategies studied by comprehension researchers in the late 1960s. Stauffer's (1969) Directed Reading-Thinking Activity focused on prediction, including reader revision of predictions as information is encountered in text. Another influence on reciprocal teaching was Manzo's (1968) ReQuest, which involved students and teacher reading part of text and then taking turns asking each other questions about it (i.e., engaging in reciprocal questioning). Through generating questions, the teacher modeled questioning for the student. The teacher also provided feedback to students about the questions they generated. Markman (1985) also influenced reciprocal teaching. She emphasized the finding that capable readers monitor whether they understand when they read and respond with repair strategies when they detect less than complete comprehension (e.g., seeking further clarification). Finally, many demonstrations existed where teaching students to summarize their understanding as they read improved comprehension and memory of text (Armbruster, Anderson, & Ostertag, 1987; Berkowitz, 1986; Brown & Day, 1983; Rinehart, Stahl, & Erickson, 1986; B.M. Taylor, 1982; B. M. Taylor & Beach, 1984). Thus, Palincsar and Brown (1984) taught students to make predictions before reading, question as they read, seek clarification when confused, and summarize after reading a section of text. They did so first in the context of a study that became the most visible comprehension strategies instructional study ever conducted.

Palincsar and Brown's first study (1984) included seventh-grade readers, who were adequate decoders but poor comprehenders. In the reciprocal teaching condition, the participants were taught the four comprehension strategies. Each intervention day began with the adult teacher discussing the topic of the day's text, calling for predictions about the content of the passage based on the title, if the passage was completely new, or calling for a review of main points covered thus far for passages that had been begun the previous day. The adult

teacher then assigned one of the two students to be the “teacher.” Adult teacher and students then read the first paragraph of the day’s reading silently, with the student teacher then posing a question about the paragraph, summarizing it, and either predicting upcoming content or seeking clarification if there was some confusion about the ideas in the paragraph. If the student teacher faltered, the adult teacher prompted these activities (e.g., “What question do you think a teacher might ask?” “Remember, a summary is a shortened version,” or, “If you’re having a hard time thinking of a question, why don’t you summarize first?”). Students were praised for their teaching and given feedback about the quality of it (e.g., “You asked that question well, a question I would have asked would have been . . .”). Students took turns as the student teacher, with a session lasting about 30 minutes. Throughout the intervention the students were explicitly informed that questioning, summarization, prediction, and seeking clarification were strategies that were to help them to understand better and that they should try to use the strategies when they read on their own. The students were also informed that being able to summarize passages and being able to predict the questions on upcoming tests were good ways to assess whether what was read was understood. There were approximately 20 days of intervention for the students in the reciprocal teaching condition, followed by 5 days of posttesting immediately after the intervention period. Eight weeks later, Palinscar and Brown conducted 3 days of long-term follow-up testing. Students in a control condition received the same pretests and posttests as strategies-instructed students but received no instruction and did not experience daily assessments.

Relative to the control condition, reciprocal teaching positively affected all measures of text comprehension and memory that were collected. The results of Study 1 provided plenty of reason for enthusiasm about reciprocal teaching. Nonetheless, with only 2 students per teacher in Study 1 and an experimenter as the teacher, it was difficult to make a case for the classroom validity of the intervention. Then in their second study, Palinscar and Brown (1984) evaluated the usefulness of reciprocal teaching in a realistic classroom situation. Four small groups of middle-school students who could decode adequately but who experienced comprehension problems participated in reciprocal teaching reading groups. Their reading was compared to students who did not receive reciprocal teaching. In general, the positive effects observed in Study 1 were replicated in Study 2, although no

standardized test data were collected in the second study.

The reciprocal teaching research had a wide-ranging impact on practice. For instance, reciprocal teaching stimulated textbook publishers to include strategies instruction, focusing on summarization, questioning, prediction, and seeking clarification in their elementary-level reading series in the late 1980s and early 1990s. Palinscar and Brown (1984) also inspired additional study of the method. Ten years later Rosenshine and Meister (1994) conducted a meta-analysis of the impact of reciprocal teaching. They concluded that the approach produced consistent, striking effects on cognitive process measures, such as those tapping summarization and self-questioning skills. However, with respect to standardized comprehension, the effects were less striking, with an average effect size of 0.3 standard deviations. A very important finding in Rosenshine and Meister’s (1994) meta-analysis was that reciprocal teaching was more successful when there was more direct teaching of the four comprehension strategies. This finding is important in light of conclusions we offer later in favor of greater direct explanation as part of strategies instruction.

Other 1980s-Era Studies of Comprehension Strategies Instruction

News of Palinscar and Brown’s (1984) work inspired a flurry of interest in teaching repertoires of comprehension strategies. Much was learned during this period about how to do such work successfully as well as how not to teach comprehension strategies.

For example, Paris and his colleagues devised and evaluated a 30-hour approach to teaching a variety of comprehension strategies in classrooms (Paris, Cross, & Lipson, 1984; Paris & Jacobs, 1984; Paris & Oka, 1986). The approach emphasized student understanding of the strategic processes. However, there was only limited application of the processes, and such teaching took place in whole classroom groups. Thus, it lacked the intensity of the teaching in Palinscar and Brown (1984). More positively, there was a lot of teacher explanation and modeling of the processes, as well as teacher-directed discussion of the strategies. The students who experienced this instruction learned about strategic processes as evidenced by being able to answer a few more questions about the strategies than students who did not experience the curriculum (e.g., Jacobs & Paris, 1987). Students experiencing the curriculum also did

better on some comprehension measures than control participants, especially measures similar to ones experienced during strategies instruction lessons. Unfortunately, the approach made no impact on comprehension as measured by standardized achievement tests (Paris & Oka, 1986).

Bereiter and Bird (1985) taught seventh and eighth grade average-achieving students to use a set of comprehension strategies to engage text actively. These strategies included: restatement of the text content (i.e., summarization), backtracking when confused (i.e., clarifying), making connections between various parts of the text, and careful reflection on text (i.e., looking for inferences that should be made, close examination of portions of text that seem important, rejection of information in text after thinking about it). In the most complete condition, a teacher first modeled and extensively explained the strategies, with students then practicing them, including making judgments about when the strategies should be used. A second condition consisted of teacher modeling and student practice, but no explanation of the strategies. Bereiter and Bird also designed two control conditions. The students in the most complete condition reported greater strategy use when they read. And their standardized test performance greatly improved as compared to the participants in the other three conditions. Bereiter and Bird's (1985) finding that explanation of strategies was important as part of good comprehension instruction was complemented by the outcomes in another study conducted by Duffy and associates (1987).

Duffy and colleagues (1987) produced an extremely well designed investigation of the effects of direct explanation strategy instruction on third-grade reading. Ten of 20 groups of weak readers were assigned randomly to a direct explanation strategies instruction condition. The remaining 10 groups of students received their usual instruction and served as controls. They taught third-grade teachers to explain the strategies, skills, and processes directly that are part of skilled third-grade reading, including both word recognition and comprehension strategies. The study took place over the course of an entire academic year. The teachers were taught first to explain a strategy, skill, or process and then to model using it for students. Then came guided student practice, where the students initially carried out the processing overtly so that the teacher could monitor their use of the new strategy. Teacher assistance was reduced as students became more proficient. Teachers en-

couraged transfer of strategies by going over when and where the strategies being learned might be used. Teachers cued use of the new strategies when students encountered situations where the strategies might be applied profitably, regardless of when these occasions arose during the school day. Thus, teacher scaffolding, where teachers provide sufficient support to keep student learning on task continued throughout the school day (as conceptualized by Wood, Bruner, & Ross, 1976). Cuing and prompting was continued until students autonomously applied the strategies they were taught. By the end of the year, students in the direct explanation condition outperformed control students on standardized measures of reading, including one of two measures of comprehension included in the study. These results had a profound effect on the reading education community. Many educators began to incorporate direct explanation, as defined by Duffy and company (1987) as a part of their comprehension strategies instructions in their own schools. Direct explanation, modeling and teacher monitored practice of comprehension strategies applications would be the heart of comprehension instruction as practiced in many elementary schools across the country (Almasi, 2003; Block & Pressley, 2002; Harvey & Goudvis, 2000).

Transactional Strategies Instruction

Teaching students to use repertoires of comprehension strategies that incorporated teacher explanation and modeling, and supported student practice of the strategies came to be known as transactional comprehension strategies instruction in the 1990s. The approach was so named because such instruction involved students responding to text (Rosenblatt, 1978), with predictions, questions, images, and summaries all reflecting student interpretations of what they were reading—interpretations effected both by the texts being read and readers' prior knowledge.

Three studies are usually cited as validation for transactional comprehension strategies instruction. In all three, the strategies instruction included extensive and long-term teacher modeling and explanation of strategies, as well as extensive and long-term student practice of the strategies.

Brown, Pressley, Van Meter, and Schuder (1996) conducted a school-year long quasi-experimental investigation of the effects of transactional strategies instruction on second graders' reading. Five second-grade classrooms receiving transactional strategies instruction were

matched with second-grade classrooms taught by teachers who were well regarded as language arts teachers but who were not using a strategies-instruction approach. The target group of students consisted of readers who were low achieving at the beginning of second grade. In the fall, the strategies-instruction and control participants did not differ on standardized measures of reading comprehension and word attack skills. By the spring, there were clear differences on these measures favoring the students receiving transactional strategies instruction. In addition, there were differences favoring the strategies-instructed students on strategies use measures as well as interpretive measures. Strategies-instructed students made more diverse and richer interpretations of what they read than control students.

Collins (1991) produced improved comprehension in fifth- and sixth-grade students by providing a semester (3 days a week) of comprehension strategies lessons. With respect to standardized comprehension performance, the strategies-instructed students did not differ from control students before the intervention. On the posttest, however, there was a 3-standard deviation difference between treated and control conditions. This is a very large effect for the treatment.

Anderson (1992; see also Anderson & Roit, 1993) conducted a 3-month experimental investigation of the effects of transactional strategies instruction on reading disabled students in grades 6 through 11. Students were taught comprehension strategies in small groups. The investigators divided students into nine groups that experienced transactional strategies instruction and seven control groups. Although both strategies-instructed and control students made gains on standardized comprehension measures from before to after the study, the gains were greater in the transactional strategies groups than in the control condition. Anderson (1992) also collected a variety of qualitative data supporting the conclusions that reading for meaning improved in the strategies-instructed condition. Strategies instruction increased students' willingness to read difficult material, their attempts to understand it, their efforts to collaborate with classmates to discover meanings in text, and their reactions and elaborations of texts.

In summary, long-term transactional comprehension strategies instruction produces positive effects on comprehension for students from grade 2 through grade 11. Such teaching begins with teacher explanation and modeling of strategies followed by students practicing the

strategies in small reading groups. As they do so, students discuss their predictions, reports of interpretive images, questions, summary comments, and reflections on how to deal with difficulties in understanding the text.

Collaborative Strategic Reading

More recently, Vaughn and her colleagues have developed a multiple strategies instruction approach for reading expository text. They refer to it as collaborative strategic reading (CSR), since students read together in collaborative groups, using the strategies to understand the text. Consistent with transactional strategies instruction, a teacher models and explains strategies to small groups of students. The strategies include making predictions about the text, clarifying when readers sense some difficulty in understanding (i.e., rereading if the problem is not one of word recognition, some word-attack strategies if it is a word the reader does not recognize), a gist strategy (i.e., finding the main ideas), and a wrapping up strategy after the text is read (i.e., asking what should be understood after reading the text, determining whether the reader learned it, and reviewing the content).

Once the students are familiar with the strategies they use them in collaborative groups. As in reciprocal teaching (Palincsar & Brown, 1984), students take turns leading the group. Other roles are shifted from student to student. Thus, one member of the group reminds students how to make clarifications when necessary. Another member provides feedback to group members. Still another is responsible for the wrap up. The fifth member of the group watches the time, moving the group along in a reading if they spend too much time on one portion of text or carrying out a strategy. In an experimental validation involving fourth graders who learned and practiced collaborative strategic reading over an 11-day period, there was a small to moderate benefit for the trained students relative to controls on a standardized comprehension test (Klingner, Vaughn, & Schumm, 1998).

Conclusions

There is no doubt that elementary-grade students can be taught comprehension strategies with benefit. Thus, when the National Reading Panel (2000) reviewed well-supported reading instruction, they concluded that students benefit from comprehension instruction. As a result, comprehension strategies instruction has been

cited explicitly in the federal *No Child Left Behind Act of 2001* as an integral part of better reading education. In particular, there is great improvement in comprehension by teaching students a repertoire of strategies that are like the strategies used by very capable adult readers (Gersten, Fuchs, Williams, & Baker, 2001; Pressley & Afflerbach, 1995).

What is discouraging is that comprehension strategies, in fact, are not being taught much in schools (Pressley, Wharton-McDonald, Mistretta, & Echevarria, 1998; Taylor, Pearson, Clark, & Walpole, 2000), at least not as extensively as in the training studies cited here. One hypothesis is that teachers themselves are not very good comprehenders, in that they typically do not actively use the comprehension strategies (Keene & Zimmermann, 1997) that are employed by the most capable of adult readers (Pressley & Afflerbach, 1995). Keene and Zimmermann (1997) reason that if teachers do not use such strategies themselves, they cannot understand them well enough to teach them, and will not recognize how much comprehension strategies can improve reading. Anecdotally, teachers who learn to teach comprehension strategies report that their own reading becomes much more active, and that they are much better comprehenders than they were previously (e.g., Pressley et al., 1992). A study needs to be conducted in which teachers are first taught how to be better comprehenders by using comprehension strategies, with the hypothesis being that learning to use comprehension strategies will enable and motivate them to teach the strategies use to their students.

Another hypothesis is that teaching comprehension strategies well is very difficult (Pressley & El-Dinary, 1997). Even teaching the individual strategies is challenging, for each is conceptually complex, requiring multiple operations to execute. For example, Williams (2003) and her colleagues (Taylor & Williams, 1983; Williams, Taylor, & Granger, 1981) have demonstrated how difficult it is to teach elementary and middle school students variations on gleaning the main idea from texts. More positively, Williams (2003) found that even students with learning disabilities get better with practice at identifying the big ideas in text. However, students with reading difficulties are at very high risk of including information in summaries of text that is tangential to the main ideas (Williams, 1993). In Williams' most recent work on the topic, students with learning disabilities have been taught to reflect on the answers to a series of

questions to identify the major themes of narrative texts they are reading (Wilder & Williams, 2001; Williams, Brown, Silverman, & de Cani, 1994; Williams et al., 2002). For example, while reading a story, these students respond to the following question prompts:

Who is the main character? What was his or her problem? What did he or she do? What happened? Was this good or bad? Why was this good or bad? The main character should have (or should not have) _____. We should (or should not) _____. The theme of the story is _____. To whom would the theme of this story apply? When would it apply? In what situation will this help or not?

In general, teaching children, including those with learning disabilities, to reflect on these questions has increased their abilities to identify main ideas in stories. The point is that it takes a lot of practice and very explicit instruction to teach children to use even one strategy so they can apply it while reading texts.

We are optimistic that comprehension strategies instruction will become much more frequent in schools in the near future. First, it is being promoted by the *No Child Left Behind* programs. Second, there are many more educational materials and associated professional development opportunities being presented to educators to increase their awareness and understanding of comprehension strategies instruction (e.g., Blachowicz & Ogle, 2001; Harvey & Goudvis, 2000). In addition, there is a cadre of researchers who are working very hard to increase both understanding of comprehension instruction (Block & Pressley, 2002) as well as how to translate new research ideas into instructional practice (Block, Gambrell, & Pressley, 2002).

Writing Strategies Instruction

Hayes and Flowers's (1980) analysis of skilled composing completely shifted the way that researchers and educators think about writing instruction. They documented that writers engage in extensive planning of what they write before they draft, followed by actual writing and revision. This is an on-going process for skilled writers in that planning, drafting, and revising inform one another. The result of this analysis has been a great deal of research on the consequences of teaching students to plan, draft, and revise. The need to do so is especially

great with children, because in the absence of such instruction, they write down the first ideas that come to their minds until they run out of ideas, which typically is shortly after starting to write (Graham, 1990; McCutchen, 1988; Scardamalia & Bereiter, 1986; Thomas, Englert, & Gregg, 1987). Therefore, children do very little planning and revising on their own.

In a more optimistic light, students respond well to writing strategies instruction. For example, Englert, Raphael, Anderson, Anthony, and Stevens (1991) taught fourth and fifth graders to plan their writing of expository text by thinking about and answering a set of questions: Who am I writing for? Why am I writing this? What do I know? (This question was a cue for brainstorming.) How can I group my ideas? How can I organize them (compare/contrast or problem/solution, explanatory or other text structure)?

As a second example, Graham's research group (De La Paz, Swanson, & Graham, 1998; Graham, 1997) successfully taught students with writing disabilities to revise. Students in grades 5 and 6 were taught to revise one sentence at a time, checking their own sentences against seven evaluative criteria: "This doesn't sound right," "This is not what I want to say," "This is not useful to my paper," "People may not understand this part," "People won't be interested in this part," "People won't buy this part," and "This is good." Then, they select one of five revision tactics to apply to the sentence: "Leave it the same," "Say more," "Leave this part out," "Change the wording," or, "Cross out and say it a different way." Grade 8 students were taught a slightly more complicated approach, involving two phases. The first phase focused on global concerns (i.e., not enough ideas, parts of the essay are not in the right order). The second part of revision focused on the local problems captured by the evaluative criteria and revision tactics covered previously.

Graham and his associates (1997, 1998) have generated a number of investigations intended to get elementary and middle school students, especially those considered to have writing or learning disabilities, to use strategies that promote effective planning, drafting, and revising in a self-regulated fashion. In these studies, the students are taught strategies by teachers who then work interactively with the students as they attempt to use the strategies during writing. The teachers model the strategies and discuss them with the students. Students memorize the steps of the strategies. The students

set goals for their writing (e.g., with respect to length) and are taught to monitor whether they have met the goals. The instruction is very individualized, and continues with teacher re-explanations and student practice until the student can carry out the strategies effectively on their own.

With 26 studies completed, the evidence is overwhelming that such instruction dramatically improves the writing of elementary and middle school students, including those with writing disabilities, regardless of the criteria employed to evaluate the writing. There have been consistent, large effects for self-regulated writing strategies instruction (Gersten & Baker, 2001; Graham & Harris, 2003). The positive effects are maintained over time and generalize to writing genres other than the training genre. The writing of elementary and middle school students can be improved substantially through cognitive strategies instruction.

Mathematical Problem Solving

There is no academic area with a longer history of cognitive strategies instruction than mathematical problem solving. Since the middle part of the twentieth century, mathematics students have implemented the principles of Polya's (1957) classic, *How to Solve It*, in which he recommends a four-part strategic approach to problem solving. These steps include understanding the problem, devising a plan to solve it, carrying out the plan, and looking back. In fact, there have been a number of successful demonstrations that teaching such an approach to elementary students improves their problem solving (see Burkell, Schneider, & Pressley, 1990). One of the best-known examples is Charles and Lester's (1984) true experimental evaluation of an instructional program based on these strategies that they conducted with fifth and seventh graders. Over the course of 23 weeks, they taught the students a variety of ways to carry out each of Polya's four steps. At the end of the experiment the students clearly benefited from the instruction. Montague and Bos (1986) devised an elaboration of Polya's approach that promoted problem solving in adolescent learners with mathematical learning disabilities. The students were taught the following steps: Read the problems, paraphrase, graphically display known and unknown information, state known and unknown information, hypothesize solution methods, estimate answers, calculate answers, and check answers. There was

clear improvement in the students' problem solving as a function of learning and using the problem solving strategies. When all of the data are considered (and there are hundreds of studies evaluating the effects of teaching Polya-like strategies), teaching the strategies has greater impact on older students than elementary-age learners (Hembree, 1992), with the effect size increasing from a small benefit in the elementary and middle school years to a large effect in the high school years. The impact on the problem solving of college students is moderate.

A group at Vanderbilt University has been successful, however, in developing mathematical problem solving strategies instruction that seems to have greater impact on elementary students, including students who struggle to learn mathematics (for a review, see Fuchs & Fuchs, 2003). The goal in this work has been to teach third-grade students mathematical problem-solving strategies that transfer to situations other than the training context. That is, the goal is for students to be able to apply a learned strategy to problems encountered on standardized tests or other novel situations, even when the problem differs superficially in a number of ways from training problems. The Vanderbilt team has succeeded in obtaining such transfer in several well-designed true experiments.

First, the students in the Vanderbilt studies received substantial instruction and practice with the specific types of problems. For example, one type of problem they learned about has a "bag problem structure." Students were informed that each bag of something (e.g., candy) had so many pieces. They were required to figure out how many bags would be required to obtain N pieces. The instruction was intended to develop a problem schema (Gick & Holyoak, 1983; Mayer, 1982), so that students recognized "bag problems" quickly and applied the correct problem solving approach (i.e., dividing N by the number of pieces in a single bag and rounding up to a whole bag; for example, for 32 pieces of candy with 10 pieces to a bag, four bags are required). Students worked cooperatively to practice solving problems consistent with the schema.

In addition to learning problem schema and associated solutions, teachers taught students the concept of transfer, for example by pointing out that babies first learn to drink from a toddler cup and then transfer their drinking skills to a real cup and eventually to a soda pop bottle. Transfer instruction also included information

about superficial ways that problems can change. Thus, the format of the problem can change (e.g., multiple choice rather than short answer, information can be presented in graphics rather than text). Key words can change (e.g., rather than "bag," the word "package" might be used). The problem can ask an additional question (e.g., "If each bag of candy cost \$4, how much money will you spend?"). The problem can be put in a larger problem solving context, with additional details to consider (e.g., "You have \$37 and your friend has \$12. . . . You also buy a hat that costs \$15").

This instruction positively affected students' problem solving, especially when the problems were more similar to training problems (Fuchs et al., 2003b). Nonetheless, there was a clear effect of learning the problem-solving strategies even on the far transfer problems that differed substantially in superficial appearance from training problems (i.e., they differed with respect to all four aspects of superficiality as well as some other novel features). In general, the complete problem-solving instruction (i.e., instruction which included lots of practice and the most explicit emphasis on transfer) produced benefits for third graders of all abilities, including students with mathematical learning disabilities.

Fuchs and colleagues (2003a) evaluated whether problem-solving instruction might be more potent with students in third grade if instruction emphasized using the strategies in a more self-regulated fashion. The enriched treatment included more instruction about general strategic tactics during problem solving such as making sure answers make sense, lining up numbers correctly to do math operations, and checking computations. To promote self-regulation, students were taught to score their problem-solution attempts using an answer key that credited both completeness of the problem-solving process and obtaining the correct answer. Then, students charted how well they did on the problem. Before the next session, students reviewed their charted scores and set a goal of doing better than previously. In addition, students scored homework with respect to process and outcome, and reported to the class how they were transferring the problem-solving strategies they were learning across the school day. Both homework performance and reports of transfer were charted by the class as a whole. In short, self-regulation was encouraged by lots of goal setting and reflection on whether goals (including transfer) were obtained.

In general, the most complete condition produced greater transfer than occurred in the other conditions. However, there was much room for additional far transfer by the students. It was still impressive that both average-achieving and low-achieving math students who received the transfer and self-regulation instruction solved more than twice as many far transfer problems than control participants who did not receive the problem-solving instruction. The fairest reading of the data across Fuchs's group (2003a, 2003b) studies is that they are making clear progress in understanding how to teach mathematical problem-solving strategies to elementary students with the goal of students being able to broadly apply the strategies (i.e., to transfer problems, including those differing in many ways from problems experienced during instruction).

Scientific Reasoning, Argument Skills, and Strategies

Inhelder and Piaget (1958) hypothesized that scientific thinking is not possible until adolescents reach formal operations. Thus, if adolescents are given a large basket of balls differing in size (i.e., large or small), color (i.e., dark or light), surface texture (i.e., smooth or rough), and ridging (i.e., ridged, not ridged) and are asked to figure out what features determine whether a ball can be served accurately (presumably when hit with a racket or paddle), it would be expected that they could do such an analysis, whereas, according to Piaget's theory children would not be able to successfully complete the task. The adolescents would know how to do controlled comparisons by testing balls differing in single characteristics to evaluate the effects of the characteristics on servability. For example, serving a large ball and a small ball, both of which were also dark, smooth, and ridged, would provide information about the effect of size. Such an approach is an example of a controlled comparison strategy.

Kuhn et al. (1988) did work that revealed much about children and young adults' use of the scientific strategy of making controlled comparisons. Specifically, they carried out studies where they presented students in third grade through college with sets of balls that either did or did not serve well. The researchers asked the participants questions as they considered the sets of balls and attempted to figure out which features mattered in determining servability. Kuhn and associates also carried out versions of the study where they asked students

to generate evidence to figure out what determined servability (e.g., for example, asked which of the sixteen possible balls might be compared to provide definitive evidence on whether size makes a difference in servability).

These researchers found that the participants had a great deal of difficulty addressing such problems. For example, they overemphasized evidence consistent with their pet theories of variables affecting servability and they underemphasized evidence inconsistent with their favored positions. Although there was improvement in working with the evidence and drawing conclusions with increasing grade level, even adults struggled with such problems. There was a great deal of support in the study for Piaget and Inhelder's insight that children do not use a control of variables strategy. More positively, consistent with Piagetian expectations, with increasing age, there was more use of the control of variables strategy. However, even the college students fell far short of the ideal of a completely rational experimenter who systematically makes all the paired comparisons that can be revealing about the variables under consideration.

Kuhn (1991) extended her work to the development of argument skills by asking teens to generate arguments about important social problems: What causes prisoners to return to crime when they are released? What causes children to fail in school? What causes unemployment? Rather than recognizing that there are no absolute right or wrong answers to these questions, most of the participants had strong opinions that they felt were correct. Although they recognized that there are contrary perspectives, they had difficulty creating counterarguments to their own beliefs, which is a classic argumentative strategy. They also had difficulty rebutting counters to their own positions, another important argument strategy. In short, the teens in Kuhn's (1991) study did not seem to argue well. They did not use the argument strategies used by those highly skilled in argument.

Kuhn's results (see Kuhn, 2002a, 2002b, for a more complete discussion of all of the evidence produced by her group) were consistent with results produced in the 1970s and 1980s suggesting that children and adults often do not think in a completely rational or scientific way (e.g., Baron & Sternberg, 1987; Perkins, Lochhead, & Bishop, 1987). They do not use important controlled comparison and argument skills, the kinds of skills presumably required to function well in the modern, scientific world. More positively, Kuhn's group (1988, Study 5; also, Kuhn & Phelps, 1982) provided evidence that at

least some students in the upper elementary level can acquire such strategies, if, while they are attempting scientific problem solving, they receive some hints from scaffolding adults about aspects of problems they should notice and how they could interpret the evidence.

A variety of educators in addition to Kuhn devised instructional programs to support the development of control of variables, argumentation, and other scientific thinking skills and strategies in response to the finding that critical and scientific thinking strategies are underdeveloped in students. For the most part, the early work on teaching such skills produced few convincing outcomes. When there were positive effects at all, they seemed small relative to the efforts required to produce them, and often failed to generalize beyond the training situation (for detailed reviews, see Chipman, Segal, & Glaser, 1985; Segal, Chipman, & Glaser, 1985). Over time, however, this picture has changed as a number of investigators have reported success in fostering higher-order thinking strategies using a range of methods (see Kuhn & Franklin, Chapter 22, this *Handbook*, this volume, for further description).

In the 1980s and early 1990s researchers interested in strategies hypothesized that students might develop or discover such strategies (e.g., making controlled comparisons) as they attempted to solve problems as part of well structured, adult supported exploration. In a problem-driven classroom such as this, the teacher monitors student interactions and learning, and scaffolds instruction by providing the hints and supports required for students to make progress (Wood et al., 1976). Student collaborative efforts were also considered important as part of effective instruction, with such interactions requiring students to evaluate the problem solutions they devised, including constructing argumentative defenses of their solutions (Champagne & Bunce, 1991). Science educators were impressed by both Vygotskian (e.g., Rogoff, 1990, 1998; Vygotsky, 1978) and Piagetian (e.g., Damon, 1990; Enright, Lapsley, & Levy, 1983; Furth, 1992; Furth & Kane, 1992; Kruger, 1993; Youniss & Damon, 1992) theoretical and empirical analyses that peer discussions promoted cognitive growth and improving reasoning skills.

This conception of learning became prominent in science education following analyses of effective science instruction characterized by teacher-supported, collaborative student problem solving. Effective science teachers scaffolded their students as they worked on scientific problems cooperatively. Students in these classrooms

discussed and argued about alternative ways of thinking about the problems and generated a variety of solutions to scientific problems (Garnett & Tobin, 1988; Tobin & Fraser, 1990; Treagust, 1991). Researchers have validated the finding through observational studies that collaborative problem solving in classrooms seemed to stimulate students to think more and better (i.e., making better arguments) than occurred during more conventional instruction (e.g., Amigues, 1988; Brown & Campione, 1990; Hatano & Inagaki, 1991; Newman, Griffin, & Cole, 1989; Pizzini & Shepardson, 1992). Also, research in this area supports the discovery that problem-solving skills (e.g., making controlled comparisons) develop more certainly in classrooms taught by teachers who are skilled in scaffolding student experimentation and collaborative problem solving (for a review of data and thinking from that era, see Glynn & Duit, 1995; Glynn, Yeany, & Britton, 1991).

There were also teachers who were not so skilled with such instruction but attempted to do it anyway. Unfortunately, but not surprisingly the outcomes were not as attractive in their settings. For example, it is very easy for individual students to dominate collaborative problem solving and discussions in such classrooms. As a result, other students do very little work or thinking (e.g., Gayford, 1989; Hogan, Nastasi, & Pressley, 2000; Hogan & Pressley, 1997). Worse yet, sometimes the students who dominate the interactions lead their fellow students astray, with fellow students following the lead since they do not know enough about the topic to recognize the inaccurate thinking being offered up by the student leader (Basili & Sanford, 1991).

Once again, Kuhn and her colleagues carried out revealing studies about this possibility. They demonstrated that peer discussions about complicated and controversial issues can promote cognitive growth. Kuhn, Shaw, and Felton (1997) had students in seventh and eighth grade and community college students engage in five dyadic conversations with peers about the merits of capital punishment. Each conversation occurred with a different partner, so that the points of view and subsequent conversations varied from occasion to occasion. Control participants experienced the same pretests and posttests as the dyadic-conversation condition participants but did not participate in conversations. Compared to the control participants, the dyadic-conversations participants improved their argument skills from pretest to posttest. Participating in the dyadic conversations increased the number of arguments a participant offered

on the posttest, the variety of arguments (e.g., offering arguments on both sides of the issue), and the sophistication of the arguments.

Kuhn and Udell (2003) studied argument skills in inner-city students in seventh and eighth grades in another true experiment. Both students who favored and opposed capital punishment were led to believe that they needed to prepare for a showdown debate on the issue. The control participants in the study (with both positions represented) experienced some dyadic practice in arguing about capital punishment, and worked with peers in the context of adult scaffolding, to generate and refine arguments in favor of their position on capital punishment. Participants in the experimental condition, again including students who favored and students who opposed capital punishment, received the same dyadic practice as controls but also participated in scaffolded, dyadic practice generating counterarguments to criticisms of their position, where they focused on rebuttals of opposing positions. These dyadic experiences in the experimental condition also provided opportunities to think and reason about mixed evidence.

Kuhn and Udell's treatment participants evidenced growth in argument from pretest to posttest, more than control participants. Particularly, they improved in making counterarguments with respect to the position on capital punishment that they opposed. The treatment participants also increased their knowledge of the topic of capital punishment as a function of the dyadic experiences in generating counterarguments. For evidence from another research group that children's argument skills improve with opportunities to practice argument, see recent work by Richard C. Anderson and his colleagues in the area of reading (Clark et al., 2003). In conclusion, children can acquire scientific thinking and argument strategies by experiencing such problems, at least when a more knowledgeable adult monitors student thinking efforts and arguments, and offers hints and general support to keep thinking and arguments on track.

A primary methodology used in Kuhn's work has been the microgenetic method. This methodology involves careful monitoring and analyses of changes in problem solving and reasoning as a function of practice (see Siegler, Chapter 11, this *Handbook*, this volume, for more detailed description of this approach). Basically, while performance improves in scientific reasoning and argument skills with practice and reflection, there is also a great deal of variability from trial to trial. Stu-

dents normally employ a mix of strategies, with the particular mix varying from trial to trial, depending somewhat on the problem and the success of first attempts to solve it (e.g., Kuhn, 1995; Kuhn, Garcia-Mila, Zohar, & Andersen, 1995). Instead of learning to problem solve and argue following a rigid strategic procedure, participants learn by practicing how to size up problems and flexibly make decisions to improve problem solving. For example, in the work on argument about capital punishment, the participants reasoned differently from trial to trial, responding to the particular issues raised by the partner in the dyadic interaction.

Conclusions

Children often do not use the strategies required to accomplish important academic tasks, such as reading, writing, mathematical and scientific problem solving, and argumentation, unless they are taught (or learn through discovery) strategies for doing so. In the past quarter century when researchers have taught children strategies matched to the demands of academic tasks and have provided scaffolded practice, they have consistently improved children's academic thinking and performances. Frequently, the effects of academic strategies instruction have been large. Researchers have obtained the most striking effects when they teach students to use a repertoire of strategies in a self-regulated fashion. Although academic strategies researchers have focused more on academically at-risk students, a broad range of elementary, middle school, and high school students seem able to learn and use strategies.

In recent years, our work has involved many observations of primary grade classrooms (e.g., Pressley, Allington, Wharton-McDonald, Block, & Morrow, 2001; Pressley et al., 2003), although this past year was spent in middle schools and a high school environment (e.g., Pressley, Raphael, Gallagher, & DiBella, 2004). What strikes us as we reflect on those experiences is that when we have observed academic strategies instruction, or problem solving and argument practice in schools, it usually has been much less complete and intense than the instruction and practice situations considered in this section. Given the clear need to improve reading, writing, mathematical, scientific problem-solving and argument skills (see the *National Assessment of Educational Progress*), it seems to us that it is time for the educator community to take the interventions re-

viewed in this section more seriously. We suggest using this work as a guide for restructuring education so that students are given more opportunities to learn the strategies that are used by excellent readers, writers, problem solvers, and rhetoricians.

CONCLUDING REFLECTIONS ON STRATEGIES DEVELOPMENT

There have been 4 decades of serious research by developmentally oriented scholars about children's use of strategies to accomplish intellectual tasks. As a consequence, much is now known about the development of strategic competence, with evidence produced in both basic and applied areas of research. The field was enhanced by studying the development of both normal children and children with exceptionalities. We review here the most important conclusions that emerge from this work, and then reflect on issues that deserve more study.

What Is Known about the Development of Strategic Competence

Although preschoolers are production deficient when given tasks that are very unfamiliar to them, preschoolers definitely can be strategic in familiar situations. Even 2-year-olds can demonstrate the use of simple memory strategies! For example, the children in DeLoache and colleague's (1985) study were definitely intentional as they looked and talked about the Big Bird doll when the goal was to remember where Big Bird was hidden. We now know that by the later preschool years, children often have several strategies that they can use when doing familiar tasks. As an example, when Siegler and Robinson (1982) asked 4- and 5-year-olds to add small numbers ($1 + 3$, $3 + 2$, $2 + 4$), they observed that sometimes children relied on their memories (i.e., they knew the answer), sometimes they counted on their fingers, sometimes they used their fingers but did not count aloud, and sometimes they just counted aloud without using their fingers.

Although the classical memory development researchers tended to focus on single strategies such as rehearsal for recall of lists of nonrelated items, categorization for lists of related items, elaboration for paired associations, there are typically multiple strategies that

can be deployed in a task situation such as those studied in the classical memory development studies. For example, there are a number of strategies that children can implement to attempt to learn paired associates. These strategies include simply saying the pairings once, saying pairings over and over, constructing verbal elaborations (i.e., embedding paired words or objects in sentences or stories), and constructing interactive images (e.g., imagining the referents of paired words or objects in interactive images). In fact, children often use different strategies over the course of learning a number of pairings (Pressley & Levin, 1977). The general point is that there are now numerous demonstrations that diversity in strategy use is more the norm than the exception. Many children have and use diverse strategies for various types of problem solving, different aspects of reading, and both the lower-order (e.g., spelling) and higher-order (e.g., revising) components in writing. Some of the strategies that children use are less effective than others. Therefore, one source of inefficiency is that children will sometimes mix effective and ineffective strategies rather than simply using the most efficient and effective approach to a task.

The evidence is overwhelming that many strategies production deficiencies can be overcome if children are provided with strategies instruction. This is an important point since strategy production deficiencies are very common throughout childhood and into adulthood (e.g., even many adult readers are not nearly as strategically active as the best adult readers). Such production deficiencies are more prevalent in populations at risk for failing to achieve (e.g., very young children, children with mental retardation, students with learning disabilities). There have been many examples summarized in this chapter of strategies that can be taught to a wide range of children.

The early work on memory strategies instruction, going back to Flavell's pioneering efforts, involved little more than telling the child what process to execute and having them do it. Such an approach produced little enduring change since students did not continue to use the memory strategies taught, even in situations very similar to the teaching situation. Over the years, strategies instruction became more complex, as it has been informed by basic theoretical analyses of cognitive strategic functioning, especially in the area of memory strategies. Thus, contemporary instruction takes into account all of the cognitive components that interact

with and determine strategic functioning. Such instruction has the following characteristics:

- Students are taught the strategies used by capable thinkers to accomplish tasks, often a repertoire of a few strategies that are used in coordination.
- Instruction begins with explanations and modeling of strategies. Teachers then provide supported practice of the strategies being learned. Practice continues until the students can carry out the procedures efficiently (i.e., using much less conscious capacity than when they first attempt the strategies). When a strategy can be carried out efficiently, it frees up conscious capacity that can be used to articulate the execution of the strategy with other components.
- Strategy practice often continues for a long time in order to get to the point that the strategy can be implemented with little effort. This permits opportunities for participants to apply the strategies being learned to a variety of materials and in a variety of situations. It also allows students opportunities to discover important metacognitive information, including where and when to use the strategies being learned and how to adapt the strategies to a variety of situations. Such metacognitive knowledge about strategies is essential if the learner is to continue using the strategies, both in situations where they were trained and new situations where the strategies are potentially applicable (Pressley, Borkowski, & O'Sullivan, 1984, 1985).
- Many strategies depend on the learner's world knowledge, with use of relevant prior knowledge encouraged as part of strategies execution. If students are able to get by without using a strategy because of a well-developed knowledge base, use of the knowledge base is encouraged. Thus, the child who knows a word by sight is not encouraged to sound out the word. A child who knows a math problem (e.g., $7 - 3 + ?$) as a fact is not encouraged to compute the answer. Encouraging reliance on prior knowledge when it is available is important because strategies execution is short-term capacity demanding. The less cognitive capacity eaten up by unnecessary strategies execution, the more capacity left over for necessary strategies execution and coordination with other cognitive components.
- The most extensive contemporary cognitive strategies instruction is designed to promote long-term,

self-regulated use of the strategies, by including metacognitive information in instruction. This includes information about when and where to use the strategies, as well as instruction to monitor the effectiveness of strategies. It also includes motivational information about the positive effects produced by the strategy, and reflections on performance before and after strategy use. There is clear expectation that students should attempt to transfer the strategies they are learning.

Although many children need instruction of at least some strategies, many children also discover many strategies on their own. Much has been learned about how they do so. A popular analytical strategy in this work has been the microgenetic design, where participants experience many trials doing a type of task with their strategies use and performances across trials analyzed (Siegler, Chapter 11, this *Handbook*, this volume). For example, the research of Kuhn and of Anderson, and their respective associates has focused on how argument strategies and skills improve as a function of arguing. Kuhn and her associates have also been studying how scientific reasoning strategies shift with practice. These studies make clear that while upper-elementary students shift their strategies use as they work and reflect on scientific problems requiring inductive reasoning (Kuhn & Pearsall, 1998, 2000; Pearsall, 1999), their initial use of strategies does not always produce great benefit. This finding is reminiscent of the utilization deficiencies reported sometimes in basic memory situations (e.g., Miller & Seier, 1994). Moreover, use of potentially efficient strategies is variable, with trial-to-trial changes in strategies deployment often observed in microgenetic studies.

It is not surprising that students' progress in using potentially potent strategies is often variable and not always beneficial. One of the most robust findings in the metamemory literature is that strategy use greatly depends on the understanding that the strategy produces performance advantage. This finding has been established in a number of very well-designed experiments carried out in the 1970s and early 1980s (Pressley, Borkowski, & O'Sullivan, 1984, 1985). When learners experience the advantages produced by a strategy, it can heighten their commitment to using the strategy in the future. This finding was also established in well-controlled experiments (Pressley, Levin, & Ghatala, 1984).

That is, when learners discover a strategy is effective, that discovery makes a difference in future use of strategies. Learner discoveries make a difference in strategy acquisition.

In short, there is growing evidence that effective strategies instruction requires development and articulation of a number of cognitive components. This contrasts with hypotheses of the past that focused on single factors in thinking and learning. Some of these hypotheses present significant challenges to the idea that teaching strategies should be emphasized at all. One version of this argument holds that thinking is much more about applying nonstrategic prior knowledge to tasks than using strategies (Anderson & Pearson, 1984; Chi, 1978). This emphasis on prior knowledge as the prime mover in thinking has given way to the understanding that world knowledge and strategies seem to work in concert in powerful thinking, whether the learner is faced with a memory task (Pressley, Borkowski, & Schneider, 1987) or the academic tasks common in school, from problem-solving (e.g., Schoenfeld, 1985, 1987, 1992), to reading (Pressley & Afflerbach, 1995) to writing (Flower, 1998).

Another long-held belief is that somehow discovery learning and discovery of strategies, in particular, result in better learning and more complete understanding than other approaches (e.g., Kohlberg & Mayer, 1972). This is so despite a very long history of discovery approaches producing less complete learning and understanding than more direct teaching (e.g., Mayer, 2004; Shulman & Keislar, 1966). That said, children can and probably do learn many important skills through discovery (e.g., Siegler, 1996). It is certainly possible to devise guided discovery situations where students are encouraged to reflect on their successes and failures as they work in a domain. This has occurred in some of the situations Kuhn (2002a, 2002b) and others have studied (Lehrer & Schauble, 2000). Good discovery learning occurs as children interact with each other, parents, and other cultural elements as they live and develop in the world (Rogoff, 2003).

The people in children's worlds may provide them with a great deal of metacognitive input by providing instruction about where and when to use skills, as well as how to adapt strategies and skills children have and are acquiring. Calls for direct instruction of strategies and skills with minimal metacognitive embellishment persist (Adams & Carnine, 2003) in spite of well-con-

trolled demonstrations that metacognitive-promoting instruction increases the effectiveness of strategies instruction (e.g., Elliott-Faust & Pressley, 1986; O'Sullivan & Pressley, 1984). A positive outgrowth of this debate is strategies instruction, and teaching in general, that combines direct instruction with metacognitive embellishment through explanations and teacher-scaffolded opportunities for students to practice strategies during real problem-solving, reading, and writing (e.g., Duffy, 2003).

In short, there are some extreme positions about the role of strategies and prior knowledge in thinking, as well as extreme positions about how to do strategies instruction (i.e., focusing only on the strategies without concern for prior knowledge or metacognitive information about when and where to use strategies), complemented by extreme positions about leaving strategies to the child's discovery. In contrast, we emphasize that more balanced views have developed as research on strategies instruction has continued over the past 4 decades. We have made the case that the most effective strategies instruction includes direct explanation and modeling of strategies, provision of metacognitive information, opportunities to discover strategies during practice, efforts to motivate strategy use by assuring students experience benefits from strategy use, and emphasis on the mixing of strategies use and prior knowledge in solving problems, reading, and writing (see Alexander, Graham, & Harris, 1998).

Much Remains to Be Learned about Strategies Instruction

The formal scientific evidence is growing that supports our claim that children can be taught cognitive strategies that serve important academic competencies in ways that result in self-regulated, long-term use, and transfer of the strategies. The effects of strategies instruction are often quite large. This provides plenty of motivation for additional work on cognitive strategies instruction in the K-12 curricula. Also, the work of Deshler and his colleagues (Deshler, Ellis, & Lenz, 1996), as well as others who have provided cognitive strategies instruction to disadvantaged learners, is inspiring. Their research and applications have affected hundreds of thousands of students with learning disabilities. These successful educational efforts have been developed through clinical efforts that greatly resemble

the instruction developed by the meticulously careful research community. As we reflect on their implementation successes to date, we think that an important research direction is determining how to disseminate such instruction more broadly, as well as to identify parts of the curriculum that might still be addressed by strategies instruction that could be developed in the future.

A great strength of the strategies literature is that much of it has been very analytical, producing nontrivial, not-always-obvious understandings about how strategies function and develop. Still, as we read this literature, again and again, we found ourselves wanting more. For example, Kuhn's (2002a) conception of strategy growth through discovery and reflection prompted us to think hard about a number of issues. Kuhn posits that as a child works in a problem domain, she or he has initial theories about what might work to achieve the goal of solving the problem. The learner tries the strategy or strategies that are initially hypothesized to work, noting whether the problem was solved, perhaps experiencing peer or adult responses to the problem-solving attempt and outcome it produced. This experience with feedback increases understanding of the situation, perhaps resulting in a new understanding about the strategies tried, or even insights about new strategies that might be applied to the situation. These new understandings inform subsequent attempts to perform the task, with additional outcomes and feedback increasing understanding further. Over a number of trials gradual increases in strategic knowledge and understanding of the task situation take place.

As we contemplated Kuhn's work, we found ourselves wanting additional research detailing more of the strategies discovered, as well as the meta-cognitive understandings that are constructed by students. We also found ourselves wanting to know just how strategic and metacognitive components interact. We were intrigued that Kuhn is finding evidence for utilization deficiencies. We wonder why participants produce strategies that seem like they should work in the situation, but do not. As theorists and researchers interested in instruction, we also wondered what might happen if more teaching occurred as the children experimented. We assume their strategy and metacognitive growth would be accelerated, but is there a downside to such learning through teaching compared to discovery? In short, as we reflected on this contribution, we found ourselves wanting to know much more about strategies—more about strategy functioning, strategy development, develop-

ment of metacognition about strategies, and strategies instruction through discovery. We add that we experienced this sense of only scratching the surface of strategies functioning and development at many points during the writing of this chapter. We hope this chapter will serve as an invitation to researchers to think about doing more work on strategies and their development. The research successes to date make clear that this is an area that can be illuminated by research. It takes little time with this literature to recognize there are many additional paths that could be followed that might lead to substantial theoretical and pragmatic understandings about how children can learn how to tackle many tasks in their world more efficiently and effectively through invention and use of strategies.

Given the importance of the academic tasks that have been studied by contemporary researchers interested in strategies instruction, we do not expect a massive exodus from study of problem solving, scientific reasoning, argument, reading, or writing in favor of a return to basic work on memory. That said, we are impressed that virtually all of these academic tasks include memory components. However, this research includes little to no study about how memory functions in these domains, or how learners might be taught so that they make the best use of their limited short-term capacity and seemingly unlimited long-term capacity (i.e., their world knowledge). For example, consider what happened when Graham (1990) prompted elementary students with writing disabilities to search their long-term memories for more information to include in essays they were writing. He found that the length and quality of the essays improved. We suspect there are many other ways in which an improved use of memory might contribute to students' academic achievements and development. Researchers who want to continue to study memory might find it exciting to conduct their work in the context of more authentic academic tasks than the memory tasks that predominated in the 1960s and 1970s. Such work has the potential for success to do much to improve the education of children, including many with intellectual disabilities. That memory strategies instruction all but disappeared in the past decade and a half does not mean it cannot reappear. It seems especially appropriate to develop a new generation of memory strategies development work as part of the development of strategies instruction that serves the needs of children as they tackle the academic demands that people ages three through adulthood face. If, as Kuhn suggested, memory development is on the

endangered topics list, we think it time that researchers rise to the challenge of getting it off the list and back in the major journals (albeit in a form enriched by what we now know about cognitive development) and on the minds of everyone who is concerned with improving children's cognitive performances.

In this chapter, we first consider basic properties of reasoning and problem solving; then we briefly survey the way our conceptions of reasoning have developed over the past few decades. Next, we review the research on children's reasoning from the perspective of current knowledge of the domain. This will include analyses of the underlying cognitive processes. We will also look for coherence in the field, such as common processes that occur in tasks that otherwise appear to be different, or principles and theories that provide parsimonious explanations for relatively diverse phenomena. In pursuit of

these aims, we review some topics in historical depth to show the important underlying factors.

CHARACTERISTICS OF REASONING AND PROBLEM SOLVING

To our knowledge, no generally accepted definition of reasoning or problem solving exists, and the distinction between them is also somewhat fuzzy. We will not attempt a formal definition; however, we note that reasoning entails operating on internal, cognitive representations of segments of the world, the goal being to yield decisions and actions that are adaptive in the person's environment. We discuss other properties as they become relevant to the research we review, but first we consider current conceptions of reasoning and see that

We would like to express our sincere thanks to Tracey Zielinski and Tarrant Cummins for their valuable help in preparing this chapter.

they have undergone major changes in the past few decades.

Origins of Current Conceptions of Reasoning

Our present knowledge about children's thinking is partly the result of the way conceptions of human reasoning in general have evolved. Pioneering work in children's reasoning was dominated by Piaget and his collaborators (Inhelder & Piaget, 1958, 1964; Piaget, 1950, 1952, 1953, 1957, 1970) whose approach was based on psycho-logic. This approach has been heavily criticized (Bjorklund, 1997; Gopnik, 1996) although there have been some spirited defenses of the Piagetian tradition (Beilin, 1992; Lourenco & Machado, 1996), as well as a recent review of Piagetian research and logical reasoning (Smith, 2002), and there are signs that constructivism, one of Piaget's main tenets, is still alive and well (Bryant, 2002; Johnson, 2003; Quartz & Sejnowski, 1997). Nevertheless, our conception of human reasoning has undergone some fundamental changes that must be taken into account in any review of the topic.

Perhaps the most important change for our understanding of children's thinking is that it is no longer considered necessarily appropriate to use logic as a norm for correct reasoning or as a model of reasoning processes. When either children or adults make what appears to be a fallacious inference, it might be because their representation of the problem differs from the one assumed by the experimenter. The inference "if p then q , q , therefore p " is a fallacy (affirmation of the consequent) in standard logic, but it might be a rational deduction if the conditional "if p then q ," were interpreted as the biconditional (if p then q and if q then p). Studies of children's understanding of logical connectives "if then" and "or" show that they are interpreted in a way that is appropriate to everyday life and that there are systematic departures from standard logical definitions (Evans, Newstead, & Byrne, 1993; Halford, 1982). Consequently, we cannot conclude there is a lack of rationality solely because some answers do not match the norms of logical reasoning.

An alternative basis for assessing human reasoning is the rational analysis criterion (Anderson, 1990, 1991), which judges rationality by the way a particular behavior promotes the adaptation of the organism to its environment. A useful example is the way decisions are based on heuristics, such as availability in memory (Tversky & Kahneman, 1973). Such heuristics lead to

some well-known cognitive illusions, but do not imply lack of rationality (Cohen, 1981). Availability in memory is often a useful guide to the frequency with which items occur in the world, and only gives illusory frequencies in circumscribed conditions. Therefore, it is adaptive to use availability in predicting events.

There is sometimes a conflict between the logical interpretation of an expression and a pragmatic interpretation based on conversational implicatures (Grice, 1975). Thus *some* might be interpreted logically as "some or all," but in conversational pragmatics, it is more likely to mean "some but not all." In everyday life, it is frequently adaptive to apply conversational pragmatics instead of standard logic, and children's reasoning in test situations reflects these adaptive processes.

The reconceptualization of reasoning processes means that we no longer see reasoning as an application of the laws of logic, but as an emergent property of more fundamental processes. Production system models (Klahr & Wallace, 1976; Simon & Klahr, 1995) neural net models (Elman, 1991; Marcus, 2001; McClelland, 1995; Wilson, Halford, Gray, & Phillips, 2001) and dynamic systems models (Elman et al., 1996; Molenaar, Huizenga, & Nesselroade, 2003; van Geert, 1998) have all provided possible mechanisms that could underlie reasoning. These alternative approaches are reviewed by Halford (2005). We consider reasoning processes for each of the tasks we review.

Domain Specificity versus Generality

Cognitive processes are frequently argued to be domain-specific rather than domain-general (Carey, 1985), or to be performed by specialized modules (Cosmides & Tooby, 1992; Fodor, 1983). There is also an intermediate position, according to which reasoning is based on pragmatic reasoning schemas of general validity induced from life experience (Cheng & Holyoak, 1985). Permission and obligation are pragmatic reasoning schemas, and their use in reasoning tasks such as the Wason selection task has yielded improved performance. Specialized reasoning processes are sometimes regarded as innate, supporting evidence being that understanding the distinction between artifacts and natural kinds (Keil, 1991), or understanding that animals move autonomously, have blood, and can die (Gelman, 1990; Keil, 1995), occur at a very early age. These findings are reflected in an increasing biological perspective

in cognitive development (Kenrick, 2001) and imply a high degree of innate specialization in reasoning.

There are also strong defenses of domain-general processes (Hatano & Inagaki, 2000; Kuhn, 2001; Kuhn, Schauble, & Garcia-Mila, 1992). It can be argued that there must be central executive processes (Baddeley, 1996) that have a coordinating function, and processes such as analogical reasoning tend to create correspondences between thinking in different domains.

Methods of Analysis of Cognitive Processes

A major change in research of both general cognition and cognitive development, beginning around 1960, was a greatly increased emphasis on detailed analysis of cognitive processes. This yielded new methodologies, and also much more detailed conceptualizations of reasoning processes. These will be two of the major themes in the review that follows.

One of the most important methods was rule assessment (Briars & Siegler, 1984; Siegler, 1981) which consisted of defining each cognitive process, or strategy, as represented by a unique pattern of responses. Doing so permitted precise and objective assessment of cognitive processes underlying each task, so we could determine not only *what* children did, but *how* they did it. This advance enabled cognitive development researchers to take the fundamentally important step from observing behavior to inferring the cognition that underlies the behavior.

An alternative method of analysis is information integration theory, which is designed to study the way an individual combines variables to estimate the value of a composite variable. It has been applied to children's understanding that $\text{Area} = \text{Length} \times \text{Breadth}$ (Anderson & Cuneo, 1978; Wilkening, 1980). Children are shown rectangular shapes that vary in both length and breadth and are asked to estimate their area. Each child's area estimates are subject to analysis of variance to determine which variables have influenced their judgments and how they are combined. If the main effects only are significant, this means they have combined length and breadth additively, but if the interaction is significant and of the appropriate (diverging) form, this means the dimensions have been combined multiplicatively. The methodology has been applied to a wide variety of concepts including the balance scale (Surber & Gzesh, 1984), and volume (Halford, Brown, & Thompson, 1986). Rule assessment and information integration theory have a further benefit in that they permit analysis of

strategies used by individual children, which avoids the artifacts that can be caused by aggregation of data over qualitatively distinct performances (Siegler, 1987).

Microgenetic methods (Kuhn, 1995; Kuhn & Phelps, 1982; Siegler, 1995; Siegler & Jenkins, 1989) have proved effective for studying cognitive change in a wide range of domains, providing detailed information about strategies, including the way they develop and the factors that influence the development, as well as individual differences. An important finding from microgenetic studies is that children's strategies progress in overlapping waves, so they may have more than one strategy available at any one time, and development consists of strengthening some strategies rather than others. A study by Chen and Siegler (2000) is particularly relevant to early development of thinking. They analyzed strategies used by 1- to 3-year-old children to reach for an object using an appropriate tool. The children progressed through a succession of strategies over three problems. Improvement occurred mainly in the modeling condition (in which an appropriate response was demonstrated) and the hint condition (where the experimenter suggested the right tool to use), and was more rapid for the older children. There was transfer of strategies to new problems, as shown by tool use on the first trial of new problems, even though the tool was different from those on which the child had been trained. This suggests that transfer was based on structural correspondence between tasks, rather than on similarity of elements of the tasks, and is therefore a form of analogy (Gentner, 1983; Halford, Bain, Maybery, & Andrews, 1998). Detailed individual differences in strategies were observed, and proficiency in the immediately preceding component of a strategy was the best predictor of progression to the succeeding component.

In this study, strategy development was observed in a remarkably direct manner as it occurred. This not only provides important information about the processes of strategy development, but it means that we no longer need to regard strategies as sufficient explanation for cognitive performances, but can refer to the factors that influence the development of strategies.

Strategies in Reasoning

Advances in conceptions of how human reasoning functions have significantly changed the way we understand development of children's reasoning. Detailed models of

strategies have been developed, drawing on the empirical analyses previously reviewed. There are also new conceptions of reasoning based on theories of analogy, mental models, categorization, cognitive complexity, and the origins of reasoning in infancy and early childhood. These will be major themes in the analyses that follow.

Strategies are now recognized as fundamental to reasoning, and growth in children's repertoire of strategies is one of the major components in the development of reasoning (see Pressley & Hilden, Chapter 12; Siegler, Chapter 11, this *Handbook*, this volume; Siegler, 1999; Siegler & Chen, 1998).

Verbal Strategies

Vygotsky (1962) proposed that, while communication is the basic function of language, it later serves a representational function in problem solving, initially as private ("egocentric") speech, and later as inner speech. Winsler and Naglieri (2003) investigated use of overt or covert private speech in 5- to 17-year-olds during a Planned Connections Task, in which they drew lines between letters and numbers (similar to the Trail Making Task, Reitan, 1971). Use of verbal representation was relatively constant at about 60% over age, but there was a shift from overt to covert use of speech. The benefits obtained from speech also changed with age. Adolescents obtained no benefit, but the younger children of lower ability who used partially covert private speech performed better. It is possible that verbal representational strategies are beneficial where the task is difficult for the participants, and therefore a benefit might be observed for older participants with a more complex task. There have also been computational models of reasoning processes that we will consider in the context of the relevant domains.

Analogy appears to be fundamental to human reasoning (Hofstadter, 2001), which might be considered more analogical than logical (Halford, 1992). Mental models (Johnson-Laird & Byrne, 1991) and pragmatic reasoning schemas (Cheng & Holyoak, 1985) might be used as analogues of the premise information in a task (Halford, 1993). Analogies are also used in mathematics (Polya, 1954), in science (Dunbar, 2001) and in art, politics, and many other areas of life (Holyoak & Thagard, 1995). Analogy is also important in knowledge acquisition (Vosniadou, 1989). Concrete teaching aids, such as those used in school mathematics, are essentially ana-

logues (English & Halford, 1995). Analogy has been shown to be important even in early childhood (De-Loache, Miller, & Pierroutsakos, 1998; Goswami, 1991, 1992, 1996, 2001; Halford, 1993).

Analogy is a mapping from a base or source to a target (Gentner, 1983), where both source and target are defined as sets of relations. Typically, relations are mapped but attributes are not, and the mapping of relations is selective, based on systematicity, that is, those relations are mapped that enter into a coherent structure. The mapping is validated by structural correspondence between relations in source and relations in target. A number of contemporary models of analogical reasoning are presented by Gentner, Holyoak, and Kokinov (2001).

Much research has been devoted to simple proportional analogy of the form A:B::C:D (e.g., horse:foal::cat:kitten). Performance on these analogies was found to improve when care was taken to ensure that children had the requisite knowledge of relations (Goswami & Brown, 1989). Thus 4-year-old children could understand the analogy between melting chocolate and melting snowmen (Goswami, 1991) because the relations between solid and melted chocolate, or between solid and melted snowmen, were familiar to them. Relational complexity theory (Halford, Wilson, & Phillips, 1998), to be reviewed later, predicts that if the requisite knowledge is available, 2-year-old children can perform proportional analogies, so even earlier success should be possible.

There is now a growing body of research into the uses of analogy in reasoning about content domains. Pauen and Wilkening (1997) found that 7- and 10-year-old children had some ability to understand the analogy between integration of weight and distance on the balance scale and integration of forces acting on two strings attached to an object. The use of graphs to represent functions also entails analogical mappings based on similarity of relations. This was investigated by Gattis (2002) with 6- to 7-year-olds. First they were taught to map single variables, such as quantity and time, to horizontal and vertical axes, then they were taught to integrate the mappings to provide a function line, the slope of which represented rate. Chen (2003) investigated how 3- to 5-year-olds used a picture analogy to solve a problem. Performance improved with age but even 3-year-olds succeeded if the difficulty of implementing the solution was reduced. If they conceptualized the infor-

mation in the source picture, they could transfer it to an analogous problem. While many studies have emphasized the analogical abilities of very young children and even infants (Chen, Sanchez, & Campbell, 1997) developmental effects continue to be observed, and are being analyzed in detail. Hosenfeld, van der Maas, and van den Boom (1997) found evidence of discontinuity in the analogical reasoning of 6- to 8-year-olds.

Mental Models and Analogy

It has been proposed that children's reasoning in tasks such as transitivity and class inclusion may be based, not on abstract principles of logic, but on mental models that are used as analogues (Halford, 1993). A transitive inference such as *John is taller than Mike; Peter is taller than John*, therefore *Peter is taller than Mike*, can be performed by mapping *Peter, John, Mike* into an ordering schema such as top-down or left-right. The ordering schema can be used as an analogue that represents the relations in the problem, and from which the inference can be easily read off. Similarly, a class inclusion problem can be performed by mapping into a familiar schema such as the family. A problem such as whether there are more apples or more fruit, can be performed by mapping the classes, fruit, apples, nonapples into family, parents, children, respectively. These processes are considered in more detail later.

Implicit versus Explicit Process

Clark and Karmiloff-Smith (1993) distinguish implicit knowledge, which is representation *in* the system, from explicit knowledge, which is representation *to* the system. Explicit knowledge is more accessible to other cognitive processes, and includes ability to modify strategies and procedures, without retraining.

Symbolic Processes in Reasoning

To serve the functions of thought, cognitive representations need to consist of symbols. Symbols are representations that have semantic referents. This is not true of all representations. Some of the representations in hidden units of neural net models do not have semantic referents (Smolensky, 1990). In addition, there must be some kind of system for operating on the symbols. Symbol systems need to have a structure that corresponds to the structure of some segment of the world or of the per-

son's environment (Halford & Wilson, 1980; Palmer, 1978; Suppes & Zinnes, 1963). Fodor and Pylyshyn (1988) defined two further properties needed by symbolic systems. They are compositionality and systematicity.

Compositionality means that, when elements are composed or combined, the components retain their identity and their meaning in the composition. So if we combine "happy" and "dog," we have "happy dog" but the components are still recoverable. We can ask: "What is the emotional state of that dog?" and the answer is "happy" or: "What is it that is happy?" and the answer is "dog." Furthermore, "happy" and "dog" mean the same (at least approximately) in the composition as when they are separate. This is not true of all representations. Some of the representations in certain types of neural net models have been criticized because they are not compositional, and the same is arguably true of categories based on prototypes.

Systematicity means that propositions can be generalized on the basis of form, independent of content. In its most absolute sense, it would mean generalization to all logically equivalent forms, but this is now recognized as psychologically unrealistic due to the well-established effects of content on human reasoning (Van Gelder & Niklasson, 1994). A more realistic interpretation of systematicity would be that if we understand a sentence with a particular form, we can understand novel sentences of a similar form. If we understand that John loves Mary, then in principle we can understand that Peter loves Jenny, Mary loves John, and so on. Systematicity is important to our ability to generate novel sentences, arguments, or inferences.

Some representations do not have the properties of symbols, but can be powerful for certain purposes. An example is prototypes, to be discussed under categorization. Such representations are said to be subsymbolic. This is only a brief account of the subtle but important distinction between symbolic and subsymbolic processes, which is relevant to aspects of infant cognition, to be considered later, as well as to other fields such as animal cognition and neural net models (Marcus, 1998a, 1998b; Phillips, 1994).

Changed Theories of Categorization

Our theories of categorization have undergone considerable revision in recent decades, and this has influenced

the way we conceptualize children's categorizations, which in turn influence their thinking.

Prototypes and Family Resemblance

A major change to the theory of categorization occurred with the realization that natural categories are not based on defining attributes but on family resemblances (Wittgenstein, 1953). Natural categories tend to be built around prototypes, or most typical instances, and membership is not all-or-none, but a matter of degree (Rosch, 1978), so a robin is a more typical member of the bird category than an emu or a penguin. Prototypes also represent correlations between attributes, such as the correlation between having feathers, flying, and building a nest. It was also demonstrated that prototype formation tended to be automatic, with little or no conscious awareness of the basis of the category (Franks & Bransford, 1971; Posner & Keele, 1968). It was also shown that prototypes could be formed by relatively simple, pattern associators (McClelland & Rumelhart, 1986) or by three-layered neural nets (Quinn & Johnson, 1997). Prototypes tend to be based on perceptible attributes, so the bird prototype tends to be based on presence of wings, feathers, flying, and so on.

Prototypes have great information-processing power. They enable recognition of category membership, the central tendency of a category, the nature and extent of variations around the central tendency, and the correlations among attributes of instances in the category. However, they have limitations that make them unable to account for some aspects of categorization. Prototypes do not appear to be compositional (Fodor, 1994) which would imply that they are subsymbolic. The symbols for "dog" and "happy" can be composed to form "happy dog," but according to Fodor's argument, the prototypes for "happy" and "dog" cannot necessarily be composed to form the prototype of "happy dog." We can acquire the concept by experiencing happy dogs, but there is no assurance that the representation of happy in the prototype of happy dog is the same as the representation of happy in other contexts such as "happy girl." Furthermore, the representations of happy and dog cannot necessarily be recovered from a learned prototype of happy dog. Other problems have emerged with theories of categorization based on similarity, including both prototype and exemplar models (Medin, 1989). These have been addressed through the development of models of categorization based on theories.

Theory-Based Categorization

Categories can be based on naive theories, such as that weapons can be used to kill people, or that animals have blood and can die (Gentner & Medina, 1998; Krascum & Andrews, 1998; Medin, 1989). One interpretation of theory-based categories is that they have an innate basis and are a precondition for learning. According to this view, learning depends on categorization, rather than the reverse, and all categorization is theory-based (see Gelman & Kalish, Chapter 16; Keil, Chapter 14; and Kuhn & Franklin, Chapter 22, this *Handbook*, this volume). However, this view has been challenged by Sloutsky (2003; Sloutsky & Fisher, 2004) who proposes learning mechanisms for category acquisition.

Another interpretation is that theory-based categories comprise propositions that are compositional and symbolic, and can be composed into higher-order propositions, such as causal relations that link lower-order propositions. According to this view, theory-based categories are compositional and are at a higher cognitive level than prototypes, which are not.

Levels of Categorization

An alternative way to define levels of categorization was provided by Mandler (1999), who described three kinds of categories: categorical perception; perceptual categorization, and conceptual categorization. Categorical perception is used to group stimuli along a perceptual dimension and to distinguish phonemes such as /p/ and /b/. Perceptual categories are learned through exposure to multiple diverse instances. The process proceeds in an automatic and unselective fashion and there is limited central access to the information being used (Moscovitch, Goshen-Gottstein, & Vriezen, 1994). The perceptual system abstracts the principal components from a set of stimuli that bear some physical resemblance to one another to form a schema or prototype, as previously described.

Conceptual categorization depends on abstract forms of similarity, such as similarities of function or kind, rather than perceptual appearances. Unlike categorical perception and perceptual categorization, conceptual categorization is under voluntary control, is selective in its operation, and is accessible to conscious thought. Perceptual information is needed to identify objects as exemplars of a taxonomic or functional grouping. Simple categorical concepts can be based on characteristics such as kind of movements and interac-

tions engaged in, which define the roles that animals and objects can take in events. Mandler (1999) stresses the importance of events to conceptual life, because of their focus on roles. Global conceptual categories develop before more specific, concrete conceptual categories. Conceptual categories provide a basis for inference. The emphasis on roles is similar to relational categories (Gray, 2003) which are defined by the role they serve in a relation. An example would be “orbiting body” (satellite, moon, planet) defined by being in orbit around a larger body. Alternatively, they can be defined by a relation such as “same” or “different” between elements (Oden, Thompson, & Premack, 1990; Zentall, Galizio, & Critchfield, 2002).

Complexity

A growing body of evidence indicates that capacity to process information increases with age, due to factors such as synaptic growth, axonal arborization, and dendritic development (Quartz & Sejnowski, 1997). However, the theory that cognitive development depends mainly on knowledge acquisition and is analogous to, perhaps even synonymous with, acquisition of expertise (Carey & Gelman, 1991; Ceci & Howe, 1978; Keil, 1991) has tended to be seen as conflicting with conceptions based on complexity or capacity. There is no logical reason to regard knowledge and capacity explanations as mutually exclusive. A counterargument is that it is more parsimonious to rely on knowledge-based explanations. While no one doubts the fundamental importance of parsimony in science, it does not imply that simplistic theories should be favored. In science it is essential to find the dimensions that provide a conceptually powerful and consistent account of phenomena, without anomalies or contradictions. To illustrate by an analogous problem, consider what would have happened in physics if it had been considered more parsimonious to treat heat and temperature as one variable, as early physicists did (Carey, 1985). The result would have been intractable contradictions, and a consistent theory of thermodynamics would have been impossible. In this chapter, we present considerable evidence that complexity affects reasoning, and there is also evidence for capacity limitations (Cowan, 2001; Cowan et al., 2003; Halford, Baker, McCredden, & Bain, 2005; Luck & Vogel, 1997). It is appropriate, therefore, to consider knowledge and capacity as complementary factors, and not rule out either a priori.

The influence of complexity on cognitive development has been a major source of study for some decades, mainly by a group of researchers known as neo-Piagetians. McLaughlin (1963) provided the impetus for this development. It was then developed by Pascual-Leone (1970), Case and Okamoto (1996), Chapman (1987, 1990; Chapman & Lindenberger, 1989), Fischer (1980), and Halford (1982). These theories have been reviewed in detail by Halford (2002) and Demetriou, Christou, Spanoudis, and Platsidou (2002). There are many differences between the formulations, but their common purpose was to explain the development of children’s cognition as observed by Piaget and others in terms of increasing information-processing ability.

More recent theories of cognitive complexity have a broader scope, and are applicable not only to Piagetian tasks but to a wide range of other tasks. Two current theories of cognitive complexity are the cognitive complexity and control (CCC) theory and relational complexity (RC) theory.

The cognitive complexity and control (CCC) theory (Frye, Zelazo, & Burack, 1998; Zelazo, 2004; Zelazo & Frye, 1998; Zelazo, Frye, & Rapus, 1996; Zelazo, Müller, Frye, & Marcovitch, 2003) proposes that preschoolers can adequately represent simple “if-then” rules, representing relations between antecedent and consequent conditions, but they cannot integrate these simple rules by embedding them under higher-order rules. Task complexity depends on the minimum number of levels of rule embedding required to solve the task successfully. Embedding involves a higher level of consciousness, which is brought about by a type of reflection that permits the rules to be considered in relation to each other (Zelazo, 2004). CCC theory has achieved considerable success in accounting for age-related changes during the preschool years.

CCC theory is well illustrated by the Dimensional Change Card Sort (DCCS) task, which requires children to switch between rules. Children sort colored shapes into two piles according to explicitly stated rule sets. Participants are shown two target cards (e.g., a red triangle and a blue square) and are given sort cards each of which differs from each target card on one dimension (e.g., a red square and a blue triangle). In the “color” game, the sort cards are placed beneath the target cards of corresponding *color*. After several trials of the color game, participants are told to switch to the “shape” game. In this, they place the sort cards beneath the target

cards of corresponding *shape*. Preschoolers sort successfully under the first set of rules (shape or color) but tend to perseverate in postswitch trials despite being reminded of the relevant rules at commencement of each trial and despite knowing the second set of rules (Zelazo et al., 1996).

According to CCC theory, preschoolers can adequately represent simple “if-then” rules, allowing effective representation of relations between antecedent and consequent conditions. Therefore, they readily learn a color- or shape-sorting rule, but they cannot embed these rules into the hierarchy of rules. Formation of these embedded rules requires children to reflect on the rules that they have learned to use (Zelazo & Frye, 1998).

Recent research has shed more light on the reasons for the difficulty of the DCCS task. The difficulty is not in reversing the sorting because 3- to 4-year-olds can make simple reversals provided there is no variation in a second dimension (Brooks, Hanauer, Padowska, & Rosman, 2003; Perner & Lang, 2002). These and other findings (e.g., Bailystok & Martin, 2004) argue against an explanation in terms of inability to inhibit a prepotent response, and support explanations based on complexity. Nor is the hierarchical structure of rules an insurmountable source of difficulty because Perner and Lang found that 3- to 4-year-olds could perform variations in the task that had the same hierarchical structure as the DCCS. They tended to fail when there was a visual clash between target and sorting cards on the irrelevant dimension. Note that in the color game, the red square must be sorted below the red triangle target, but it matches the blue square in shape. Similarly, in the shape game, the blue triangle must be sorted below the red triangle target, but it matches the blue square in color. The visual clash hypothesis receives some support from the study by Towse, Redbond, Houston-Price, and Cook (2000), who found that 3- to 4-year-olds could switch from shape to sorting by color when there were no target cards. When target cards were present, performance was similar to that observed in the standard DCCS task. Performance can be improved if children identify cards in terms of the postswitch dimension before sorting (Kirkham, Cruess, & Diamond, 2003; Towse et al., 2000). The performance of 4-year-olds worsens when the sorted cards are left face-up (Kirkham et al., 2003). These results suggest that the salience of the preswitch attributes is a factor in the difficulty of the DCCS task.

The findings of Deák, Ray, and Pick (2004) might also be interpreted in these terms. They presented object triads in which the hybrid object (e.g., rectangular magnet) had the same shape as one target (e.g., rectangular eraser), but a different function. The hybrid object had the same function as the other target (e.g., round magnet), but a different shape. The 3-, 4-, and 5-year-olds in the switch group sorted the hybrid objects according to shape in block 1, then function in block 2 (or the reverse). Children in the control group sorted by either shape or function in both blocks. Although the function rule was more difficult than the shape rule, there was no difference between the switch and control groups in block 2. With the exception of the 3-year-olds, who experienced difficulty sorting by function, children performed relatively well on all preswitch and postswitch rules. One interpretation is that switching between sorting by a perceptual (shape) and a semantic (function) variable is easier than switching between two perceptual dimensions of approximately equal salience as required in the standard DCCS. If functions are less salient, then the visual clash that occurs in the standard DCCS might be avoided in this modified version.

Zelazo et al. (2003) argued against several explanations of children’s difficulty. These were working memory limitations, representational redescription, and inhibition of particular stimulus configurations or the preswitch dimensions (but see Kirkham et al., 2003 for a different view). The findings of Zelazo et al.’s (2003) nine experiments using standard and modified versions of the DCCS were interpreted as showing that errors occur because rules (e.g., if blue then here, if red then there) are activated in the preswitch phase and this activation persists during the postswitch phase. However, there was also some evidence for the negative priming account, which attributes children’s difficulty in the postswitch phase to their failure to disinhibit the previously irrelevant rule. Successful sorting by color in the preswitch phase entails selection and activation of color rules (if blue then here, if red then there). Focusing on the relevant (color) rules might result in automatic inhibition of the irrelevant (shape) rules (if rabbit then here, if boat then there). Sorting correctly by shape in the postswitch phase requires that the shape rules be activated (disinhibited). In the negative priming version used in Experiments 8 and 9, values on the dimensions that were relevant during the preswitch phase (blue and red in the example) were replaced (e.g., by yellow and

green) in the postswitch phase. Persistent activation of the preswitch rules cannot explain children's failure in the postswitch phase on this version, yet children performed poorly. Experiment 9 established that negative priming occurs only when children must actively select one pair of rules against a competing alternative, that is, when there is a conflicting mismatch between target and test cards during the preswitch phase. When there is no conflict or visual clash between target and test cards in the preswitch phase, children are able to sort according to the postswitch rule. There seems to be some consistency between these studies, in that children experience difficulty only when they must shift between incompatible or conflicting rule-pairs. Halford and Bowman (2003) proposed, on the basis of relational complexity theory, to be considered next, that the visual clash and salience of the preswitch attributes prevented the DCCS from being segmented into two simple subtasks, and required participants to process a more complex rule in which game, color versus shape, constituted an additional variable that had to be processed. They also found that 3- to 4-year-olds could perform a hierarchically structured task when it could be segmented, but not when it was resistant to segmentation, as in the DCCS task.

The Relational Complexity (RC) Metric

Halford, Wilson, et al. (1998) define complexity as a function of the number of variables that can be related in a single cognitive representation. This corresponds to the *arity*, or number of slots (arguments) of a relation, because each slot of a relation corresponds to a variable. One of the simplest relations is a binary relation, such as "an elephant is larger than a mouse." The larger-than relation has two slots or arguments, one for a larger and one for a smaller entity. Each slot can be instantiated in a number of ways: "elephant larger-than mouse," "mountain larger-than molehill," and so on. Consequently, each slot represents a variable or dimension. In general, an n -ary relation is a set of points in n -dimensional space. Quaternary relations (4 related variables) appear to be the most complex that can be processed in parallel by most adult humans, though a minority can process quinary relations under optimal conditions (Halford et al., 2005).

An example of a cognitive task involving a unary relation would be a binding between an instance and a category; "Rover is a dog" assigns Rover to the dog category, and can be represented in predicate calculus

terms as dog (Rover). The commonest relations in everyday life are binary relations, which include larger-than, faster-than, wiser-than, and so on, but also less obvious ones such as contained-in, or cuts (as in knife cuts apple).

An example of ternary relations would be arithmetic operations such as addition, defined as the set of ordered 3-tuples add { . . . , (3,2,5), . . . , (4,3,7). . . }. Some important cognitive developmental reasoning tasks such as transitive inference, hierarchical classification, and appearance-reality, have been analyzed as requiring this level of complexity (Andrews, Halford, Bunch, Bowden, & Jones, 2003; Halford, 1993; Halford, Wilson, et al., 1998). A good example of a quaternary relation would be proportion, because it is a relation between four variables, $a/b = c/d$ (e.g., $2/4 = 5/10$).

Normative data suggest that the median ages at which children acquire the capacity to process a given level of complexity are 1 year for unary relations, 1 to 2 years for binary relations, 5 years for ternary relations, and 11 years for quaternary relations (Andrews & Halford, 2002; Halford, 1993; Andrews, Halford, Bunch, Bowden, & Jones, 2003). Norms have been determined most precisely for ternary relations in the domains of transitivity, hierarchical classification, cardinality, comprehension of relative clause sentences, hypothesis testing, and class inclusion (Andrews & Halford, 2002). Acquisition is not sudden or stagelike, but gradual. The percentage of children estimated to be capable of processing ternary relations was 16 at ages 3 to 4, 48 at age 5, 70 at age 6, rising to 78 at ages 7 to 8 years. Correspondence was found across domains, and tasks at the same level constituted an equivalence class of equal structural complexity. Tasks in all domains loaded on a single factor, and factor scores were correlated with age ($r = .80$) and fluid intelligence ($r = .79$). Other studies have observed correspondence between property inferences for hierarchical categories, transitive inference, and class inclusion (Halford, Andrews, & Jensen, 2002), between processing sentences with embedded clauses, hierarchical classification, and transitivity (Andrews, Halford, & Prasad, 1998) and between concept of mind, transitivity, hierarchical classification, and cardinality (Halford, Wilson, et al., 1998). There is, therefore, substantial evidence of correspondence between ternary-relational tasks in a wide range of domains.

Complex tasks are *segmented* into components that do not overload capacity to process information in parallel. However, relations between variables in different

segments become inaccessible (just as the 3-way interaction would be inaccessible if a 3-way experimental design were analyzed as 2-way analyses). Processing loads can also be reduced by *conceptual chunking*, which is equivalent to compressing variables (analogous to collapsing factors in a multivariate experimental design). For example, Velocity = Distance/Time, but can be recoded to a binding between a variable and a constant (e.g., Speed = 50 kph; Halford, Wilson, et al., 1998, Section 3.4.1). Conceptual chunking reduces processing load, but chunked relations become inaccessible (e.g., if we think of velocity as a single variable, we cannot determine what happens to velocity if we travel the same distance in half the time). The study by Halford and Bowman (2003), considered earlier, showed that when the DCCS task could not be segmented, it was performed at an age consistent with the norms for ternary-relational tasks; but when it could be segmented, it was mastered by younger children. The color and shape rules are binary-relational and can be represented as:

$$\text{Attribute}_{\text{color/shape}} \rightarrow \text{Sort}$$

whereas the combined rule is ternary-relational due to color/shape being an extra dimension, and can be represented as:

$$\text{Game, attribute}_{\text{color/shape}} \rightarrow \text{Sort}$$

Complexity analyses are based on principles that define when chunking and segmentation are possible. The core principle is *variables can be chunked or segmented only if relations between them do not need to be processed*. Two additional principles are:

1. Effective relational complexity for a cognitive process is the least complex relation required to represent the process. This can be determined algorithmically by a decomposition and recombination technique (Halford, Wilson, et al., 1998, Section 3.4.3).
2. Where tasks entail more than one step, the processing complexity of the task is the relation that must be represented to perform the most complex process involved in the task, using the least demanding strategy available to humans for that task (Halford, Wilson, et al., 1998, Section 2.1).

According to relational complexity theory, children can perform analogies if they can represent the relevant relations. Consequently, analogies based on unary relations should be possible at 1 year, those based on binary relations should be possible from 1.5 to 2 years, and those based on ternary relations at 5 years. Current data appear to be broadly consistent with this prediction. The most contentious prediction is that analogies based on ternary relations will not be possible before 5 years. Goswami (1995) claims to have shown that 3- and 4-year-olds performed ternary-relational analogies, but Halford, Wilson, et al. (1998) argued that simpler strategies were not taken into account. It is also important that complexity analysis take account of decomposability of tasks. An analogy based on relations linking three variables will only be processed as ternary-relational if it is not possible to segment the representations into simpler subtasks.

In proportional analogy A:B C:D, the binary relation between A and B is mapped to a binary relation C and D. This mapping can be segmented into two binary relations, because relations between source and target pairs are not explicitly processed in analogical mapping. A proportional analogy such as 2:5::3:4000 is validated because the same relation, “less than,” occurs in source and target (i.e., $2 < 5$ and $3 < 4,000$), but it is not a proportion because relations between 2 and 3, or between 5 and 4000, are not specified. This contrasts with a proportion, where relations are defined between all four variables (e.g., in $2/4 = 5/10$, the same relation occurs not only between 2-4 and 5-10, but also between 2-5 and 4-10), and the concept consists of more than binary relations. Therefore, the so-called proportional analogy is not a proportion.

There is evidence for a developmental shift from mapping of attributes to mapping of relations (Gentner & Rattermann, 1998; Rattermann & Gentner, 1998). The relations in question are typically binary relations. Attributes can be conceptualized as propositions that are equivalent to unary relations and are less complex than binary relations, so the shift might in part be from simpler to more complex relations. This is not to suggest that relational knowledge acquisition is unimportant.

The interaction between complexity and strategies is neatly demonstrated in a study by Stiles and Stern (2001) of 2- to 5-year-old children’s ability to make block constructions. They found that strategies varied with age and with the pattern to be constructed, but also that children used different strategies with more

complex patterns. Complexity appeared to be influenced not only by the number of components that had to be integrated in any one step, but also by the strategy employed, some strategies being more demanding than others. Similarly, Cohen (2001; Cashon & Cohen, 2004; Cohen & Cashon, Chapter 5, this *Handbook*, this volume), found that an information overload forced infants to process information in a simpler, more primitive way.

Summary of Complexity Research

Cognitive complexity and control (CCC) theory and relational complexity (RC) theory developed in parallel, but have some common ground, so some translation is possible between the hierarchical complexity analysis of CCC theory and the number of variables analysis of RC theory. Relational complexity theory applies to both hierarchically structured and nonhierarchical representations and has been applied to adult as well as child cognition. Cognitive complexity and control theory has been applied to the theory of executive functions (Zevela et al., 2003). The theories complement each other; both have established important principles governing the way complexity affects performance, and the body of empirical evidence is growing.

A reservation that is sometimes expressed about complexity analyses is that they are “pessimistic” because they are seen as denying possibilities for improvement. Leaving aside the question of whether such value judgments have a place in science, complexity analyses can actually point the way to improvements. Better understanding of what makes tasks complex can assist in devising simpler tasks that can identify capacities of younger children. Proportion is inherently complex because it is defined by relations between 4 variables, and it is predicted that it will be difficult for children under 11 years to master completely. This does not preclude useful mastery of components of proportion, such as the concept of a fraction, which is a relation between two variables and should be understandable by 2 years of age, with suitable presentation (see Geary, Chapter 18, this *Handbook*, this volume). As described later, many precocious performances are due to simplification, and in some cases complexity analyses have yielded predictions of previously unobserved capabilities.

The assumed opposition between complexity and experience factors is further removed by evidence that experience is likely to increase capacity, due to neural plasticity (Quartz & Sejnowski, 1997). Thus, not only

does cognitive development depend on both capacity and knowledge, but experience may contribute to the development of both.

Complexity has long been recognized as a difficult concept, but there is increasing common ground about the conceptualization of complexity, the ground rules for analyzing tasks, and the basic parameters values, both in cognitive development and in general cognition. We also find complexity to be useful for interpreting task and developmental effects in the field, as subsequent sections show.

Origins of Thinking in Infancy

Although infant cognition is considered elsewhere (Cohen & Cashon, Chapter 5, this *Handbook*, this volume), research has revealed some infant cognitive processes that are important precursors of later reasoning, and it is appropriate to consider them here. We need to consider what criteria should be used to determine whether infant cognition entails reasoning, as it is performed later in childhood and in adulthood.

Image schemas (Mandler, 1992) are seen as conceptual primitives in the 1st year of life that form building blocks of higher cognition. They include self-motion, animate motion, agency, path, support, and containment. Image schemas comprise linked elements, but the components of an image schema are fused and are inaccessible to other cognitive processes. They are not compositional or systematic in the senses discussed earlier and therefore are not symbolic.

Recognition of Cause

Infants' perception of cause (Leslie & Keeble, 1987) seems similar to image schemas and configurations in that it is a modular representation and is computed automatically without being influenced by cognitive processes outside the module.

Content-Independent Cognition

There is evidence from quite different sources that infants have some ability to process structure, independent of content. Tyrrell, Zingaro, and Minard (1993) selectively reinforced infants for looking at either a pair of identical toys or a pair of nonidentical toys by playing a short recording of a human voice when they fixated the positive pair. This appears to be a highly effective training procedure, and infants of 7 months not only learned the discrimination, but showed transfer to new

pairs of toys that embodied the relation on which they had been trained. Marcus, Vijayan, Bandi Rao, and Vishton (1999) habituated 7-month-old infants to three-word sentences of the form ABA or ABB constructed from an artificial language, then tested them on three-word sentences composed of artificial words not used in habituation. Infants were familiarized with a 2-minute speech sample comprising three repetitions of each of 16 utterances (e.g., “ga ti ga,” “li ti li”). In the test phase, 12 sentences that were either consistent (e.g., “wo fe wo”) or inconsistent (e.g., “wo fe fe”) with the habituation sequences, were presented. Infants looked longer toward the side where the sentences with the novel structure were presented. Thus they appeared to have represented the structure independent of content.

There has been a controversy as to whether the infants learned rules (Altmann & Dienes, 1999; Marcus, 1999; Seidenberg & Elman, 1999; Shastri, 1999) or whether the observed transfer could be based on processing of associations between patterns. It is possible that the pairs used by Tyrrell et al. (1993) and the triads used by Marcus et al. (1999) could be processed by representing degree of difference between stimuli, and this would provide a basis for transfer to sets of elements with a similar difference, but dissimilar materials. This is an important step toward symbolic processes, but it does not have all the properties of symbolic processes such as compositionality and systematicity.

Infant Quantitative Reasoning

The evidence for infants' quantitative understanding comes primarily from studies using the habituation/dishabituation and violation of expectations paradigms, which capitalize on the fact that novel or surprising events capture attention. Research based on these methodologies has demonstrated three main findings. First, infants aged 6 to 12 months discriminate between displays with different numerosities (e.g., Starkey, Spelke, & Gelman, 1990). Most studies show success with small numerosities only; however, Xu and Spelke (2000) also demonstrated successful discrimination with set sizes of 8 versus 16, but not 8 versus 12. Second, from around 5 months, infants appear to have some understanding of addition and subtraction events involving small numbers because they look longer at arithmetically incorrect outcomes (Simon, Hespos, & Rochat, 1995; Wynn, 1992a. See, however, Cohen & Cashon, Chapter 5, this *Handbook*, this volume). Third, infants demonstrate sensitivity to the ordinal relations between

sets of different numerosities. Brannon (2002) habituated infants to either ascending or descending sequences of three numerical displays (e.g., 4, 8, 16 or 16, 8, 4), then tested them with both ascending and descending sequences with novel numerical values. In Experiments 1 and 2, 11-month-olds (but not 9-month-olds) dishabituated to the novel test sequences (cf. Tyrrell et al., 1993). Several models have been proposed to account for these and other empirical findings.

Meck and Church (1983) proposed an accumulator mechanism to characterize representation of nonverbal numerosity in human adults (Whalen, Gallistel, & Gelman, 1999) and infants (Xu & Spelke, 2000). According to this model, the nervous system has the equivalent of a pulse generator that generates activity at a constant rate. There is also a gate that opens to allow energy through to an accumulator that registers how much energy has been let through. In counting mode, the gate opens for a set amount of time for each item. The total energy accumulated is an analogue representation of number. For example “_ _” represents one, “_ _ _” represents two, and “_ _ _ _” represents three. The entire fullness of the accumulator, comprising all of the increments, represents the numerosity of the set of items counted. This single magnitude exhibits scalar variability. Successful discrimination of quantity is subject to Weber's law (discriminability of two magnitudes is a function of their ratio). Scalar variability means that numerosity is never represented exactly in the nonverbal or preverbal mind, with the possible exception of small (1 to 3 or 4) numerosities (Gallistel & Gelman, 2000).

Simon (1997) applied Kahneman and Treisman's (1984) object file mechanism, which is used in object recognition and tracking, to quantification in infancy. Infants are said to construct an imagistic representation of the experimental scene, creating one object-file for each object in the array. Infants represent numerosity implicitly, but there is no distinct symbol for the numerosity of the set and there is no counting process. Numerical equivalence is established by comparing two representations either by evaluating one-to-one correspondence or by comparing files on some continuous dimension. The absolute limit on number of individuals that can be represented in parallel and stored in short-term memory (STM) establishes an empirical set-size signature. This model accounts for quantification of sets of four or fewer objects, but it predicts high error rates and failure with larger numerosities.

Like the accumulator model, the amount model (Clearfield & Mix, 2001; Mix, Huttenlocher, & Levine, 2002) incorporates analogue representations of quantity; however, unlike the accumulator model, there is no counting mechanism. Early quantification of both discrete and continuous quantities is based on nonnumerical cues such as the combined surface area or contour length of the elements. Infants have a general sense of amount rather than discrete number. They can use spatiotemporal information to individuate objects from an early age, but do not apply this information in quantitative situations. Representations based on an undifferentiated sense of quantity are inherently inexact, but some success would be expected based on part-part or part-whole comparisons to reference quantities in the visual scene. Clearfield and Mix (2001, p. 256) argued that because number and amount tend to covary in the environment, such representations would be sufficient to discriminate between amounts in many situations.

Carey (1996) concluded that the object file model is sufficient to explain infants' addition and subtraction involving small numbers (e.g., Simon, 1997; Wynn, 1992a), but for operations involving larger numerosities, an analogue system of representation is required. Similarly, Xu (2003) interpreted infants' numerical discriminations as indicating the existence of two systems of representation. One is an object-tracking system with a set size limit of three or four items; the other is a number estimation system in which discrimination success accords with Weber's law.

These models provide important indications of the set quantification processes that might account for infant numerical performances. Like the models of content-independent transfer discussed earlier, they do not include symbols or symbol systems that are accessible to other cognitive processes and do not appear to have the properties of compositionality and systematicity. They have not, at least as yet, been shown to be symbolic, but they are important precursors of symbolic processes.

Infant Category Formation

There is extensive evidence that infants can form prototypic categories (Cohen & Cashon, Chapter 5, this *Handbook*, this volume; Pauen, 2002; Quinn, 1994, 2002, 2003; Strauss, 1979; Younger, 1993; Younger & Fearing, 1999). The familiarization/novelty preference paradigm, in which preference or recognition of novelty is indicated by looking time, is commonly used in these studies. Infants are familiarized with different exemplars of

the same category, then tested for preference of a novel stimulus from the same category and a novel stimulus from a different category. Preference for the novel stimulus from the different category is taken as evidence that infants categorized the other stimulus as belonging to the familiar category, and therefore as less novel. A typical study is that by Younger and Fearing (1999) in which 4-, 7-, and 10-month-old infants were familiarized for 15 seconds with five pairs of cats and five pairs of horses, then given six 10-second test trials, two with each of the following:

1. Novel cat paired with a dog.
2. Novel horse paired with a different dog (two basic level contrasts).
3. Novel cat or horse paired with a car (global level contrasts).

All age groups showed a preference for the car in (3) but only 10-month-olds showed a preference for the dog in (1) and (2). This tends to support the generalization that global category representations, such as animals, tend to be formed first and are later differentiated into more specific or basic categories such as dogs, cats, and horses. The perceptual nature of prototypes, the relative automatic way in which they are formed, the simplicity of the associative learning mechanisms required to learn them, and their lack of compositionality, as noted earlier, suggest that they are more primitive than later categorizations. Their presence in infants as young as 3 months may provide building blocks of later categorization.

Mandler (2000) proposes that infant categorization goes well beyond prototypes and comprises both perceptual and conceptual categories. Prototypes are basically perceptual, as noted, but conceptual categories are based more on function, goals, causes, and essences, which go beyond perceptual attributes. Function is observable to some extent, so a ball is identified by the fact that it rolls, but there is an aspect of function that goes beyond what is immediately observable, such as that a ball can be used to play a game. Cause also is unobservable because, as Carey (2000) points out, "attribution of causality goes beyond spatiotemporal analysis" (p. 38). Infants might categorize dogs, cats, and horses together because of their inner essences that cause them to be what they are.

To support her proposal, Mandler and McDonough (1996) tested the ability of 14-month-olds to make

inductive inferences. First they saw a dog being given a drink, or sleeping in a bed. Alternately, they were shown a key being turned against a model car door. Then they were shown a different animal and a different vehicle. The children tended to model actions with objects from the same category, so they imitated giving a drink to another dog, not to a car, and key turning against another vehicle, not to an animal. Infants also tended to overgeneralize these properties, such as substituting a frying pan for a cup or a bath for a bed (Mandler & McDonough, 1998). Similar findings were reported for 12-month-olds by Waxman and Markow (1995).

Whereas perceptual categories and prototypes are useful for object recognition, conceptual categories permit inductive inferences that go beyond perceptual phenomena. Conceptual categories in infants certainly appear to be important precursors to the categorical inductions at which young children are so adept.

Mandler proposes that conceptual categories are acquired by perceptual analysis, "in which perceptual input is attentively analyzed and recoded into a new format" (Mandler, 2000, p. 18). However, Carey (2000), although generally supportive of Mandler's proposals, is skeptical that perceptual analysis constitutes an adequate explanation. She suggests that conceptual categories, like core knowledge, derive from innate learning mechanisms in intuitive mechanics and intuitive psychology. See also commentaries by Gibson (2000), Nelson (2000), Quinn and Eimas (2000), and Reznick (2000).

These findings of conceptual knowledge in infants are important, but there is a lack of information about both the cognitive processes involved and the mechanisms by which they develop. Like Carey (2000), we do not find perceptual analysis a convincing account of conceptual category acquisition without further demonstrations of its adequacy. However, Mandler makes another proposal that we find more plausible. This is that "it appears that infants observe the events in which animals and vehicles take part and use their interpretation of the events to conceptualize what sort of thing an animal or vehicle is" (Mandler, 2000, p. 26). This fits well with our own position that the transition to symbolic cognitive processes, which appears to begin around the end of the 1st year, depends on representation of relations. Events can be conceptualized as relations, so that, for example, unlocking a car with a key is a relation between the key and the car, or between a person, key, and car. If infants develop the ability to represent relations late in the 1st year, they would be able to gen-

eralize on the basis of similarity between relations. As Halford and his collaborators have argued (Halford, 1997; Halford, Wilson, et al., 1998; Phillips, Halford, & Wilson, 1995), relations are more accessible than associations, and if conceptual categories are based on relations, they would be more accessible than perceptual categories that are based on associative mechanisms. While this explanation is insufficient in itself, it might suggest fruitful avenues for further research and theoretical modeling.

Our knowledge of infant cognition has been greatly enriched, but in subsequent sections, we consider how infants' capabilities compare with those of children. Keen (2003) has shown elegantly how infant capacities relative to those of toddlers can be exaggerated by different task demands. Infants' abilities are demonstrated solely by looking, whereas toddlers are often required to perform selection, which involves prediction and planning of a motor response. When these differences are removed, the apparent precocity of infants disappears. This is a salutary warning of how easy it is to overlook the effect that even apparently trivial procedural differences can have on the cognitive processes required in a task.

CONCEPTS AND CATEGORIES IN CHILDHOOD

Concepts and categories are an important basis for many inferences. The categories children have, how they acquire them, and the way they use them to make inferences are an essential part of children's reasoning and problem solving.

Prototype Categories

As discussed in the section on the origins of thinking in infancy, there is evidence that infants form prototypical categories, based on perceptible attributes, and they use conceptual categories based on function, goals, causes, and essences. Prototype categories remain important later in childhood, as they are for adults, but there is some evidence that specific exemplar information becomes more important by 11 years (Hayes & Taplin, 1993). In early childhood, there is a mushrooming of categorical development, resulting in many kinds of categories, and providing for powerful inferences.

Some categories are defined by function rather than by appearance (Keil, 1989). Kemler Nelson, Frankenfield, Morris, and Blair (2000) found that 4-year-olds more often extend the names of novel artifacts on the basis of demonstrated functions, as opposed to appearances, when the function helps to make sense of the artifact's structure, and when they respond slowly and deliberately.

Theory-Based Categories

The observation that even young children make inductive inferences about categories that go beyond observable properties is consistent with categories based on theories. The property induction methodology has revealed that children have what appears to be sophisticated knowledge of categories (Carey, 1985; Deák & Bauer, 1996; Gelman & Markman, 1986, 1987; Gelman & Kalish, Chapter 16, this *Handbook*, this volume; Gelman & O'Reilly, 1988; Lopez, Gelman, Gutheil, & Smith, 1992).

While there is considerable variation, the basic logic of these studies is that participants are first shown a target picture of a familiar category, the category is named, and they are told an unfamiliar but plausible fact about the picture. They are tested for generalization of the fact to instances of the same or different categories that are similar or dissimilar to the target. They could be shown a picture of a dog and told it has a spleen inside (Carey, 1985), or shown a picture of a bluebird and told that it lives in a nest (Gelman & Coley, 1990). Then they are shown one or more of the following: a similar instance of the target category (another dog, another bluebird); a dissimilar instance of the target category (another animal); instances of a different category that is nevertheless similar to the target (e.g., pterodactyl that was similar to the bird). Typically, children are told the category to which the instance belongs. It has been consistently found that children, even those as young as 2 to 3 years of age, generalize to the same category, independent of appearances. Thus they have considerable ability to infer properties on the basis of category membership. This is remarkable, given that the properties are often unobservable to the child and that perceptible similarities may not provide a basis for categorization, though Sloutsky (2003) has proposed that similarity still has potential to account for children's categories. The categories are usually natural kinds, either living things such as plants and animals, or naturally occurring enti-

ties such as shells or lumps of mineral. However, generalizations based on material categories (e.g., wood) or object artifacts (e.g., chairs) have been observed (Kalish & Gelman, 1992). Furthermore, 3- to 4-year-old children selected a basis for categorization appropriate to the decision being made, so they categorized by object type (e.g., chair) when deciding in which room an object belonged, but by material type when deciding whether an object would be hard or soft. These findings seem to suggest that children's inferences are based on schemas that children have for various domains. However, the processes young children employ in making category-based inferences remain an important question in the field of children's reasoning.

Essentialism

S. Gelman (2003, Gelman & Kalish, Chapter 16, this *Handbook*, this volume) has proposed that children's categories are based on *essences*, which are unobservable properties that cause things to be the way they are. She proposes further that essentialism is an ingrained cognitive predisposition that emerges early in childhood, that does not appear to depend on direct instruction, and that children's categories are based on early recognition of the causal basis of the properties of natural kinds.

The main kinds of empirical evidence for the essentialist position are the nonobvious property inferences that young children make on the basis of category membership, and their recognition that categories remain constant, despite changes in appearance or attempts at transformation. Young children tend to recognize that having blood and bones is linked to other properties, such as movement, gender, and certain traits, and this knowledge goes beyond the specific facts that children have learned (Gelman & Wellman, 1991; Simons & Keil, 1995). By about 8 years of age, children recognize that animals cannot be converted into a different species by changing their appearance or the way they behave, whereas artifacts can be transformed (Keil, 1989).

Language is an influence on development of essentialist categories, but not the sole driver, according to Gelman (2003). Names, or labels for categories, appear to play a role in development of essentialist categories. Names tell children which entities belong to a particular category, and the knowledge that a child has associated with a name indicates whether it refers to a kind. For example, "this animal is a cat" lets the child know that it

has the properties the child has learned about cats, whereas “this animal is sleepy” indicates an ephemeral state rather than a kind.

Essentialism contrasts with many other domains we review in this chapter because there is little information as to how children’s essentialist categories are formed, nor is it clear what kind of reasoning process might account for these performances. We cannot supply a ready-made model, but we would like to draw attention to an algorithm that corresponds to some properties of children’s categories. This is the Relcon (Relational Concept) model developed in our laboratory by Brett Gray (2003). In essence it works like this. Suppose we consider what we know about some everyday object, such as a chair. We retrieve facts from semantic memory, such as “a chair can be sat on,” “a chair can be made of wood,” “a chair can be found in a living room.” Now suppose we retrieve from semantic memory, other objects that have these same attributes; for example, “a table can be made of wood,” “a table can be found in a living room,” “a table can be found in a dining room,” “a radio can be found in a living room.” Now we continue our reflections by retrieving other attributes of the entities we have retrieved, such as “food can be placed on a table” or “you can listen to a radio.”

Gray has shown that, with appropriate trimming of objects that share a subthreshold number of attributes with others, this process converges to a stable category representation. Furthermore, it captures some of the fundamental properties of theory-based categories, including the prototypicality—family resemblance correlation, and context sensitivity. The categories so formed are based on family resemblance, because no attribute belongs to every member of the category, and many attributes belong to very few members. Such an algorithm can account, at least in principle, for nonobservable attributes, because some attributes are attributed to the category when they have not been observed for some objects in the category. The propositions stored in semantic memory are not structurally complex in terms of relational complexity theory, being reducible to binary or ternary relations. Development of the category will depend more on knowledge accumulation than on processing complexity, which is consistent with Gelman’s (2003) claims. The model is also consistent with Gelman’s claim that essentialist concepts are not based on simple associative mechanisms, but are based on theories. The components of the knowledge are proposi-

tions, and theories are composed of propositions. Furthermore, the algorithm captures the dependence of essentialist categories on labels because labels are essential to the relational knowledge theory from which it was derived (Halford, Wilson, et al., 1998; Wilson et al., 2001). While this algorithm has not been developed specifically to account for children’s essentialist categories, it might provide a simple and plausible mechanism that is relevant to this development. This proposal supports the suggestion of Sloutsky and Fisher (2004) that learning processes might account for some of the phenomena that are attributed to innate predispositions. One outcome of this research might be to show that some learning mechanisms, which in principle are relatively simple, can produce powerful cognitive processes through prolonged interaction with an enriched environment.

Class Inclusion and Hierarchical Classification

According to Markman and Callanan (1984), the major intellectual achievement lies not in the formation of individual classes represented in isolation, but rather in the ability to relate these classes to one another. Relating classes hierarchically greatly enhances an individual’s inferential capabilities. For example, knowing that a newly encountered entity is an animal allows us to infer properties that are characteristic of animals (e.g., it eats, breathes, moves around), and knowing it is also a fish enables us to infer attributes common to fish (has gills, lives only in water) and the likely absence of other properties (has feathers, flies, barks).

Blewitt (1994) explained the development of classification in terms of a developmental sequence of “knowing levels.” Progress to higher levels is characterized as increasing explicitation of children’s implicit knowledge of hierarchies, which occurs as the result of experience-related factors and the endogenous process of reflective abstraction. At Level I, no actual knowledge of hierarchies is granted. Children can form categories at different levels of generality, but they might fail to include the same objects in more than one category. For example, they might use words like *dog* and *animal* appropriately, except that *animal* would not be used to refer to a dog. At Level II, they include the same objects into categories at different levels of generality. As evidence for Level II knowledge, Blewitt (1994) cited Welch and Long’s (1940) research in

which children who identified dogs as *dogs*, also identified dogs and other animals as *animals*. In Blewitt's research, 2- and 3-year-olds accepted both basic level and superordinate level labels for the same objects suggesting that children could multiply categorize the same objects and hence that they had implicit knowledge of the hierarchical relation between categories. While Level I and II skills are present by the age of 2 years, working out the full implications of hierarchies may take many years. The stage of hierarchical categorization (Levels I and II) is followed by one or more stages of hierarchical inference. At Levels III and IV, children can draw inferences from hierarchies, but their inferential skills depend on their explicit understanding of the intercategory relations. Knowledge of these relations is incomplete at Level III; however, qualitative inferences about novel objects and categories are possible. They can deduce for example, that if dogs are animals, and "rumpies" are dogs, then "rumpies" are animals. Quantitative inferences, such as those required in Piagetian class inclusion tasks, involve an appreciation of interclass relations as asymmetrical and are not possible until Level IV. Thus the constraining factor is the ability to construct explicit representations of the hierarchical relations between classes. The complexity of such representations might be the reason for the late acquisition of Blewitt's Level IV skills.

Research by Diesendruck and Shatz (2001) also suggests that young children have some awareness of inclusion relations. They investigated 2-year-olds' sensitivity to the taxonomic relations between objects and to the hierarchical relation implied by different linguistic input. They presented sets of four objects, two target objects (A, B) and two distracters. Object A (e.g., shoe) was labeled using its familiar basic-level label (shoe). Object B (e.g., sandal) was given a novel label (fep). During presentation, either an inclusive or exclusive relation (Experiment 1) or no relation (Experiment 2) was specified between the targets. For example, *Here is a shoe. Here is a fep. A fep is a kind of shoe* (inclusive) or *A fep is not a shoe* (exclusive). After playing with the objects for a few minutes, the child was asked; *Can you show me a shoe? then Is there another shoe? Can you show me a fep? Is there another fep?* Children's responses were coded in terms of how they interpreted the semantic relation between the novel and familiar labels. *Mutually exclusive* responses were those where the child picked

only object A as the referent for the familiar label, and only object B as the referent for the novel label. *Subordinate* responses were those where the child chose A and B as referents of the familiar label and only B as a referent for the novel label. Subordinate responses are consistent with an inclusion relation between the labels, but might also reflect other overlapping relations. *Synonymy* responses were those where the child chose both objects as referents of both labels. *Familiar-only* responses were those where the child chose A and B as referents of the familiar label, but did not choose object B as referent of the novel label. Children's sensitivity to the taxonomic relations between objects and to the hierarchical relation implied by different linguistic input was inferred from their mutually exclusive and subordinate responses. Children were less likely to make mutually exclusive responses when an inclusive rather than an exclusive relation was provided. This suggests some sensitivity to inclusion relations. However, the frequency of subordinate responses was unaffected by this factor, suggesting that their understanding of hierarchical relations was incomplete.

One of the most paradoxical findings in cognitive development research is children's failure to answer the classical class inclusion question investigated by Inhelder and Piaget (1964). The task entails presenting children with an inclusion hierarchy such that a major subclass A and its complement A' are included in a superordinate class B then asking them to compare the relative numerosities of B and A. For example, if shown seven apples and three bananas, then when asked if there are more apples or more fruit, children below about 7 to 8 years of age typically say there are more apples. When asked why, they often refer to the minor subclass A': That is, they would say, "because there are only three bananas." There is no doubt that this phenomenon occurs as it has been replicated multiple times. See reviews by Brainerd and Reyna (1990), Halford (1982, 1989, 1993), and Winer (1980). The question is not whether it happens, but why.

Early explanations tended to be of two main kinds. Piaget and his collaborators (Inhelder & Piaget, 1964; Piaget, 1950) attribute young children's failures to deficiency in inclusion reasoning. However other explanations have focused on children's tendency to answer on the basis of subclass comparisons. That is, they compare A, not with B, but with A', so in the preceding example, they would compare apples with bananas. This makes

their explanation, “because there are only three bananas” understandable, even if the justification for it remains just as obscure.

The paradox is all the greater because it is common to observe that children who give the wrong answer nevertheless seem to know all about the inclusion hierarchy that is presented. In our preceding reference answer, the children would know that apples and bananas are both fruit, they could point to all the fruit in the display, as well as to all the apples and all the bananas, they know that if you take away the bananas you will still have fruit left, and so on.

Why do children reason this way? Numerous theories have been proposed to answer this question, and all tend to argue that children interpret class B to mean class B *but not A*. That is, “fruit” refers to nonapple fruit, bananas in our example. Part of the problem here is that the question form is unusual, as we do not normally ask about the relative quantities of superordinate classes and their subclasses. It is easy to construct a scenario in which even adults might give a seemingly illogical answer to such questions. Suppose you lived in a neighborhood with a large number of dogs, and someone asked whether there are more dogs or more animals in your neighborhood. You might well assume that the questioner wanted to know whether there are more dogs or more other kinds of animals, and as the animals in the neighborhood are mostly dogs, you might answer, “there are more dogs.” This implies that the test is flawed because the question is easily misinterpreted, or reinterpreted in a way that may be rational in the adaptive sense discussed earlier, but is different from what the experimenter intended.

Methods have been developed to correct children’s answers for the number of guesses and subclass comparisons (Hodkin, 1987; Thomas, 1995; Thomas & Horton, 1997). Furthermore, an entirely different way of implementing the inclusion relation by Halford and Leitch (1989) yielded similar findings. Children aged 3 to 6 years were asked to distinguish between sets that entail an inclusion hierarchy, such as a triangle and a square both of which are red, and noninclusive sets such as two red triangles (identical pair), or a red triangle and a blue square (pair different on both dimensions). Six-year-olds could do this, but 4-year-olds could not, even after extensive training, even though the procedure was child appropriate. Another innovation has been to assess class inclusion and hierarchical classification by property inference (Greene, 1994; Johnson, Scott, & Mervis, 1997)

rather than by the quantitative comparison method that has been used traditionally. Correct inferences require recognition of the asymmetrical relation between categories at different levels of the hierarchy. For example, properties of fruit apply to apples, but the reverse is not necessarily true, because apples have properties not shared with other fruit. Johnson et al. (1997) found that children aged 3 to 7 years showed some sensitivity to the hierarchical level of categories, but there was a marked increase with age. There was a discrepancy between ability to name objects at different hierarchical levels and understanding of hierarchical structure. Experiment 3 investigated understanding of basic-subordinate inclusion relations using quantified inclusion questions (e.g., *A banyan tree is a kind of tree. Are all banyan trees trees?*) and property judgment questions (e.g., *A banyan tree is a kind of tree. All trees have lignin all through them. Do all banyan trees have lignin all through them?*). The question type did not influence performance. However, performance improved with age, from 3% of the 3-year-olds performing above chance level to 32% of the 5-year-olds and 67% of the 7-year-olds. There was an effect of domain knowledge in that 5- and 7-year-olds made more correct judgments with familiar (fire truck: has siren) than unfamiliar (bike: has crank-set) properties.

Greene (1994) investigated 6-year-olds’ understanding of the relations expressed in a four-level inclusion hierarchy, which related different classes of *imps*, imaginary creatures from outer space. Memory demands were minimized by using a tree diagram to depict the properties of imps at each hierarchical level. Results showed that 6-year-olds did not appreciate the asymmetrical nature of the inclusion relation.

There have been many claims that young children succeed on class inclusion if given age-appropriate tests (McGarrigle, Grieve, & Hughes, 1978; Siegel, McCabe, Brand, & Matthews, 1978). However, these studies have been criticized because performances were not shown to be better than chance or because they permitted a structurally simpler reasoning process (Halford, 1989, 1993). One of the most famous demonstrations was by McGarrigle et al. (1978) who presented an array of steps with a teddy bear at one end, a chair near step 4 and a table near step 6. The inclusion test entailed asking whether the teddy had more steps to the chair or more steps to the table, and 3- to 5-year-olds performed better than chance. The number of steps to the chair is included in the number of steps to the table in the display, but this does not necessarily mean that the children employed in-

clusion logic. It is entirely possible that the task was performed by comparing two lengths, and McGarrigle et al.'s own data suggest that this was the process used by the children (Halford, 1989, 1993).

Analysis of the study by McGarrigle et al. (1978) illustrates two points. First, comparison of two lengths is binary-relational and is therefore simpler than the inclusion task that is ternary-relational (to be discussed). There is value in finding structurally simpler tasks that younger children can perform, but we need to be aware that this is the case, so the findings are not misinterpreted. Second, it is easy to fall into the fallacy of assuming that cognitive processes that are in our minds when we devise a task are the processes the children actually use. Ingenious experimenters see an inclusion relation in the display of steps, but it does not follow that children generated their answers by processing this relation. Although this test was acclaimed as disconfirmation of Piagetian stage theory, more recent evidence makes it unlikely that it measured the class inclusion concept defined by Piaget. It would be reasonable to conclude that, although some ingenious methodological improvements have been made, the difficulty that young children have in understanding inclusion has not been removed.

More recent research has demonstrated that class inclusion entails a processing load. Rabinowitz, Howe, and Lawrence (1989) developed a formal model for diagnosing the subprocesses that are involved in class inclusion, thereby helping to obviate assessments based on guessed processes. They also added a color dimension to class inclusion, and found that this reduced performance even of older children and adults, suggesting that class inclusion reasoning is sensitive to processing load effects.

Two recent theories have proposed that the processing load imposed by class inclusion lies in mapping the inclusion principle into the problem. The first is Brainerd and Reyna's (1990, 1993; Reyna, 1991) fuzzy trace theory. They contend that children understand the cardinality principle—that if A is a proper subset of B, then there are more B than A. Apples are a proper subset of fruit (because there are also nonapple fruit) so there are more fruit than apples. To perform correctly, they have to apply the cardinality principle to the inclusion relations in the problem—that A and A' are both subsets of B. However, children also encode the subset relations in the problem, and these are more salient because the relative sizes of A and A' are represented physically in the display (we can see there are more apples than bananas in the reference display). By contrast, the inclusion rela-

tions are more subtle and conceptual. This tends to make it difficult to apply the cardinality principle to the inclusion relations, as it leads children into comparing the relative magnitudes of the subsets. Consequently 5- to 9-year-old children benefited from cues that prompted them to retrieve the cardinality principle.

The second contemporary theory is relational complexity theory (Halford, Wilson, et al., 1998) which was applied to class inclusion by Andrews and Halford (2002). There is common ground between fuzzy trace theory and relational complexity on this issue, insofar as both see the problem primarily in the mapping of the inclusion principle, or cardinality principle as Brainerd and Reyna call it, into the inclusion problem. However, Halford (1993) proposes that inclusion reasoning could be based on a schema, induced from experience with inclusive sets, which would serve as a mental model. A child's experience of a family, which includes parents and children, might provide a suitable mental model. This schema is mapped to an inclusion problem by analogical reasoning processes, discussed earlier, which means that the mapping is validated by structural correspondence. The difficulty of the task stems at least partly from the structural complexity of the relations. Andrews and Halford agree with Brainerd and Reyna that the structural complexity of the inclusion task is a factor in its difficulty.

Andrews and Halford (2002) interpret this difficulty in terms of the relational complexity metric. Inclusion entails relations among three classes, B, A, and A'. In terms of our reference example, apples and nonapple-fruit are included in fruit. This is a ternary relation between three classes; (fruit, apples, nonapple-fruit). There are also three binary relations; (fruit, apples); (fruit, nonapple-fruit); (apples, nonapple-fruit), but no single binary relation is sufficient for understanding inclusion. It is not enough to know that apples are related to fruit because, unless the relation between fruit-and nonapple-fruit is also considered, it is not possible to distinguish inclusion from complete overlap (Johnson et al., 1997). Therefore, the inclusion hierarchy cannot be decomposed into a set of binary relations without losing the essence of the concept. Therefore, the inclusion relation is inherently ternary. Furthermore, it cannot be simplified by conceptual chunking. We can chunk bananas, pears, and oranges into the single class nonapple-fruit, and we still have the inclusion hierarchy fruit, apples, nonapple-fruit. But if we chunk apples, bananas, pears, and oranges, we lose the

inclusion hierarchy, because we would then have the class of fruit, and a class of (apples, bananas, pears and oranges), but we have no complementary subclass. Therefore, Andrews and Halford argue that the inclusion hierarchies cannot be reduced to less than a ternary relation.

The rest of the difficulty is because, as Halford (1993) has pointed out, it is only possible to determine that fruit is the superordinate by considering relations between all three classes. Fruit is not inherently a superordinate: It is the superordinate in the reference task because it includes at least two subclasses. Similarly, apples is not inherently a subordinate because if the hierarchy had been apples, Delicious apples, and Meuble apples, apples would have been a superordinate class. To assign fruit, apples, and nonapple fruit to the correct slots in the hierarchy requires that relations between all three classes be processed. Consequently, the difficulty of class inclusion is due to the requirement to map the inclusion principle or schema into the inclusion problem. The inclusion schema is inherently ternary-relational. If it is based on experience with (say) families, then it consists of a relation between family, children, and parents. Identification of the superordinate depends on the correct mapping of superordinate to superordinate and subordinates to subordinates (in our examples, fruit must be mapped to family). The difficulty of this mapping would explain why the task is so difficult for young children who also have difficulty with other ternary-relational tasks (Andrews & Halford, 2002). It also explains why it causes some difficulty for older children and adults, who show evidence of significant processing loads with other ternary-relational tasks such as transitive inference.

There is some degree of consensus that class inclusion performance depends on integration of the components into a valid solution strategy (Brainerd & Reyna, 1990; Rabinowitz et al., 1989). Relational complexity theory would explain this by proposing that recognition of the binary relations between B and A, B, and A', and A and A' imposes a lower processing load than integration into the inclusion relation, which is a ternary relation between B, A, and A'. It is easy to recognize that A is part of B, as also is A' (apples are parts of the collection of fruit, as also are bananas), and that A' is the complement of A (apples and bananas are different kinds of fruit). However, these binary relations do not constitute an inclusion relation, which depends on the ternary rela-

tion between B, A, and A'. The child who processes only binary relations is effectively looking at a three-dimensional structure through a series of two-dimensional windows. Such a child appears to know everything about the task, yet has never synthesized that knowledge into a coherent mental model. It is consistent with this view of class inclusion that any cues that indicate to children which is the superordinate class should help with the problem. This is because they tend to circumvent the considerable processing load required to map the problem and inclusion schema by matching the complex relations entailed in each.

Relational complexity theory has suggested why class inclusion and hierarchical classification are difficult before age 5, whereas category induction is attainable by 3-year-olds (Halford et al., 2002). Category induction involves a relation between a category and its complement. This is a binary relation, whereas class inclusion is a ternary relation. A property inference procedure based on that of Johnson et al. (1997) and carefully matched to that used with category induction, was developed to assess class inclusion. It was found that category induction was mastered by 3-year-olds, whereas class inclusion was mastered at a median age of 5 years, and the latter was predicted by other ternary-relational tasks. The study supports early competence in that the attainment of 3-year-olds is recognized as valid, but it also demonstrates an age effect because older children can master a more structurally complex concept. The study suggests that category induction and class inclusion are really one paradigm at two levels of complexity, which has potential to add some parsimony to the field.

Later developments in class reasoning include recognition of necessity (Barrouillet & Poirier, 1997), and understanding of double complementation, vicariant inclusion, and the law of duality (Müller, Sokol, & Overton, 1999). Müller et al. tested hypotheses derived from Piagetian theory about the relative order of difficulty of class reasoning tasks using a sample of children aged 7 to 13 years. Tasks required the coordination of increasingly complex affirmation and negation operations. Subclass comparisons were predicted to be the easiest because they involve only positive observable characteristics and no negation. Correct responses to class inclusion questions require that children conserve the including class (B) while making quantitative comparisons between it and the included class (A). This in-

volves constructing the including class (an affirmative operation) and then reversing this operation (a negative operation) to decompose the including class. Children are said to construct each subclass through negation under the including class. Subclass comparison and class inclusion were assessed using sets of 15 picture cards depicting, for example, two kinds of fruit (9 apples, 6 bananas). There were three questions, subclass comparison, traditional inclusion questions, and inclusion questions with wider reference (e.g., *In the whole world are there more bananas or more fruit?*).

Vicariance operations are closely related to understanding of hierarchically related classes, but indicate that thinking has become more flexible and mobile. These operations allow children to understand that a class B can be partitioned in ways that leave the class B invariant (i.e., $A_1 + A_1' = A_2 + A_2' = B$). Thus flowers can be divided into roses and nonroses, or daisies and nondaisies. The different divisions are complementary substitutions of the same whole. Vicariance operations also allow understanding of vicariant inclusion, that each primary class (A_1) is included in the complement of the other primary class (A_2'). Thus the class roses is included in the class nondaisies; therefore nondaisies is the more numerous class (Müller et al., 1999).

Müller et al. (1999) assessed vicariant inclusion and double complementation using displays of clay balls arranged in color groups (6 red, 2 green, 3 yellow, 2 blue). After ensuring that children could identify the complement sets (e.g., not green), five questions were posed. Two questions required subclass comparisons (e.g., *Are there more red balls or more green balls?*); two required vicariant inclusion (e.g., *Are there more balls that are red or more balls that are not green?*); and one involved comparison of two complement sets (e.g., *Are there more balls that are not yellow or more balls that are not blue?*). Double complementation was hypothesized to be easier than vicariant inclusion but more difficult than class inclusion. A still later development involves the Law of Duality, which states that the complement A' of a subclass (A) is larger than the complement B' of its superordinate class (B). Thus the class nonroses is larger than the class nonflowers. This is said to involve nesting a class inclusion relation ($A + A' = B$) into a higher order class inclusion relation ($B + B' = C$). Law of Duality was assessed using the materials described for class inclusion with additional cards depicting cherry, lemon, tree, flower. One question referred to

this display (e.g., *Are there more things that are not bananas or more things that are not fruit?*, and another had wider reference *In the whole world are there more things that are not bananas or more things that are not fruit?*) Class reasoning problems and problems based on the four argument forms of logical implication were presented. Logical implication, like the law of duality, was hypothesized as a formal operational attainment.

Results of a Rasch analysis indicated the presence of a single underlying dimension and the following order of increasing difficulty: subclass comparison (least difficult); class inclusion; double complementation; vicariant inclusion and logical implication (equally difficult); Law of duality (most difficult). With the exception of logical implication, this ordering is consistent in most respects with predictions of Piagetian theory. Error analyses indicated that first graders had difficulty with class inclusion and double complementation tasks. Most third graders failed the vicariant inclusion task. Most fifth graders failed the Law of Duality task.

CONSERVATION AND QUANTIFICATION

Conservation has declined in importance as a research topic in recent years, but it was a core domain for many years and the accumulated research on it is prodigious. This research has not so far yielded really clear answers to all the core questions. Nevertheless, we will consider how much coherence can be discerned in this large volume of data.

Conservation was a pivotal concept in Piaget's study of the child's conception of number (Piaget, 1952). He proposed, "conservation is a necessary condition for all rational activity" (p. 3) and every notion presupposes conservation, so inertia is conservation of rectilinear motion, a set is a collection that remains unchanged as relationships between its elements are unchanged, and so on. While there would be consensus about this rational analysis of conservation as a concept, there has been great controversy about the psychological measurement of conservation, and its attainment by children.

There have been many tests for conservation (Halford, 1982), but all entail recognizing that collections of material remain constant over certain transformations. Conservation of continuous quantity can be assessed by presenting two equal quantities in identical, transparent

cylindrical vessels (e.g., two identical glasses of fruit juice). After establishing that the child recognizes the quantities are the same, one quantity is transformed by, for example, pouring it to a taller and narrower vessel. The child is then asked whether the quantities are the same or, if not, which one is more. Conservation of number or discontinuous quantity can be assessed by presenting two sets of objects in one-to-one correspondence, so the equality of the sets is apparent, then transforming one set by extending or compressing it. After the transformation, the child is tested for recognition that the quantities remain the same as before. The classical finding is that young children tend to say the quantities are now unequal because they no longer appear equal after the transformation. For example, pouring liquid into a taller and narrower vessel makes it appear more because the increase in height is greater than the decrease in width (because volume of a cylinder varies as a direct function of height and as the square of width), and making a row of objects longer makes the set appear more numerous. There is no reason to doubt that young children give nonconservation answers to these tests, because the findings have been replicated many times. There has been a great deal of doubt, however, what this shows about their understanding of conservation of quantity.

Some possible explanations for young children's apparent lack of understanding are quickly eliminated. For example, children who give nonconservation answers typically recognize that the quantity will be the same again if returned to its original configuration (e.g., if poured back to the original vessel, or if the row is returned to its original length). They also recognize that it is still the same material, that nothing has been added or subtracted and that there have been changes in two variables, for example, that the liquid quantity increased in height but decreased in breadth, or that the sets increased in length but decreased in density (due to increased space between elements). There has therefore been some mystification as to why they give nonconservation answers. Proponents of the Piagetian position held that nonconservation represents genuine lack of understanding of the invariance of quantity, but there have been many other explanations such as the following: The child was misled by the transformation, which made it appear that quantity or number had changed (Bruner, Olver, & Greenfield, 1966); the child misinterpreted the words used in the test believing, that "more" referred to height of the liquid or length of the row, rather than to

quantity (Donaldson & McGarrigle, 1974); or there was a conflict between knowledge of conservation and appearance of the display (Acredolo & Acredolo, 1979; Bryant, 1972).

Perceptual Factors, Compensation, and Conservation

The proposal that children are misled by the appearance of the transformed quantity received some support from the finding that they tend to conserve more if the change in dimensions is screened from view (e.g., if the taller vessel is covered with a screen, and the liquid it contains after the transformation is visible only through a small hole in the screen, so the increase in height is not apparent). These experiments have been interpreted as showing that children could demonstrate their knowledge of conservation when they were not misled by appearances. Perhaps the most cogent evidence for this view was provided by Gelman (1969) who showed that children of approximately 5 years were more likely to conserve if they were taught by means of an oddity training procedure that quantity, rather than length, was the relevant dimension.

The emphasis on recognition of quantity is important, but a stable mental model of quantity would seem to require understanding how it relates to other dimensions. Length is not irrelevant to number of objects in a linear array but is highly correlated with it, as is height of a column of liquid with quantity. Suppose that someone has a glass of beer, and after being distracted, notices that the height of the column of liquid is reduced. The person knows, without having witnessed any transformation, that the quantity of beer is now less than before. And surely this knowledge is relevant to understanding of quantity. We would be reluctant to attribute conservation knowledge to a person who failed to recognize that a change in height of a column of liquid, with the diameter held constant, implied a change in quantity. Variables such as height of a column of liquid, or length of a row of objects, are correlated with continuous quantity or number respectively, and they provide useful cues. Thus understanding of conservation can hardly depend on simply learning to ignore dimensions like height, width, length, and so on. Rather it would seem to require a mental model that includes a stable representation of the relations between these dimensions and the more subtle one of quantity.

Piaget (1952) proposed that conservation depends in part on knowing the compensating nature of the changes

in height and width, or length and density, in tasks such as those previously described. However many nonconserving children recognize compensation. Children may well recognize that width of a liquid decreased as its height increased, yet they still fail to conserve. A related hypothesis that compensation knowledge facilitated conservation acquisition in training studies (Curcio, Kattef, Levine, & Robbins, 1972) was found not to be supported when the correlation of both variables with pretest conservation was partialled out (Brainerd, 1976). This dissociation between conservation and compensation is paradoxical when we consider that compensation in some form is logically related to, perhaps even necessary for, conservation. For example, an increase in height of a liquid, with width maintained, is logically inconsistent with the quantity of liquid remaining unchanged. If we conclude that quantity remains constant while height increases, we *must* conclude that width decreases. A possible explanation is that compensation is much easier than conservation. Brainerd's (1976) data lend some support to this because nonconserving children performed at a much higher level on compensation than on conservation in a pretest. But the question remains why compensation should be easier than conservation, especially if there is a close logical connection between the two concepts.

Another approach to understanding conservation is to study the acquisition process, and this has yielded numerous training studies, which are reviewed by Field (1987) and Halford (1982). Many training procedures have achieved some success in improving conservation performance, yet no procedure appears to have been entirely successful. Children's performances are usually mixed, even after extensive training. It is difficult to establish the reason for this, but it is possible that acquisition depends jointly on suitable experience and on ability to construct a consistent mental representation of the phenomena. Thus conservation, more than a lot of concepts, might depend on appropriate reasoning processes being applied to input from the environment. It is also possible that there is no one path to conservation acquisition, but that a variety of strategies can be employed. In a microgenetic study, Siegler (1995) found that children often progressed from explanations of conservation based on length to explanations based on the transformation, but this was not a simple transition, and many different patterns were apparent. Furthermore, Siegler found that the number of explanations given was a good predictor of conservation acquisition. This is

consistent with the pluralist approach advocated by Caroff (2002) according to which cognitive development can progress by different pathways. It is entirely possible that recognition of height, or length, might not be distractions, and might not conflict with conservation acquisition. Conservation might depend, not on ignoring these variables, but on developing an integrated mental model that includes the transformation as well as the dimensions of height and width, or length and density.

Thus conflict between length (or height) and number (or quantity) may be just a step along the road to conservation acquisition. A person with a mature concept of conservation does not experience conflict between length and number, but recognizes that compensating changes in length and density are consistent with constant number. According to this argument, conservation acquisition would depend, not on finding a single relevant variable, but on integrating length and spacing with number, or height and width with continuous quantity, as Halford (1970) proposed. It should depend on knowing the relations between these three variables, such as how quantity increases if either height or width is increased without changing the other, or how an increase in one will be accompanied by a decrease in the other, whenever quantity remains unchanged. This provides an unexpected explanation for the failure of compensation to predict conservation. The reason is that compensation is a relation between two variables, length and density. In terms of the relational complexity metric, this is a binary relation. However, it is inadequate to predict conservation. The relation among all three variables, length, density, and number, provides a useful set of constraints. This is a ternary relation, and is more structurally complex than the relation between length and density, which would explain why the latter, binary relation develops earlier and does not predict conservation.

It is an important feature of conservation that the null, or no change transformation, is not obvious as such. If we pour liquid from a short-wide to a tall-narrow vessel, we would only know that the quantity was unchanged if we calculated the volumes of both columns of liquid and compared them, by the formula $V = \pi R^2 H$, where V = Volume, R = Radius, and H = Height. However, this is a calculation that even adults would make rarely, if at all, and it is unlikely that it is ever made by children when they learn to conserve. Yet we are sure that pouring liquid from one vessel to another leaves quantity unchanged, even though the

vessels are of different shape. Invariance of number is perhaps easier to assess, because when rows of objects are extended or compressed, the number of objects resulting can be determined more readily, especially when the sets are small. This does not explain how we know that counting provides an accurate indication of number. It is clear that we have learned to rely on counting to determine the numerosity of sets, but this begs the question of how we acquired that knowledge.

Similar problems arise if we rely on inversion as a criterion of number or quantity. Transformations such as pouring, extending, or compressing transformations can be inverted, so all dimensions will be the same as before, but to reason this way begs the question of how we know inversion indicates conservation. After all, there are many invertible transformations that do *not* leave the relevant quantity unchanged. A stretched rubber band can be returned to its original dimensions, but this does not imply that its length was unchanged when it was stretched. If we think about it, we may be surprised to realize that there is nothing inconsistent in saying that quantity can be increased by pouring to a taller-narrower vessel, and reduced by pouring back again. We only know this assertion is incorrect because of our understanding of quantity. Alternatively, we might say that it is because of our theories about quantity. However, a theory of conservation requires a specification of the theory, and an explanation of how a child arrives at the right theory, which brings us back to the same set of issues.

Part of the answer to this problem may be that conserving transformations are associated with compensating changes and are not directly observable. Conservation is a property that depends on relations between variables, in this case length, density, and number, or height, width, and quantity. It also depends on developing an understanding of quantity, or what might be called a *theory* of quantity. Children would need to understand that counting is a valid way to assess numerosity of sets, or they would need to learn to estimate quantities of liquid in different shaped vessels.

Estimation of quantity in different-shaped vessels might seem insuperably difficult, but this obstacle might be more apparent than real. Research on neural net models of cognition, as well as empirical studies of prototype formation, has shown that it is possible to develop representations of central tendency by relatively simple and automatic mechanisms. The neural net model of conservation by Shultz (1998) is relevant here. Using

a cascade correlation architecture, in which hidden units were recruited as required, Shultz showed that conservation could develop by training the net to predict the equality of two sets on the basis of length, density, identity of transformed row, and the transformation performed (addition, subtraction, elongation, compression). The net was trained to predict whether the transformed row was more than, less than, or equal to, the nontransformed row. The only training input was information about error in the output of the net, that is, information about the discrepancy between output and the correct prediction of equality or inequality of the rows. This procedure was sufficient for the net to progress from an early focus on length and density to a focus on the transformation performed.

Once the transformation is fully understood, it might no longer be necessary to refer explicitly to dimensions. Thus if I see liquid poured from vessel to vessel, and I am sure that nothing has been added or subtracted, I know quantity remains the same without examining height or width. My knowledge of quantity has taught me that the transformation is sufficient to make a correct judgment of equality of quantity. However, I still know the links between the transformation and the dimensions, and I can refer to them if required. Thus, if I see a pouring transformation (without addition or subtraction) and I also know that height was increased, I can infer that breadth must have been decreased.

Age of Attainment of Conservation

The traditional Piagetian finding was that conservation was not typically attained until the age of 7 to 8 years, which was also the age at which other concrete operational tasks were attained. This finding, however, like many of Piaget's age norms, has been the subject of many challenges (Bryant, 1972; Gelman, 1972; McGarigle & Donaldson, 1975; Mehler & Bever, 1967).

A paradigm developed by Bryant (1972) was seen as crucial in demonstrating conservation ability in 3- to 4-year-old children. Children were shown two rows of objects in one-to-one correspondence, with an object in one row unmatched, so it was clear that there were more objects in that row. Then they were shown two equal-length rows with uneven spacing and in which the objects were not in correspondence. The number of objects in each row was the same as with the first display, so there was again one more object in one row than in the other. The first display produced above-chance judg-

ments, and the second produced chance level judgments. The crucial result was that, when the above-chance display was transformed into the chance display, even 3- to 4-year-old children conserved; that is, having correctly judged that one row was more before transformation, they continued to maintain that the same row was more after the transformation. This judgment could not have been based on the posttransformation display because it yielded only chance judgments, so the children's performance reflects the influence of the pretransformation judgment on the posttransformation judgment. In this respect, it achieves something similar to the Piagetian conservation task, but without the interpretation difficulties caused by the conflict between number and length criteria.

Doubts have been raised about the validity of this assessment of conservation. One possibility is that because the posttransformation display provides no basis for judgment, children might default to their pretransformation judgment. Halford and Boyle (1985) presented displays of equal numbers of objects and of equal length, but with variable spacing and therefore no correspondence between objects in the rows. Children saw a succession of transformations from one display to another. Because neither display provided a criterion for judgment, a default judgment based on the first display was not an option. However, if children knew that number remained invariant across the transformations, they should show some consistency, judging the same row as more or (in Experiment 4 where "same" judgments were permitted) judging both as the same, both before and after the transformation. The 3- to 4-year-olds failed to show any consistency across transformations, whereas 6- to 7-year-olds did. When Bryant's (1972) procedure was repeated with "same" judgments being allowed as well as "more" and "less" judgments, findings of conservation by 3- to 4-year-olds were not replicated.

Sophian (1995) used a similar procedure to Bryant (1972) but assessed whether children's pretransformation judgments were based on length or number, and whether they showed indications of counting. The 3-, 5-, and 6-year-olds showed a strong association between observable counting, responding on the basis of number and conservation. There was very little evidence of conservation before age 6. Sophian's study provides important evidence of the link between conservation and knowledge of number.

Sophian also included a condition in which, instead of transforming a row, a different row was substituted.

Her argument was that the default hypothesis of Halford and Boyle (1985) implies that children should be as likely to maintain their pre- transformation judgment after substitution as after transformation. There was no tendency to maintain judgments after substitution, and conservation was much better after transformation, apparently in disconfirmation of the Halford and Boyle hypothesis. Note, however, that children would realize that the pre- and posttransformation rows were different objects in the substitution condition (otherwise their judgments would be the same as in the transformation condition, because substitution is the only way that condition differed from the transformation condition). Therefore, a modified default hypothesis would fit Sophian's findings. This would be that, if the children knew the pre- and posttransformation displays contained the same sets of objects, and if there was a basis for quantity judgment in the pre- but not in the post- transformation display, they would maintain their pretransformation judgment. However when the object sets were not the same, as in the substitution condition, the pretransformation display would provide no basis for judgment, and the children would guess, showing no evidence of conservation. Either way, the studies by Halford and Boyle (1985) and Sophian (1995) cast real doubt on claims that conservation has been demonstrated before age 5.

McGarrigle and Donaldson (1975) modified the conservation of number of task by employing an "accidental" transformation in which a "naughty teddy" accidentally transformed one of the rows, thereby avoiding any suggestion that the experimenter intended to change the number of objects in the row. A significant improvement in conservation was observed in children of 4;2 (4 years, 2 months) to 6;3. When the accidental transformation procedure was replicated by Halford and Boyle (1985) a significant improvement was observed in children aged 3;5 to 4;7, but performance did not exceed chance. Siegal, Waters, and Dinwiddie (1988) showed improvement in conservation but their findings are more consistent with Halford and Boyle (1985) than with Bryant (1972) in that they found an age effect over the age range 4 to 6 years, and they did not demonstrate above chance conservation under the age of 5 years.

Perhaps the most precocious claimed demonstration of conservation was that by Mehler and Bever (1967) with 2-year-olds. They showed children two equal rows of objects in one-to-one correspondence. In the crucial manipulation, one row was compressed and two objects

added. Two-year-olds correctly chose the more numerous row, although it was shorter. This demonstrates that 2-year-olds can ignore length cues in some circumstances, but as Halford (1982) and Miller (1976) pointed out, it does not demonstrate that they recognized the transformation as number conserving, because simply observing that objects were added would enable making a correct choice.

Do training studies provide evidence of earlier conservation? In some ways, training outcomes provide a better estimate of capacity for conservation, because the estimate is less contaminated by knowledge deficiencies. However, training has not produced a major shift in the age of attainment, as most successes have been achieved with children at or above age 5 (Field, 1987; Halford, 1982).

There have not been many explicit theories of conservation, perhaps due to the difficulty in discerning a clear and consistent set of principles in the evidence. Simon and Klahr (1995) developed the Q-SOAR model, based on Newell's (1990) SOAR architecture, to account for Gelman's (1982) study of number conservation acquisition. Children are asked to say whether two equal rows are the same or different based on counting, then are asked to say whether they are still the same (or different) after transformation. Inability to answer this question is represented in Q-SOAR as an impasse. The model resolves this by quantifying the sets before and after the transformation, noting that they are the same, and develops the knowledge that the transformation did not change the numerosities, and therefore is conserving (Klahr & Wallace, 1976).

Number

At some point, children must integrate their early quantitative knowledge into a coherent system that supports a mature understanding of number. This would include understanding of Gelman and Gallistel's (1978) five counting principles (one-to-one correspondence, stable order, cardinal word, abstraction, order irrelevance). It would also include acquisition of the number words of the language and their correct sequence, recognition of numerical equivalence of sets, the ordinal relationships between smaller and larger sets, the compositional relationships within sets, and the conservation of number. There are many different views regarding the age of acquisition of these skills and their order or emergence. We will examine this literature because of its relevance to the development of early quantitative concepts and to

some themes such as conceptual coherence. Geary (Chapter 18, this *Handbook*, this volume) provides a more comprehensive review of the development of mathematical understanding.

Huttenlocher, Jordan, and Levine (1994) examined young children's ability to match numerically equivalent sets and perform simple calculations with concrete materials using a procedure that did not require knowledge of number words. They found no reliable evidence of nonverbal calculation ability in children younger than 2.5 years, whose responses suggested reliance on an approximate quantification mechanism, as described earlier. Children aged 2.5 years and above performed better. Their responses were interpreted as evidence for use of a mental model in which imagined entities and transformations (adding or subtracting) are mapped analogically onto actual objects and their movements. The mental model incorporates several important principles. There is a one-to-one mapping between the elements in the mental model and the concrete objects. The mental model as a whole represents the cardinal value of the set of objects and numerosity increases (decreases) as objects are added (removed). Huttenlocher et al. described children's use of these mental models as a symbolic activity that emerges after the approximate skills of infancy, and prior to the conventional skills of school-age children. This ability to perform nonverbal calculation with small numbers is related to intellectual competence, suggesting that it is a manifestation of a general symbolic capacity rather than an innate modular capacity.

Acquisition of the conventional counting system is a protracted process that extends from about 2 to 4 years of age. Children know that number words refer to numbers, and can perform the count routine, well before they recognize that specific number words refer to the cardinal value of a set. Wynn (1992a) showed a picture of one blue fish and four yellow fish and asked, "Can you show me the four fish?" Even children aged 2;6 succeeded on this task. Success in choosing between four and five animals tended to occur at about 3;6 years. Later acquisitions include coordinating pointing with counting, realizing that counting yields the cardinal value of the set (cardinal word principle), and partitioning sets.

The cardinal word principle (Gelman & Gallistel, 1978) is assessed using various tasks. In the *How many* task, children count a set of stimuli, then they are asked, *How many (stimuli) were there?* Credit is given if children restate the final word of their count sequence without recounting the set. The age by which children succeed on this task varies between 3;6 (Wynn, 1990, 1992b) and

4;8 (Hodges & French, 1988). This variation might reflect differential rates of false positives and false negatives. False positives occur if children merely repeat the last word of the count without understanding that it indicates the numerosity of the set counted (Fuson & Mierkiewicz, 1980; Wynn, 1990). False negative assessments occur if children interpret the question as a request for a recount of the items, or if they mistakenly infer that their initial count was inaccurate (Wynn, 1990).

Wynn (1992b) suggested that the *Give-a-Number* task is a more reliable test. If children understand that numbers refer to sets of specific numerosities, they should show some success at forming or identifying such sets. In the task used by Wynn (1990, Experiment 2), children formed sets of one, two, three, five, and six toy dinosaurs from a pile of fifteen. Wynn's results suggest that success on *How Many* and *Give me X* tasks emerges at about the same age (3;6). Frye, Braisby, Lowe, Maroudas, and Nicholls (1989, Experiment 1, after condition) used a modified version of this task. Children counted sets of 4, 5, 12, and 14 counters; then they were asked, *Give me X – 1 objects* on half the trials and on the remaining trials, *Give me X objects*, where X is the cardinal value. The children (mean age 4;6) found this task more difficult than the *How many* task. However, differences in set sizes, or the requirement to select a subset ($X - 1$) of the elements could account for the later age of mastery.

Understanding of the cardinal word principle appears to facilitate recognition of numerical equivalence. Mix (1999) investigated this using a matching task that required explicit comparison of sets. Target cards contained 1 to 5 black disks (high similarity condition), red pasta shells (low similarity, homogeneous sets), or collections of objects (low similarity, heterogeneous sets). The matching choice cards contained the same number of dots as the target cards, whereas the foil cards contained either $n + 1$ or $n - 1$ dots, where n = Number of elements on the target card. Choice cards were matched to each other on density or array length. Recognition of numerical equivalence emerged at around 3;6 for the high similarity condition, at around 4;6 for the low similarity, heterogeneous sets condition. Only those children with high scores on the *How Many* and *Give-a-number* tasks recognized equivalence in the low similarity objects-to-dots condition (see Mix, 1999, p. 279).

A minimal understanding of the cardinal word principle also facilitates ordinal comparisons. Brannon and Van de Walle (2001, Experiment 2) trained 2- and 3-year-olds to find a sticker under one of two trays. Dur-

ing training, the stickers were always hidden under the tray that held 2 boxes, and not under the tray that held one box. Approximately 72% of children met the learning criterion. The test phase consisted of six trials with novel numerosities. Successful transfer was evidenced by above-chance performance on all six comparisons. *How Many?* and *What's on this Card?* tasks were also administered. In the *What's on this Card* task, children described (using number words) cards that depicted varying numbers of objects. Children who performed poorly on this task performed at chance level in the test phase of ordinal comparison task, whereas those children who gave at least one correct cardinal response performed better. Similar patterns emerged when the participants were classified according to performance on the *How Many* task, suggesting that understanding of the cardinal word principle is necessary for ordinal comparison.

Rouselle, Palmers, and Noël (2004) used an explicit comparison task similar to Brannon and Van de Walle (2001) to investigate numerosity comparison. Three-year-old children were presented with pairs of cards. Each card depicted a set of sticks, and children indicated the more numerous set. Displays varied in terms of set size, ratio between the sets, and the type of perceptual support for the numerosity comparison. The probability of success on the comparison task was lower for pairs presented in the surface condition, which offered the least perceptual support, and higher for pairs with a ratio of 1:2 than for pairs with ratios of 2:3 or 3:4. Only those children who demonstrated some cardinal knowledge (assessed by *How Many* and *Give a Number* tasks) performed above chance level in all three perceptual conditions. Children without cardinal knowledge succeeded in conditions that provided more perceptual support. The results suggested that minimal cardinal knowledge was necessary, but perhaps not sufficient for successful numerical comparisons in the absence of strong perceptual support.

These studies provide evidence for some degree of coherence in children's understanding of number. They suggest that the ability to quantify the numerosity of sets is related to other aspects of their understanding including recognizing numerical equivalences and discriminating sets based on their ordinal value.

English and Halford (1995) and Andrews and Halford (2002) proposed three mental models of how the conventional count sequence might map onto children's conceptual understanding of number. The three models (successor, sets, and inclusion) are shown in parts a, b,

and c respectively of Figure 13.1. The performance of children in the studies investigating the cardinal word principle, numerical equivalence (Mix, 1999), and ordinal comparisons (Brannon & Van de Walle, 2001; Rouselle et al., 2004) can be described in terms of these models.

In the successor model, numerals are assigned to individual objects, and there is a succession relation between objects. This model does not support the cardinal word principle because it implies that the final count

word refers to the last object counted rather than to the entire set. Neither would it support numerical equivalence and ordinal comparison judgments because there is no representation of relative numerosity.

In the sets model, numerals are assigned to sets, and there is a magnitude relation between the sets. The sets model would enable children to recognize that a count word refers to the entire set of objects. It would yield success on *How Many*, *Give me, X* and *What's on this Card* tasks. It would also support success on numerical equivalence and numerical comparisons tasks, because judgments could be based on the magnitude relation. The sets model would not enable principled understanding of the order irrelevance principle, which specifies that cardinal value is unaffected by the order in which items are counted. It differs from the how-to-count principles (one-to-one correspondence, stable order, cardinal word) in that it specifies the absence, rather than presence, of a constraint on counting procedures. Order irrelevance depends on understanding that any object can be counted, provided that it has not been counted before. Thus previously counted objects must be distinguished from those not yet counted. This information is not incorporated in the sets model, because each number is assigned to a set, and previously counted objects are not distinguished from the currently counted object.

Unlike the sets model, the inclusion model (English & Halford, 1995, p. 82) can account for understanding the compositional relations between sets. In this model, each counting number is mapped to a set of sets of equal magnitude; the numbers occur in a fixed sequence; the sets to which the numbers are mapped increase in magnitude by one element with each successive number; each set is included in the next larger set; and counting continues until all objects are assigned to a counted set.

The inclusion model has some important consequences. The first is that the last number in the count routine represents the set of all objects counted and not just the final object counted. Thus the model embodies an understanding of the cardinal word principle. The inclusion model facilitates recognition of the compositional relationships among subsets and sets. For example, the set corresponding to the cardinal number five can be thought of as containing two subsets: one whose cardinal value is four and the other with a cardinal value of one. The subset of four in turn contains subsets with cardinal values of three and one and so on. Representation of the compositional relationships would seem to be necessary if children are to recognize that the set as a

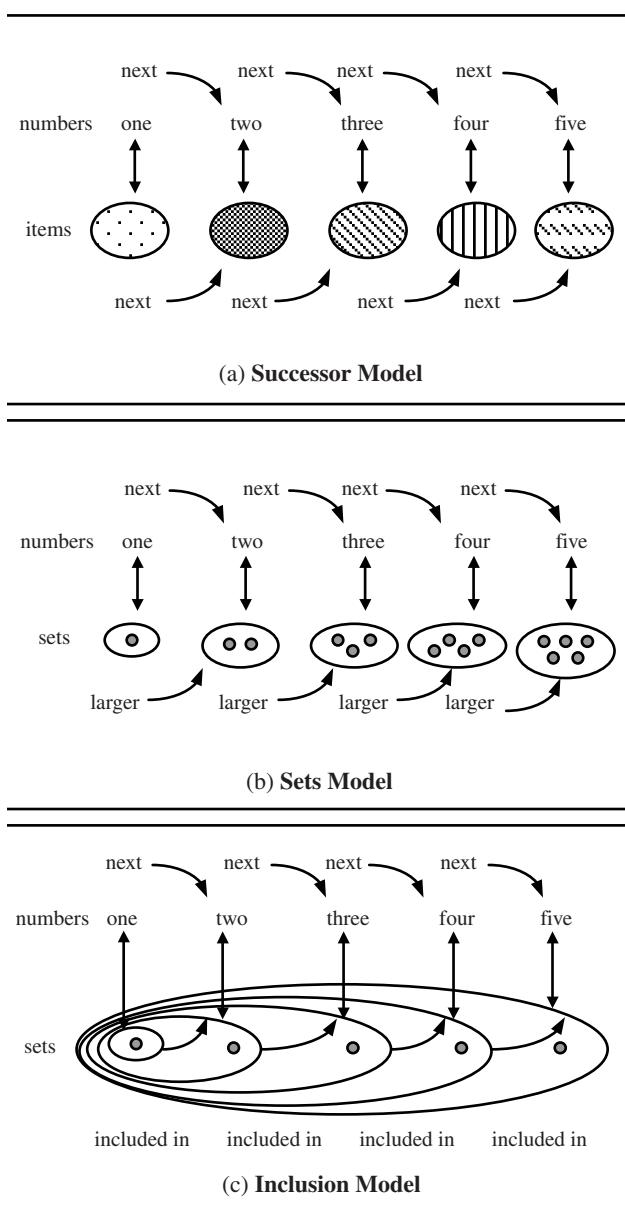

Figure 13.1 Three mental models for counting: (a) Successor model, (b) Sets model, (c) Inclusion model.

whole (cardinal value of five) is invariant under variant partitionings (e.g., 1 + 4; 3 + 2; Resnick, 1989). This model would support understanding of tasks that involve partitioning of sets. It would also support the order-irrelevance principle because it distinguishes between elements that have been previously counted and those that have not. Thus each set of x elements consists of a subset of $x - 1$ previously counted elements, plus one element that is currently being counted.

Frye et al. (1989, Experiment 2) used an error detection technique to assess order-irrelevance and found that children (mean age 4;0) judged the cardinal values of nonstandard (valid) counts as incorrect, suggesting that these children did not understand order irrelevance. However, responses elicited using this technique are difficult to interpret. It is unclear whether children judge the validity of the counting procedure alone (that nonstandard counting orders are acceptable) or whether they also consider the impact on cardinal value (that nonstandard and standard counting orders yield the same cardinal value). Baroody (1984) referred to these as the *order irrelevance tagging schema* and the *order irrelevance principle* respectively. Baroody had children first count the array from one end and then predict what the cardinal value would be if they counted from the opposite end. His results showed that 45% of kindergarteners (mean age 5;6) and 87% of first graders (mean age 6;8) correctly predicted that the cardinal value would be unchanged. Andrews and Halford (2002) reported similar findings. Children under 5 years experienced difficulty understanding the order-irrelevance principle when assessed using Baroody's reverse count technique. A similar age of attainment was observed for a task that involved partitioning a set of seven bananas in different ways.

The research involving normally developing children indicates that the order-irrelevance principle and set partitioning are mastered later (5 to 7 years) than the cardinal word principle and ordinal judgments (3 to 4 years). Geary (2004) reported that children with mathematical learning disabilities have poor conceptual understanding of the order-irrelevance principle, although they understand the cardinal word and stable order principles. These findings can be explained in terms of relational complexity.

The mental models shown in Figure 13.1 differ in complexity. The successor model incorporates the succession relation, whereas the sets model incorporates the magnitude relation. The succession relation is binary, as it can be defined on a minimum of two entities,

for example, $next(6, 5)$ or more generally, $next(x, x - 1)$, where x is the number assigned to an object. The magnitude relation is also binary. It can be defined on a minimum of two entities, $larger\ than\ (x, < x)$. The inclusion model is more complex because it depends on the relation among three entities: numerosity (x); numerosity ($x - 1$) and numerosity (1). The set of items previously counted ($x - 1$) and the currently counted item (1) are included in the set (x). This is a ternary relation. The later mastery of tasks that require the inclusion model is consistent with the greater complexity that it entails.

RELATIONAL REASONING

Reasoning often entails processing relations. Analogy entails mapping between relations, as described earlier, but there are other domains that rely on relational processing, the most commonly investigated form being transitive inference, which we will consider next.

Transitive Inference

A transitive inference is an argument of the form that, for any a, b, c , where R is a transitive relation, then given premises aRb, bRc , the conclusion aRc may be inferred: $(aRb, bRc \rightarrow aRc)$. For example, if $a > b$ and $b > c$, then $a > c$, given that " $>$ " ("more than") is a transitive relation. Examples of transitive relations are larger than, heavier than, faster than, and older than. A relation such as *next in line to* is intransitive because if a is next in line to b and b is next in line to c , it will never be the case that a is next in line to c . Relations such as *loves* are non-transitive (neither transitive nor intransitive) because if a loves b and b loves c , then it is not necessarily true that a loves c . However, it is possible that a loves c if, for example, a is mother of b and c .

Transitive inferences are important to the development of children's reasoning skills because they are essential to many forms of inference about quantities. Transitivity of an asymmetrical binary relation is a defining property of an ordered set. That is, if we order A, B, C, D, E for size, from smallest to largest, then $A < B, B < C, C < D, D < E$, but also $A < C, A < D, A < E, B < D, B < E, C < E$. Less than ($<$) is an asymmetrical relation because if $A < B$ then $B > A$. An ordered set is essential to an ordinal scale, so transitivity in some form is essential to ordinal, interval, and ratio scales, that is, to any quantification beyond a nominal scale.

Transitive inference has been extensively researched in cognitive development, having been important at least since the pioneering work of Piaget, who reported that it was not understood until late in childhood. This was probably because the tests that were used tended to impose demands beyond those that are necessary for making the inference. For example, Piaget, Inhelder, and Szeminska (1960) showed children one tower of blocks on a table and another on the floor, so they could not be directly compared, and gave the children a rod that could be used to measure the towers to determine which was taller. This requires an inference that, for example, Tower A < rod < Tower B, therefore Tower A < Tower B. It also requires certain strategies and a knowledge of measuring techniques, which might account for understanding developing relatively late.

There have been many subsequent attempts to develop assessments of transitivity that are more appropriate for young children. Braine (1959) developed a nonverbal assessment, but this was criticized by Smedslund (1963), and Miller (1976) concluded that it did not resolve the issue.

However, an alternative assessment technique, developed by Bryant and Trabasso (1971), has proved influential. Children were taught relations between color-coded sticks, of varying lengths, such that A < B, B < C, C < D, D < E. Extensive training was used to ensure that the premise information was retained. Then the children were tested on all possible pairs, A ? B, A ? C, . . . B ? C, D ? E, being asked to supply the relation indicated by the question mark. The crucial comparison is B ? D because it was not taught in training, and it avoids false positives that might result from pairs that involve end elements, such as A ? B, and that can be answered by the nontransitive strategy of noting that A is (always) large (or E is small). On the B ? D pair, 3- and 4-year-old children performed above chance. This finding was widely accepted as problematic, not only for the Piagetian finding that transitive inference ability developed in late in childhood, but also for Piagetian stage theory because transitivity had been identified with the concrete operational stage, the onset of which was claimed to occur around 7 to 8 years. An extensive literature resulted from controversies that developed about this issue (see reviews by Breslow, 1981; Halford, 1982, 1989; Thayer & Collyer, 1978).

However, the controversy about the age of attainment of transitive inference ability, though undoubtedly important, was probably not the most far-reaching implica-

tion of this work. Riley and Trabasso showed that both adults and children performed this task by assembling the elements into an ordered array (Riley, 1976; Riley & Trabasso, 1974; Trabasso, 1975, 1977) and that performance was affected by both serial position and symbolic distance effects. To demonstrate the latter, one element, F, was added to the set, so that E < F was represented. This permitted inferences B < D or C < E to be contrasted with B < E, while still avoiding end elements. Inferences B < D and C < E both require one step (i.e., B < C and C < D → B < D or C < D and D < E → C < E) whereas B < E requires two steps (B < C and C < D → B < D: B < D and D < E → B < E). Logical reasoning analysis predicts that the two-step inference would be harder because of the extra reasoning step required. However, the results indicated that the two-step inference, B < E was easier, with both greater accuracy and shorter latencies. The greater ease is due to the symbolic distance effect; it is easier to recognize B < E because they are more widely separated in the cognitive representation of the series.

This finding is important because it shows that transitive inference is not necessarily, or even typically, performed by application of logical inference rules, but by a process that is more appropriately identified with mental models. That is, the ordered array A < B < C < D < E (< F) serves as a mental model of the elements in the task and the relations between them. Such an ordered array would greatly facilitate learning the premise pairs. Once the array is constructed, any comparison between two elements can be read off from it by a simple memory retrieval process that is almost perceptual (Thayer & Collyer, 1978). Furthermore, essentially the same processes were used by participants aged from 4 years to adulthood. Insofar as this solution is based on heuristics, it bears a resemblance to the reasoning phenomena discovered by Kahneman, Slovic, and Tversky (1982), and it tends to argue against logical reasoning models of human inference and more in favor of the mental models approach advocated by Johnson-Laird (1983).

The processes that Riley and Trabasso found to be employed in this task might reflect the procedure, which entailed extensive training on the premise pairs. However the model of Sternberg (1980) based on a more conventional presentation of premises, produced similar conclusions. The Sternberg model provides a detailed account of transitive reasoning processes, including interpreting the premises and producing a representation of the ordered array, and accounts for a high proportion

of variance in solution times. As with the work of Riley and Trabasso reviewed earlier, essentially the same processes were used by children and adults.

This finding was a powerful argument against Piagetian stage theory, which held that each stage of cognitive development was characterized by a different psychologic, which implied different reasoning processes. Thus research on transitivity in this era added to evidence that cognitive development was continuous rather than discontinuous, and was more a matter of adjusting parameter values than qualitative changes.

The discovery that both children and adults performed the task by constructing a mental model in the form of an ordered array raises the question of whether the task can be used as an indicator of logical reasoning ability, given that logical reasoning does not appear to have been employed. Further reflection indicates that the issue is not so simple. The construction of an ordered array appears to entail implicit use of the transitivity principle in some form because transitivity of an asymmetric binary relation is a defining property of an ordered set. If we assume that construction of the ordered array demonstrates some grasp of transitivity, then we have to conclude that the training phase of Bryant and Trabasso's (1971) procedure was the true test of transitivity, because the array was constructed initially to learn the premises. Consequently, we have to examine the training phase to determine whether it constitutes a valid test of transitivity.

Two features of the training procedure might have inflated estimates of children's transitive reasoning. The first was that premise pairs were initially presented in ascending or descending order ($A < B$, $B < C$, $C < D$, $D < E$ or the reverse) and this would undoubtedly have helped children order the premise elements correctly. Second, children who failed to learn the premises were eliminated, but these children may have been unable to order the premise elements and thus failed because they did not have the necessary intuitive grasp of transitivity. When these factors were eliminated, preschool children failed on the task (Halford & Kelly, 1984; Kallio, 1982). Consequently, it is doubtful whether the Bryant and Trabasso paradigm demonstrates transitivity in children under 5 years, although Adams (1978) confirmed their major findings for 5-year-olds. Notice that doubt is also raised as to whether performance of children under 5 years is qualitatively similar to that of older children and adults. Before we can address such questions, we have to find out why young children have difficulty with this task.

One problem with the Bryant and Trabasso (1971) assessments is that they are based on extensive training in the premise relations ($A < B$, $B < C$, . . . etc.). This was done to ensure that false negatives did not occur due to forgetting the premises. Such extensive training, involving many repetitions of the premises (often hundreds) is atypical of transitive inference problems, and of reasoning problems generally, which usually entail a single presentation of the premises. The repetition might distort the reasoning processes, and it is not justified to assume that inferences based on multiple presentations are equivalent to those based single presentations.

A more appropriate procedure was developed by Pears and Bryant (1990). Premises were presented as pairs of colored blocks, one above the other (A above B , B above C , C above D and D above E) but with the pairs arranged randomly to avoid any cues about the correct order of elements in the integrated array. This presentation provides a mnemonic aid to guard against false negatives due to memory failure. Children were required to build a tower with another set of blocks of the same color as those in the premises, and with a top-down order consistent with the premises (A above B above C above D above E). Four-year-olds were able to perform significantly better than chance, though the levels of performance were not high.

These findings appear to show that children understand transitive inference considerably earlier than suggested by Piaget, yet the failure of many children under 5 years, including virtually all children below 4 years, suggests there may be a problem for young children in understanding transitivity. The question is: What is this problem? Early analyses by Chapman and Lindenberger (1988) and Halford (1982) as well as an empirical study by Oakhill (1984), suggested that working memory load might be a factor in transitive inference.

To assess this question, we will briefly consider some of the adult transitive inference literature, because it contains evidence that transitive inference imposes a relatively high processing load (Foos, Smith, Sabol, & Mynatt, 1976; Maybery, Bain, & Halford, 1986). The cause of the load is that, when premises must be integrated in working memory, information from both premises must be processed in a single decision. This phenomenon is accessible to introspection. Consider the premises: *John is taller than Mike; Peter is taller than John*. We need to consider both premises to assign any element to a slot in an ordered array. The premise *John is taller than Mike* enables us to assign John to the first

or second slot, but we need the premise *Peter is taller than John* to determine that John should be assigned to the second slot. Similarly, we need both premises to determine the correct assignment of the other elements. Premise integration is responsible for many errors in reasoning about ordinal position of elements in a series (Foos et al., 1976). It also produces load effects in adults as determined by probe reaction times (Maybery et al., 1986), and it is sensitive to frontal lobe functioning (Waltz et al., 1999).

Markovits, Dumas, and Malfait (1995) suggested a strategy that might make the Pears and Bryant task simpler than intended. If children first identified the relevant premises, B above C, and C above D by the presence of the common term C, they might recognize that B should be above D because of their relative position in these premises. They modified the premise presentation by including neutral white blocks so the premises were presented as White above A, A above B, and B above C, C above White, thereby neutralizing the effect of the relative positions of the critical elements A and C in the physical displays. With this presentation, success was not achieved until about 8 years. On the other hand, participants might have found it difficult to interpret the white blocks, given that they had no relation to the elements that had to be ordered. Markovits et al.'s hypothesis is reasonable, but it would imply that the task was reduced to processing a binary relation between B and D (or A and C) based on their ordinal positions in the display. However Andrews and Halford (1998) found a clear differentiation between tasks based on binary relations and those based on ternary relations, with all children 4 years and above succeeding on the former, but success on ternary relations occurred at a median age of 5 years.

In adults, the processing load of premise integration produces errors and increases decision times, but the task is performed with high accuracy. But what effect does this load have on reasoning of young children? Andrews and Halford (1998, 2002) presented premises in a similar manner to Pears and Bryant (1990) but controlled the amount of premise information required to perform the task. In the binary-relational condition, children were required to build a tower by placing pairs of blocks in accord with one premise at a time (e.g., place B above C in accordance with the premise, then add D, producing the top-down order B, C, D). As each premise represents one binary relation, this requires only one binary relation to be processed in each step. In

the ternary-relational task, children were required to place blocks B and D in the correct order. To recognize that B should be placed above D, two premises—*B above C* and *C above D*—have to be processed to determine that the top-down order is BCD, from which B above D can be deduced. This task entails assigning three blocks to ordinal positions in a single decision, and therefore is ternary-relational (Andrews & Halford, 1998; Halford, 1993). Whereas success rates were high for 4-year-olds on binary-relational problems, transitive inferences requiring ternary relations were made by 20% of 4-year-olds and 50% of 5-year-olds (Andrews & Halford, 1998). This is consistent with the findings of Pears and Bryant (1990).

A procedure that permits elements to be ordered by considering one binary relation at a time can produce very different processes from those that are required for ternary relations. This is especially true where premises are presented multiple times. If the pairs $A < B$, $B < C$, $C < D$, $D < E$ are presented repeatedly, it is possible to detect that A is always *less* and that E is always *more*, so A and E can be detected as end elements. Having recognized (say) A as an end element, then B can be concatenated with it by processing the relation $A < B$, yielding the sequence AB. Now C can be concatenated with the set by processing $B < C$, yielding ABC, and so on. Thus the entire sequence can be constructed using only one binary relation at each step. By contrast, when BD must be ordered by reference to the premises, the relations $B < C$ and $C < D$ must be integrated in working memory to produce the ordered triple BCD, and this imposes a higher processing load. Thus these two procedures can induce very different processes and impose different processing loads.

The finding of Andrews and Halford (1998) implies that the structural complexity of transitive inference may be a factor in the difficulty that young children have with it. The requirement to process both premises in a single decision places a limit on segmentation, because neither premise can be processed fully without taking the other premise into account. This means that transitive inference is in the category of tasks that are difficult because they cannot be readily segmented into subtasks. An alternative explanation might be that children under 4 to 5 years lacked the requisite strategy for integrating the premises. There are factors that cast doubt on this explanation. First, processing load effects were found in university students by Maybery et al. (1986) even after hundreds of trials with the same pro-

cedure, which strongly suggests that load is a factor in the task, even if not the whole explanation. Second, Andrews and Halford (2002) found similar age norms for transitivity and ternary-relational tasks in other domains, and it would be very difficult to explain the difficulties of young children in this diverse set of tasks in terms of a strategy. It seems reasonable to conclude therefore that structural complexity, as measured by the relational complexity metric, is a factor in the difficulty that young children have with transitive inference. There is also the problem that strategy development itself needs to be explained, and it, too, may be a function of structural complexity.

Development of transitive inference strategies was modeled by Halford et al. (1995). Strategies were guided by a mental model of an ordered set, based on experience with ordered sets of at least three elements. The architecture of the model was based on a self-modifying production system. Early strategies processed only one relation at a time, but this led to error, resulting in weakening of the productions responsible and development of new ones that took account of two relations.

A significant change to our understanding of the transitive inference process was made by the fuzzy trace model of Reyna and Brainerd (Brainerd & Kingma, 1984; Reyna & Brainerd, 1990). The essential idea is that transitive inference ability is independent of ability to recall literal premise information. Children's performance on transitive inference and memory probe tasks was more consistent with a fuzzy, gistlike memory trace than with verbatim recall of premises (Brainerd & Kingma, 1984). This means that, instead of literally recalling ordered arrays such as $A < B < C < D < E (< F)$, as suggested earlier, children stored global patterns such as "things get larger from left to right." Memory for literal premise information occurs only where the reasoning task requires it. Memory-reasoning independence seems surprising at first, but it is well established in reasoning domains (Brainerd & Reyna, 1993). An important implication of fuzzy trace theory is that different forms of the transitive inference problem will entail different types of memory trace.

An additional process has been inserted into transitive inference models by Wright (2001), who postulated a mechanism called the "transitive-switch" that determines whether a relation is transitive. This would avoid erroneous transitive inferences based on nontransitive relations, such as loves. This mechanism can be

based on implicit knowledge about whether a relation is transitive. One type of cue as to whether a relation is transitive is whether it is represented by a verbal label that contains the suffix *er*, such as *taller*, or is preceded by a quantitative adjective such as *more* as in *more popular*. Wright also suggests that the creation of an ordered representation may entail either a low-level associative process, or a cue-based process that is somewhat reminiscent of Sternberg's (1980) model. For example, the premise *John is taller than Mike* might be coded as *John is tall+; Mike is tall*, then these linguistic deep structural base strings are integrated to form the ordered array.

Transitivity of Choice and Learning of Order

The Bryant and Trabasso paradigm has been adapted for use with nonhuman animals. A seminal study was that of McGonigle and Chalmers (1977) who trained squirrel monkeys to choose one member of each pair in a series ($A + B -, B + C -, C + D -, D + E -$, where $[+]$ indicates a rewarded choice and $[-]$ indicates it is nonrewarded). To assess transitivity of choice, they were tested on untrained nonadjacent pairs, with most interest focusing on B and D , because $B+$ and $B-$ had occurred equally often in training, as had $D+$ and $D-$, and because the animals had not been trained on that pair. Monkeys showed a 90% preference for B over D , and basically similar data have been found with species ranging from pigeons (von Fersen, Wynne, Delius, & Staddon, 1991) to chimpanzees (Boysen, Berntson, Shreyer, & Quigley, 1993) and human children (Chalmers & McGonigle, 1984).

There is evidence that at least some transitivity of choice tasks are performed by associative processes, without representation of structure. McGonigle and Chalmers (1977) found reduced performance on triads, so monkeys were much less efficient at choosing B in the presence of C and D than in the presence of D alone. This would not be expected if the task were performed by integrating representations of relations, as described for transitive inference tasks. If the task were performed by integrating relations such as $AB, BC \dots DE$ to form an ordered array A, B, C, D, E , as proposed for transitive inference, then it would be predicted that if B is preferable to D it should be preferable to C and D together, because B occurs earlier in the series than both. Other investigations have also raised doubts as to whether transitivity of choice is comparable with the transitive inference paradigm. Wynne (1995) applied

the Bush and Mosteller (1955) and Rescorla and Wagner (1972) models to data reported by von Fersen et al. (1991). These associative learning models predicted transitive choice (B versus D), plus serial position effects and the symbolic distance effect (better discrimination between elements further apart in the series). Other work corroborates this conclusion. Couvillon and Bitterman (1992) demonstrated that transitivity of choice data can be accounted for by simple associative learning models. The production system model of Harris and McGonigle (1994) is compatible with associative learning accounts. In their model, each production rule expresses a tendency to select or avoid a given stimulus. The surface form of the model appears different from associative learning accounts of transitivity of choice, but the model is consistent with associative models in that it attributes performance to the strength of the tendency, acquired as a function of experience, to respond to each stimulus. All these models are associative in the sense that they postulate response tendencies associated with stimuli, without transformation or composition into more complex structures.

There are other reasons to distinguish transitivity of choice from the transitive inference paradigm. Whereas transitive inference implies an ordinal scale of premise elements, in transitivity of choice there is no such scale underlying the relationship (Markovits & Dumas, 1992). Furthermore, the transitive inference task is performed dynamically in working memory, following a single presentation of premises, whereas transitivity of choice is based on representations created incrementally over many trials, and can be performed by associative processes.

The sensitivity of these paradigms to changes in procedure is demonstrated by a major difference in performance that can be produced by the seemingly trivial change of adding a pair to a series. If the pair F + X- is added to the series X + A-, A + B-, B + C-, C + D-, D + E-, E + F-, the structure becomes circular rather than linear, because the series implied by the pairs is closed. With pigeons, this causes reduced, but still above chance, discrimination of adjacent pairs, performance on the test pair BD is no longer better than chance, and serial position effects disappear (von Fersen et al., 1991). The task can no longer be learned by elemental association, but it can be learned by configural association. Both the Bush-Mosteller and Rescorla-Wagner models predict chance responding on all pairs (Wynne, 1995) because every element is

equally associated with reinforcement and nonreinforcement (in the preceding set of pairs, each of A, B, C, D, E, F, X occurs with [+] and [-]). However, the observed effects are predicted by a configural learning model in which a stimulus (say B) that acquires associative strength in the presence of C (B|BC) is different from the stimulus that loses associative strength in the presence of A (B|AB) (Wynne, 1995). Each pair is learned as a separate discrimination, and nothing is learned that corresponds to the circular structure of the series. This study illustrates how very similar procedures, in this case differing only in the presence or absence of the pair F + X-, can produce markedly different performances.

Terrace and McGonigle (1994) found evidence that children and monkeys form a linear representation of a list of stimuli, whereas pigeons did not. Participants were trained by the simultaneous chaining paradigm in which they were trained to respond first to A, then to A followed by B, then to A followed by B followed by C, and so on. The physical configuration was varied from trial to trial to ensure responding was based on a sequence of elements rather than to a spatial pattern. Having learned the sequence A, B, C, D, E, pigeons responded correctly to sequences of nonadjacent elements provided they included an end element, such as the sequences AB, AC, AD, AE, . . . , DE. This appears to be consistent with the associative processes demonstrated by Wynne (1995) in the transitivity of choice paradigm. However, when required to respond to a pair of items from a list, latencies of monkeys and children, but not pigeons, were a function of distance from the beginning of the list, suggesting that the representation of the list was searched to locate the ordinal position of each item.

Holcomb, Stromer, and Mackay (1997) trained 4-year-old children in overlapping two-stimulus sequences (A > B, B > C, C > D, D > E, E > F) using a procedure similar to that of Terrace and McGonigle (1994). They then tested them in two-stimulus sequences (e.g., B > D, B > E, . . . , A > C, . . . , A > E), and longer sequences (e.g., A > B > C, B > C > D, . . . , B > D > E). Transfer from training to test sequences tended to be high. The success of children in sequences of more than two stimuli (e.g., B > C > D) differentiates the findings from the performances of monkeys reported by McGonigle and Chalmers (1977). The results are consistent with an integrated representation of an ordered set, and associative processes do not appear to be sufficient to account for the performances. The study is important for the training techniques used, which appear to be a consider-

able advance on previous methods for teaching sequences. It is not entirely clear how the sequence representations were constructed, but concatenation would appear to be possible (e.g., represent AB, then ABC).

The transitivity of choice paradigm has the merit that it permits a wide range of species and procedures to be compared within the same paradigm, and it illustrates how some complex tasks can be performed by associative learning processes. However, the number and importance of the differences between the transitive inference paradigm and the transitivity of choice paradigm suggests that it is unwise to regard them as equivalent. Despite this, it is not uncommon to refer to both as measures of transitivity, as though they were equivalent measures of the same construct. On the surface, this appears to facilitate an optimistic account of animals' and young children's cognition, by making it appear that all are capable of the reasoning underlying transitivity. In the longer term, however, such assumptions are more likely to lead to conceptual confusion. What we know nowadays about cognitive processes should at least make us wary of assuming that such different procedures induce the same cognitive processes. As we have seen, there is extensive evidence that in fact they induce quite different processes that also make very different demands on processing resources. Performance of transitivity of choice by associative learning makes minimal demands on processing capacity; whereas integration of relational representations in working memory is difficult for children under 4 to 5 years of age and produces a measurable, and persisting, processing load even with university students. It is true that transitivity of choice can be performed by children, who are likely to use associative processes, but this reflects the demands of the paradigm. It does not show that animals and younger and older children all typically make transitive inferences by the same processes. As discussed, there is evidence that different processes may be used in at least some tasks by different species, and by children of different ages. Terrace and McGonigle (1994) proposed that young children were unable to seriate objects as required in the Piagetian seriation task because their unidirectional search strategies did not develop until after 7 years, as indicated by their lack of differentiation between monotonic and nonmonotonic sequences.

The concept of the middle element in a set of three is relevant to children's understanding of an ordered set because it is defined by relations to elements on either

side (e.g., smallest < middle < largest). Rabinowitz and Howe (1994) showed that there was an improvement in children's ability to identify the middle element over the age range 5 to 10 years, although there were variations due to which dimension was used (e.g., physical size, shade of blue, body parts). Children who were trained on two dimensions were better able to transfer to a new dimension than those who were trained on one dimension, consistent with a number of findings in the analogy literature (Gholson, Eymard, Morgan, & Kamhi, 1987; Gick & Holyoak, 1983).

Relational Problems of Deduction

Research with transitivity and serial order tasks represents only a small fraction of the possibilities for inferences based on relations, but comparatively little research has been devoted to the wider topic. An encouraging start in this was made by English (1998) using problems such as the following:

There are five houses along one side of a street. Use the clues to work out who lives in the middle house.

- The Smiths live beside the Wilsons but not beside the McDonalds.
- The Jones live in the second house on the left.
- The Wilsons live somewhere between the Taylors and the McDonalds.
- The Jones live beside the Taylors. (English, 1998, p. 250)

Four principles emerged from the problem solving of 264 children from Grades 4 through 7 (English, 1998, pp. 255–256):

Principle 1: Construct an initial model by selecting a premise that most readily yields an explicit problem-situation model.

Principle 2: Integrate premises where appropriate, and select premises that can be integrated most readily with an existing model/s.

Principle 3: During the course of model development and refinement, recognize when more than one new model, or tentative solution model, is possible.

Principle 4: Verify model construction, development, and refinement during the course of problem solution.

Mental model theory (Johnson-Laird & Byrne, 1991) and relational complexity theory, discussed earlier,

were found to give a good account of the relative difficulties of different problem forms.

Relational Problem Solving

Fireman (1996) conducted a microgenetic analysis of 6- to 8-year-old children's performance on a standard 3-disc Tower of Hanoi (TOH) problem. The TOH has three pegs and discs that vary in size. The goal is to shift all discs from peg A to peg C by shifting only one disc at a time, and without ever placing a larger disc above a smaller one. The task, together with the somewhat similar Tower of London task (Shallice, 1982), has been extensively used for research in problem solving with adults (VanLehn, 1991) and children (Klahr & Robinson, 1981). Fireman found that children's success depended largely on whether they made a transition from indeterminate actions (moves that were legal but inefficient or suboptimal) to an adequate solution plan. This transition required strategy development rather than strategy selection. Developing a successful plan entails processing embedded relations between discs and pegs in the task. For example, in order to move disc 3 (largest) from peg A to peg C, it is necessary to move discs 1 and 2 to peg B, and in order to move disc 2 to peg B it is first necessary to move disc 1 to peg C. Development of an efficient strategy requires that as much as possible of this structure be represented. The complexity of steps in a TOH problem can be quantified by relational complexity theory (Halford, Wilson, et al., 1998, Section 6.1.3).

Cohen (1996) studied strategy in 3- to 4-year-olds using a "play store" task in which the goal was to provide specific numbers of tomatoes, starting with different configurations. For example, if the order was for four tomatoes and there was a carton that already contained three tomatoes, the optimum strategy was to add one tomato, but if there was a carton with five tomatoes, subtraction of one tomato was the optimal strategy. Children's strategies quickly became more efficient, as indicated by reduced numbers of unnecessary moves.

Fast Mapping and Exclusivity

Although fast mapping might not normally be interpreted as relational reasoning, it does appear to entail understanding of the relation of exclusivity. There is evidence that 2-year-old children understand this binary relation (Markman & Wachtel, 1988). A child who

knows the meaning of "cup" and is shown a cup and a painter's palette, then asked, "Which one is the pilson?" tends to choose the palette. The child understands that if "pilson" and "cup" each refer to one of the objects (the "exclusivity" bias) and knows which object is the referent of "cup," it follows that the other object is the referent of "pilson." We could interpret this as indicating that children represent a binary relation of exclusivity that has two slots; exclusive (-,-), and the words are mapped into these slots, which is another case of analogy. If one object fills one slot, the other object fills the other slot. Furthermore, the representation is established dynamically, following a single presentation.

Logical Deduction and Induction

Two of the topics that have been most extensively studied with children are conditional reasoning and causal reasoning. Both of these are examined in the chapter on adolescent reasoning by Kuhn and Franklin (Chapter 22, this *Handbook*, this volume). Because reasoning based on mental models is a major theme of this chapter, we will consider how it applies to conditional reasoning.

Mental Models in Conditional Reasoning

A conditional is an expression of the form p implies q , or if p then q , written symbolically as $p \rightarrow q$. There are four possible argument forms, two of which are valid and two are fallacies. The valid forms are modus ponens ($p \rightarrow q, p$, therefore q) and modus tollens ($p \rightarrow q, \neg q$, therefore $\neg p$). The invalid forms are, denial of the antecedent ($p \rightarrow q, \neg p$ therefore $\neg q$), and affirmation of the consequent ($p \rightarrow q, q$ therefore p). Much research has been devoted to determining whether children distinguish valid from invalid argument forms, the influence of a number of variables, especially problem content, on their reasoning, and the processes they use to make their inferences.

Content affects syllogistic reasoning through the belief bias effect, in which prior knowledge and beliefs about the world tend to influence conclusions (Simoneau & Markovits, 2003). However, even young children show some ability to make inferences from contrary-to-fact premises. Richards and Sanderson (1999) showed that 2- to 4-year-olds were capable of counterfactual thinking if they were encouraged to use their imagination (e.g., to imagine that the counterfactual premises were true on another planet).

Mental model theory has enjoyed considerable success in accounting for reasoning processes in adults (Johnson-Laird & Byrne, 1991) and has been reformulated to account for most findings in development of conditional reasoning by Markovits and Barrouillet (2002). Mental models are iconic representations of the premises that have the status of analogues, as discussed in the introductory sections of this chapter. For conditional reasoning, the major premise $p \rightarrow q$ would be represented initially as follows:

$p \quad q$
...

The first line represents a state of affairs in which p and q are both true, and there is a link between them. The dots on the next line represent implicit recognition that other possibilities exist. According to the model of Markovits and Barrouillet (2002) the representations will be fleshed out to give explicit representation of other possibilities as follows (where $\neg p$ represents “not p ”):

$p \quad q$
 $\neg p \quad \neg q$

This corresponds to a biconditional interpretation of the major premise, that is p implies q and q implies p ($p \leftrightarrow q$). Then the representation is further fleshed out as follows:

$p \quad q$
 $\neg p \quad \neg q$
 $\neg p \quad q$

This corresponds to the canonical interpretation of a conditional (it is isomorphic to the truth table for a conditional). It does not correspond to a biconditional interpretation because it implies $p \rightarrow q$ but not $q \rightarrow p$.

The fleshing out is performed by retrieving information from semantic memory about relations that are appropriate for the content of the problem, using the minor premise as a supplementary retrieval cue. The fleshing out is governed by availability of examples in semantic memory and by the complexity of the resulting representation. Predictions are made by examining what inferences can be made by fleshing out the mental model in different ways.

Markovits and Barrouillet (2002) assume that children of 5 to 7 years will only be able to add one relation

to the simplest model, so they can flesh it out in one of two ways, depending on the minor premise. Modus tollens and denial of the antecedent entail minor premises that include negations, so they tend to activate the complementary class in semantic memory. The children can then retrieve a case of $a \rightarrow \neg q$, where a is an element that is different from (“alternative to”) p , and \rightarrow represents some kind of relation or link between a and $\neg q$. Thus the model is expanded as follows:

$p \quad q$
 $a \rightarrow \neg q$

This is equivalent to a biconditional interpretation. This would yield correct inferences in the form of modus ponens because when p is true, q is true, and modus tollens because when $\neg q$ is true, $\neg p$ (a) is true. However, it also yields inferences of the form affirmation of the consequent, because it does not represent cases where q is true, but $\neg p$ is true.

If the minor premise is “ q is true,” this will activate cases of elements that are linked to q , yielding the model:

$p \quad q$
 $b \rightarrow q$

where b is different from p . This will lead to the correct inference that if q is true, it is uncertain whether p is true or not true, so affirmation of the consequent will be rejected. Similarly, denial of the antecedent will be rejected because cases of $\neg p$ and q are represented. Retrievability from memory will depend on the content of the premises, so if the major premise were “if an animal is a dog then it has legs,” children can easily retrieve alternative cases such as “cats have legs,” “horses have legs.” Therefore, the theory predicts that resistance to denial of the antecedent and affirmation of the consequent will depend on the ease with which alternative cases can be retrieved. This is consistent with findings of content effects (Barrouillet & Lecas, 2002; Markovits et al., 1996). Manipulations that encouraged production of alternative conditions led to more rejection of affirmation of the consequent and denial of the antecedent inferences (Simoneau & Markovits, 2003). Disabling conditions (Cummins, 1995) can also be retrieved from semantic memory, possibly leading to rejection of modus ponens inferences. For example, if the major premise were “if it rains, the street will be wet”

and the minor premise is “it is raining” then the correct inference is “the street is wet.” A disabling condition might be “the street is covered (e.g., by an overpass)” in which case the inference will be rejected. The strength of association of disabling conditions has an effect on conditional reasoning (De Neys, Schaeken, & d’Ydewalle, 2003).

The theory of Markovits and Barrouillet has been applied to both class-based conditionals, where the major premise is in the form “All A are B” and causal conditionals, such as “If a rock is thrown at a window, the window will break.” Causal conditionals require more complex processing, according to the theory, because of the requirement for a naive theory to generate alternative and disabling conditions. It has also been applied to inferences based on premises that are contrary to world knowledge, such as: “If a car has lots of gas, then the car will not run.” (Simoneau & Markovits, 2003, p. 971). If the minor premise is “The car has lots of gas,” the correct (modus ponens) inference is that the car will not run. This requires that world knowledge must be inhibited. Simoneau and Markovits (2003) showed elegantly that there is an interaction between memory retrieval and inhibition. Older adolescents, who have more efficient retrieval, were more likely to reject modus ponens inferences, even though instructed to suppose that the major premise is true, because they are more likely to retrieve disabling conditions. Thus their reasoning is less logical than that of younger adolescents. When the adolescents were first given a contrary-to-fact problem, there was less tendency to reject the modus ponens inference. The contrary-to-fact problem helped participants to inhibit disabling conditions retrieved from memory.

The theory of Markovits and Barrouillet (2002) accounts for many findings of the effects of premise content on conditional reasoning. Even some studies that are not specifically interpreted by Markovits and Barrouillet appear to be consistent with it. For example, the effect of fantasy, as observed *inter alia* in the study by Richards and Sanderson (1999), or the effect of instruction as observed by Leevers and Harris (1999), could be interpreted as inhibiting retrieval of knowledge from semantic memory. It also makes many novel predictions, such as that belief bias interacts with other features of the task (see Markovits & Barrouillet, 2002, pp. 23–30).

The theory is also consistent with processes that have been found to have wide applicability in cognition and

cognitive development, including analogy theory, mental model theory, retrieval from semantic memory, and cognitive complexity theory. Although the theory is limited to inferences made from premises and has not so far been applied to related tasks such as the Wason selection task, it takes an important step toward providing greater theoretical coherence in the field and generates many useful predictions. Such theories can do a lot to sharpen research issues.

Other issues go beyond the developmentally reformulated mental model theory. One of these concerns the important issue of conversational implicatures and their effect on inferences. Noveck (2001) showed that 7- to 9-year-olds are more likely than adults to adopt the logical interpretation of *might be x* as including *must be x* rather than the conversationally pragmatic interpretation *might but not must*. However mental model theory can presumably accommodate conversational implicatures in terms of their influence on the construction of mental models representing the premises. There appear to be possibilities for further theory and empirical research here.

Logical and Empirical Determinacy

The ability to recognize determinacy of inferences is important in both scientific and everyday reasoning. An inference is *logically determinate* when the conclusion necessarily follows from the premises because of the logical form of the argument. Modus ponens, $p \rightarrow q$, p therefore q , is a valid argument form and the conclusion, q , is necessarily true, given the premises $p \rightarrow q$ and p . Affirmation of the consequent, $p \rightarrow q$, q , therefore p , is not a valid argument form because the conclusion, p , is not necessarily true. There is considerable evidence that both children and adults find it difficult to determine when an argument is logically determinate. Johnson-Laird (1983) has shown that people tend not to check whether a mental model is the only one implied by the premises, so they sometimes fail to recognize that a conclusion that follows from the first mental model they construct is not necessarily true because it is not true in alternate models. There is considerable evidence that recognition of logical determinacy tends to develop later in children than ability to make inferences (Markovits, Schleifer, & Fortier, 1989; Moshman & Franks, 1986; Osherson & Markman, 1975). Ruffman (1999) showed that children under 6 years did not understand logical consistency, even though

they could remember the premises, which were presented in a variety of formats, and could recognize factual inconsistency. An interesting finding was that understanding of logical consistency was positively related to number of older siblings in the family.

Reasoning is *empirically determinate* if a verbal description of a situation is consistent with only a single state of affairs. Again, however, there appear to be limitations to children's ability to recognize empirical determinacy. One reason for failure is a "positive capture" strategy in which one possibility is accepted without checking alternatives. Another is children's imperfect understanding of logical connectives *if*, and *or* (Braine & O'Brien, 1998). A third is that children do not recognize the need to distinguish between logical and conversational pragmatic interpretations of statements. An example is that "some" in conversation usually means "some but not all" because conversational implicatures (Grice, 1975) mean that if one meant "all," one would not say "some"; but logically "some" is interpreted as "some or all." These difficulties appear consistent with the limitations observed by Johnson-Laird in adult reasoning and are not unique to children.

Morris and Sloutsky (1998, 2002) showed that children below 11 to 12 years did not distinguish between logical and empirical problems because they did not fully represent the state of affairs implied by the propositions, but tended to base conclusions on only the first part of the evidence. Furthermore, some individuals showed this pattern consistently across a set of problems, suggesting that its occurrence was systematic rather than random. A possible benefit of the strategy is that it reduces processing load, but prolonged instruction led to improved performance. Fay and Klahr (1996) and Klahr and Chen (2003) have found that much younger children recognize empirical determinacy in some contexts, such as that a necklace of red beads must have been made by beads from a particular box if it was the only one containing red beads, but that the box used is indeterminate if more than one box contains red beads. However, 4- to 5-year-olds showed a pronounced positive capture strategy and training was more effective with 5- than with 4-year-olds. English (1997) showed that preadolescents improved their recognition of indeterminacy if they received training that induced both acceptance of lack of closure and construction of more complete models, but not if they received only one.

SCIENTIFIC AND TECHNOLOGICAL THINKING

Scientific reasoning applies to some specialized domains, but it also offers insights into the nature of reasoning processes in general and the way they develop. We will consider some of the major domains in which the development of scientific concepts has been researched. Again, reference should be made to the chapter on adolescent reasoning by Kuhn and Franklin (Chapter 22, this *Handbook*, this volume).

Basic Dimensions and Their Interrelations

The basic dimensions of the physical world include time, distance, speed, mass, specific gravity, and heat. There are interrelations between the basic dimensions: Speed = Distance/Time, area is length \times breadth, volume is length \times breadth \times height, heat is temperature \times specific heat \times mass, and so on. Understanding these basic dimensions and their interrelations is important for understanding everyday and scientific phenomena. Early research into these concepts was influenced by Piaget and his collaborators, but other approaches have developed since. There are also classic treatments of the developmental psychology of time by Friedman (1978, 1982).

Time, Speed, and Distance

Siegler and Richards (1979) applied the rule assessment technique to time, distance, and speed, and found a progression over three levels of rule in 5- to 11-year-olds. At the lowest level, Rule I, children based their judgments on a single factor such as stopping point; at Rule II, they considered a second factor if situations were equal on the first factor (stopping times if stopping points were the same); and at Rule III, they considered all variables. Wilkening (1981) and Wilkening, Levin and Druyan (1987) used information integration theory, using a turtle, guinea pig, or cat to represent different speeds. The animals were run for different distances or times, and children were asked to estimate the remaining variable. It was found that 5-year-olds combined time and speed multiplicatively in their estimates of distance, but they combined distance and speed additively to represent time, and used only distance to estimate speed, ignoring time. In a cross-sectional study, Matsuda (2001) had 4- to 11-year-old children judge

relations between all three variables using toy trains traveling at varying speeds down tracks of varying lengths for varying durations. The younger children tended to process relations between pairs of variables, the positive relation between time and distance and speed and distance appearing first. The inverse relation between speed and time developed later, suggesting that younger children tended to base their judgments on a “more is more” relation, and only later differentiated this from the “more is less” relation between time and speed. Understanding of the system defined by all three variables developed around 10 to 11 years of age. The findings were confirmed in a longitudinal study. Whereas there is consensus that more complex concepts develop later, different methodologies have yielded somewhat different age norms suggesting that although methodologies are sophisticated and sensitive, there is scope for further refinement.

A neural net model that simulates the development of velocity, time, and distance concepts has been developed by Buckingham and Shultz (2000) based on the cascade correlation algorithm. Additional hidden units were recruited as the network progressed to more advanced rules, to capture the increased dimensionality of the task. This suggests that development of the concept may depend on increased representational capacity, consistent with the suggestion of Matsuda (2001). Friedman (2003) investigated whether young children understand the unidirectional nature of some changes over time, and found that even 3- to 4-year-olds could discriminate forward and reversed presentations of breaking a cookie or dropping a block.

Area

Information integration theory has been used to study children’s understanding of area. A classic finding is that young children tend to combine length and breadth additively, whereas after approximately 5 years of age they combine them multiplicatively (Anderson & Cuneo, 1978; Wilkening, 1979, 1980). A possible explanation is that additive effects can be segmented, so one can estimate the effect of a change in (say) length, then add the effect of breadth, but dimensions that are combined multiplicatively interact and cannot be segmented. To put this another way, with multiplicative combination, the effect of change in length is modified by any change in breadth, and vice versa. Therefore, in terms of relational complexity theory, additive combi-

nation amounts to two successive binary relations (length, area) and (breadth, area), whereas multiplicative combination precludes decomposition into separate relations and has the effective relational complexity of a ternary relation (length, breadth, area). Silverman, York, and Zuidema (1984) found evidence consistent with the hypothesis that additive composition of length and breadth might reflect decomposition into subtasks.

Concept of the Earth

The concept of the earth is interesting because of its relevance to everyday thought, because it entails some complex relational concepts, and because it entails a conflict between observation and culturally transmitted information. The earth appears more flat than spherical when viewed from the perspective of a person living on the surface but we are taught, and photographs taken from space show us, that it is spherical. The resolution of this discrepancy is that the enormous diameter of the earth makes it look flat to an observer on the surface. Another naive belief is that, perhaps by analogy with familiar objects, the earth must be supported, otherwise it would fall. Cultural information, however, is that because the earth orbits the sun, it does not need to be supported. To understand this requires some kind of intuitive mental model of orbital motion, which entails complex relations, including the balance between gravitational attraction between sun and earth, and the centrifugal effect of traveling in an orbit. Another conflict is due to common observation that unsupported objects fall, and cultural information that people can stand at any point on the spherical earth, including positions that appear to be “down under.” The resolution of this depends on a more sophisticated mental model of gravity, as an attraction between two bodies. Objects fall because of attraction between the mass of the object and the mass of the earth.

Conceptual development cannot be based on simply substituting culturally transmitted information for common observation. We cannot forget or ignore that objects fall. To develop a mental model of gravity, we have to integrate observation with cultural information. This means understanding that the reason objects fall is that they are attracted toward the center of the earth. This means recognizing the correspondence between two relations: Attraction between object and earth corre-

sponds to an object falling toward the ground. Four variables make this a complex concept.¹

In general, understanding the earth involves some complex relations and higher-order relations, so complexity is inevitably a factor in understanding the concept of the earth.

Vosniadou and Brewer (1992) used a structured interview technique that included asking children to draw their conception of the earth, with first- to fifth-grade children. The children's conceptions seemed to reflect attempts to reconcile the conflicting notions previously mentioned. Children would draw a flattened sphere with people standing on top, or a hollow sphere with a horizontal platform inside for people to stand on, or even dual earths, one round and one flat. Some cultural influence has also been observed. Indian children tend to believe that the earth is supported by a body of water, a notion that is not observed in American or Australian children (Samarapungavan, Vosniadou, & Brewer, 1996). There are many similarities between conceptions in different cultures (Candela, 2001). This is possibly because there is a strong logic inherent in the nature of the earth and its relations to other cosmological bodies, as well as to such phenomena as the day-night cycle, seasons, and the effect of gravity.

Vosniadou and Brewer found evidence of mental models with some degree of coherence. If children thought that the earth was spherical, they were less likely to think it was possible to fall off the edge. However, the mental models interpretation has been challenged by Nobes et al. (2003), who found fragmented knowledge with 4- to 8-year-olds. Fragmentation may be typical of young children's conceptions, but on theoretical grounds it is hard to see how a concept of the earth could develop without some conceptual coherence. How

can we understand that the earth is spherical without recognizing that its flat appearance is due to its large diameter, or that gravitational attraction between the earth and objects explains why people can stand at any point on the surface. The finding by Hayes, Goodhew, Heit, and Gillan (2003) that children only progressed toward a spherical conception of the earth if they received instruction about both the size of the earth and gravity, seems to be consistent with the coherence theoretical view. Consistency of answers might be a function of the method of questioning. Vosniadou, Skopeliti, and Ikospentaki (2004) found that forced choice questioning increased the number of scientifically correct answers, but there was more internal consistency among answers elicited by an open method.

Balance Scale

The balance scale comprises a beam balanced on a fulcrum with equally spaced pegs on each side on which weights can be placed. It was widely used in Piagetian investigations of cognitive development; but independent of specific theories, it is important theoretically and methodologically as a medium for studying children's understanding of proportion, and of the interaction between four variables. The past quarter century has seen considerable theoretical and methodological development, probably spearheaded by Siegler's (1976, 1981) rule assessment analysis. Siegler identified four rules: With Rule I, children consider only weights; with Rule II, they also consider distance, but only if weights on the two sides are equal. With Rule III, they consider weight first, then distance; but they have difficulty if the greater weight occurs on one side and greater distance on the other. With Rule IV, the torque principle is applied, according to which the side with the greater torque, defined as the product of weight and distance, went down. If torques on the two sides are equal, the beam balances. Children progressed from Rule I at age 5 to Rule III in adolescence. Rule IV tended to be rare, even in adults.

Surber and Gzesh (1984) conducted an information integration theory analysis. They found that 5-year-olds tended to use distance rather than weight, but in other respects children's progression was consistent with that found by Siegler. Information integration methodology can distinguish whether weight and distance are combined multiplicatively or additively, as noted earlier,

¹There is a correspondence between falls-toward (object, ground) and attraction-between (object, earth). The first relation occurs because of the second, so *because* is a higher-order relation linking the two binary relations. According to relational complexity theory analyses, there are four variables corresponding to the two slots in each binary relation. Conceptual chunking or segmentation might reduce the processing load here, but this can only happen after the concept has developed. Consequently, development of a mental model of gravity is likely to prove difficult for young children, though it should be possible to devise teaching techniques that would give them a partial understanding.

and not even adults used the correct multiplicative combination consistently. Surber and Gzesh also found that children tended to use a compensation rule, according to which balance could be achieved by changing one dimension to compensate for a change in the other dimension, rather than Siegler's Rule III. The compensation rule is essentially an additive rule.

More recent research has resulted in some modifications of a rule-based conception. Jansen and van der Maas (2001) found that there is a discontinuity in the transition between Rule I and Rule II, as defined by the cusp model, a derivative of catastrophe theory. Rule II may require the ability to encode a second variable (Siegler & Chen, 1998), and this might entail a shift to a qualitatively different, or at least more complex, cognitive process. Latent class analyses by Jansen and van der Maas (2002) showed that children use rules, but not always consistently, and there was evidence of an additive rule in place of Siegler's Rule III. Their findings were consistent with Siegler's overlapping waves model of development, implying that rules are not used exclusively, but children of a given age might use more than one rule. They, too, found evidence that some transitions between rules were discontinuous.

Most studies have used response accuracy, or response patterns, as the dependent variable but van der Maas and Jansen (2003) used response times. Cluster analysis yielded six categories of performance, corresponding to Siegler's four rules, plus a compensation rule and a category that could not be interpreted as any rule. An apparently paradoxical finding was that young adults were slower to solve balance scale problems than children, due to using more complex rules. There were also some findings that modified the way the rules were originally defined. Children using Rule II considered distance on all items, not only when weights were equal, but they did not know how to combine it with weight. It was also found that whereas response patterns tended to be homogenous for items of a given type (as found in previous rule assessments), response times were not necessarily homogeneous.

Boom, Hoijtink, and Kunnen (2001) also used latent class analysis and found six classes of responses, two of which did not correspond to rules. They also suggested that development of the balance scale concept might entail both discrete and more gradual transitions. Rules might provide a somewhat idealized account of children's concept of the balance scale, but categorization into just four rules might reflect the restricted number

of item types used in early studies and the restriction of the data to response patterns rather than decision times. More recent statistical assessments have indicated a more complex picture.

Children as young as 2 to 3 years have some understanding of the balance scale. Discriminations of weights with distance constant, or distances with weight constant, entail representing the binary relation between two weights, or two distances, according to relational complexity theory (Halford, Wilson, et al., 1998). These discriminations should be possible at the age when other binary-relational concepts are mastered (Halford, 1993). Items that entail integration of weight and distance require at least ternary-relational processing; this should be mastered by 5 years and should be predicted by other performances at the same level of complexity. These predictions were confirmed by Halford, Andrews, Dalton, Boag, and Zielinski (2002). Complexity theory was instrumental in the discovery of previously unrecognized abilities in young children, but the weight and distance discriminations, while better than chance, were not as systematic as the rule-governed behavior displayed by 5-year-olds, and are most appropriately interpreted as precursors. Note that making the apparatus and procedure more child friendly, while necessary to elicit optimum performance from young children, was not sufficient because the same procedure was used with ternary-relational tasks, and these were not mastered until 5 to 6 years.

McClelland (1995) developed a three-layered net model of children's understanding of the balance scale. The architecture comprises four sets of five input units, representing one to five weights on pegs one to five steps from the fulcrum, on both left and right sides. There are four hidden units, two of which compare weights and two compare distances, while the output units compute the balance state. The model captures crucial developmental results, and its progress through training has some correspondence to the course of development as defined by Siegler's (1981) rules. An interesting property is that training results in the units representing larger weights, or larger distances, having greater connection weights to the hidden units. Thus metrics for weight and distance emerge as a result of training and are not predefined in the net. This shows how structure can emerge from interaction with a learning environment.

This model computes the balance state as a function of weight and distance on left and right sides of the bal-

ance beam, but understanding the balance beam also entails other functions, such as determining weight or distance values that will make the beam balance (Surber & Gzesh, 1984). For example, if $W_l = 3$, $D_l = 2$ and $W_r = 2$, what value of D_r will make the beam balance? (Answer = 3). Complete understanding of the balance scale would include being able to determine any variable given the others. The model has restricted generalization because if it is trained (say) on two or three weights on either side, it cannot generalize to problems with four or five weights (Marcus, 1998a), but it would be reasonable to expect that children would achieve this generalization. The model makes some important advances, but does not fully capture understanding of the concept as it is exhibited in middle childhood.

CONCLUSION

Markovits and Barrouillet (2004) have noted a marked decrease in developmental work on children's reasoning recently. A possible reason is that the motivation to either support or rebut Piagetian theory has declined in importance, and has not been entirely replaced by a new paradigm for development of reasoning. Another factor might be research on infant cognitive abilities, which are sometimes seen as equivalent to the conceptual development that was once thought to occur in middle childhood. Thus Houdé (2000) interprets infants' performance as reflecting conservation of number, whereas Piagetian measures of the same concept are seen as also requiring inhibition of conflicting strategies. Similar arguments are made for class inclusion, where the difficulty of the Piagetian tests is attributed to the need to inhibit the subclass comparison strategy (Perret, Paour, & Blaye, 2003).

Claims that reasoning in infancy is equivalent to that in middle childhood cannot be based solely on rebuttal of Piagetian research. They must be reconciled with the large and diverse body of work that points to strong distinctions between cognitive abilities in infancy and middle childhood. The literature on the distinction between symbolic and subsymbolic processes spans many areas within psychology and several other disciplines. Children who are operating at a symbolic level can do many things that are not possible for infants operating at a subsymbolic level, as the literature we reviewed earlier in the chapter shows. It would be necessary to explain these differences, and it does not seem plausi-

ble that they are entirely attributable to growth of inhibitory control with age. In conservation, we saw how it was necessary to integrate length and number information, and it is not sufficient simply to inhibit attention to length. In class inclusion, avoidance of subclass comparison is not straightforward, but depends on representing the relations between superordinate and subclasses to determine which of the three possible comparisons is the appropriate one. And the concept of the earth cannot be developed by inhibiting knowledge that the earth appears flat when standing on its surface, but must be based on integration of this observation with knowledge of the great circumference of the earth.

Far from research on reasoning in childhood being rendered redundant by discovery of full-fledged infant reasoning capacities, the scope for research on development of reasoning is greater than ever. The fundamental changes that have occurred in our understanding of reasoning in recent decades create a wealth of opportunities for innovative investigations of children's thinking. A development that appears to have great potential is the mental models approach of Markovits and his collaborators. These researchers have shown the potential of a reasoning process based on fleshing out mental models by retrieving information from semantic memory. The model of Markovits and Barrouillet (2002) forms useful links between research on reasoning processes and the powerful influence of knowledge on children's reasoning.

There is also scope to reinterpret some demonstrations of precocious reasoning by applying more refined complexity analyses. We have seen many instances where younger children's reasoning reflects simpler tasks, but this can only be appreciated if we have a complexity metric for assessing the tasks. Such reassessments would in no way deny either the validity or the importance of reasoning capabilities that have been discovered. Rather, a number of benefits might flow from them. One is methodological, in that we should be more aware that when we change test procedures we also change the processes that children are likely to use. Much of the research on precocity has assumed that the same concept can be measured by a variety of assessments, with little attempt to verify that the observed performances do in fact reflect the same cognitive processes; but we have seen how often this strategy has led to fallacies. Another possible benefit is that complexity assessments might contribute to a more orderly

and coherent interpretation of the database. As Frye and Zelazo (1998, p. 836) noted:

Developmental psychology is commonly recognized as the study of change, but without a method for ordering the changes, the phenomena become as disorganized as those in the physical sciences would be without a periodic table.

Complexity analyses have also contributed to discovery of new abilities. Complexity need no longer be seen as a difficult concept to apply in experimental research because of the progress in techniques for analyzing and manipulating task complexity. Some of the major parameters of cognitive complexity have now been determined, as evidenced by the widespread consensus that adult cognition is limited to approximately four independent entities processed in parallel and that even quite different methodologies have converged on similar age-related capacities in children.

Having surveyed the literature on the development of reasoning, we can only remark on the awesome progress that has been made. However, we are equally impressed with the prospects for further discoveries.

The interdisciplinary field of cognitive science represents an important way to study cognitive development. It offers insights on the mind in development that are not always apparent when considering cognitive development more narrowly from the perspectives of one of the main constitutive domains of cognitive science: psychology, linguistics, computer science, neuroscience, anthropology, and philosophy. This chapter examines several ways in which a cognitive science approach has helped frame and address questions about cognitive development that either would not have been posed at all, or would have been posed in different ways when emerging from each of the disciplines. There are clear benefits to this approach, but there are also major challenges imposed by the need for researchers to master methods and theories across several disciplines. As the depth of knowledge in each local discipline increases rapidly, how can researchers who stay abreast of these new developments also take advantage of scholarship that is much farther afield from their usual area of work? This chapter illustrates ways to combine the necessary depth in any single field with the benefits of breadth as well.

The most powerful contribution of cognitive science lies in the ways in which convergences across disciplines offer insight not available from the perspective of just

one. By building on insights, paradigms, methods, and models in other disciplines that are focused on the same or similar problems and questions, a cognitive science approach repeatedly offers new ways of understanding familiar phenomena. It also helps us see new phenomena through its unique lens. The idea of the benefits of research that incorporates diverse viewpoints is hardly new. At least since the time of Bacon, the value of converging forms of evidence was seen as important to induction (cf. Heit & Hahn, 2001). More than 150 years ago, just as the different sciences were starting to become recognized as distinct, the British polymath William Whewell discussed the insights offered by *the consiliences* that occur when widely divergent forms of evidence for a common pattern emerge (Whewell, 1840/1999). The recognition of cognitive science, however, as an arena in which important convergences could occur is far more recent, having gained serious attention roughly 30 years ago (Bechtel, Abrahamsen, & Graham, 1998; Keil, 1991, 2001). While relatively new, the benefits from this convergence have been among the most impressive of any interdisciplinary effort.

Developmental research has been the most prominent area of cognitive science in which theories and research have come together to yield powerful new insights. What

is it about the study of the development of cognition that brings together theory and empirical research in psychology, linguistics, neuroscience, computer science, anthropology, and philosophy in ways that are rarely seen in studies of the mature form? This chapter focuses on how the study of the developing mind tends to bring together ideas in the cognitive science disciplines in especially fruitful ways. In particular, it illustrates how patterns of change over time in developing organisms are more likely to foster awareness of common problems across the disciplines.

The analogous chapter, “Cognitive Science and the Origins of Thought and Knowledge,” which appeared in the previous edition of this *Handbook* (Keil, 1998), approached the topic by considering fundamental questions about the mind and how they are best informed by considering them from the vantage points of several distinct disciplines. Questions such as how to quantify entities, recognize individuals, or communicate successfully were considered. This way of understanding what cognitive science is and its impact on development has been highly effective and continues to be a prominent way of motivating and conducting research. One need only look at current research on the development of quantitative understanding (e.g., Deheane, 1998; Wynn, 1998), object tracking and individuation (e.g., Leslie, Xu, Tremoulet, & Scholl, 1998; Munakata, 2001; Scholl, 2004), and communication (e.g., Bloom, 2000; Gleitman & Bloom, 1998; Lightfoot, 1999; MacWhinney, 1998; Yang, 2004) to see the lively and productive benefits of a research strategy that poses questions in ways that draw on several disciplines at once.

This chapter could easily be an incremental review of those basically interdisciplinary questions and an update of the dramatic advances in research in each of these areas. The earlier chapter, however, provides a road map of sorts that would easily enable readers to make such extensions on their own. Instead, I have taken a different approach here. This chapter focuses on basic questions about cognitive development that have been posed in psychology for many decades, often for more than a century. It then explores how those questions have changed so as to be more inclusive of insights from other disciplines that make up the cognitive sciences. These changes occur both because of an emerging awareness of related questions in those other disciplines and because of a recognition of the limitations of posing them in their traditional narrow terms. The result has been a shift both in how the questions are posed and in the na-

ture of the likely answers. The strategy of the prior chapter was to start with developmental questions that were intrinsically interdisciplinary and show how different disciplines converged to answer them, whereas the strategy here is to focus on long-standing developmental questions that have traditionally been seen as centered in psychology and to show how their scope and breadth have changed. In the end, there is a convergence from both strategies on similar kinds of questions, but this account tends to reflect more closely the historical pattern from the perspective of psychologists. In addition, the questions addressed here are meant to be distinct from those of the earlier chapter so as to consider different perspectives. They are all posed in domain-general terms as opposed to the domain-specific format that governed the prior *Handbook* chapter. This shift does not mean that domain specificity is irrelevant to the answers to these questions; it merely uses a point of departure to organize this material. The final section of this chapter confronts domain specificity versus generality directly and, in doing so, links this chapter more closely with the prior one.

The questions addressed here are shown in the Chapter Contents. Ten questions are addressed here:

1. What is the initial state?
2. Is there an adapted mind?
3. Does development proceed from the concrete to the abstract?
4. What is the nature of conceptual change?
5. What is the difference between learning and development?
6. What are the representational formats underlying developmental change?
7. What is the role of implicit and explicit cognition in development?
8. What is the role of association and rules in development?
9. Are there developmental universals?
10. What constitutes a cognitive domain and how does domain structure influence development?

BEGINNINGS

The earliest periods of cognitive development are of great interest to scholars from a wide range of disci-

plines. A focus on these periods leads naturally to questions about initial states and about the ways in which the mind might be adapted for learning.

What Is the Initial State?

At least since the writings of Plato and Herodotus, scholars have asked about the “initial state” of the human child. What is the best way to characterize the newborn’s cognitive architecture and capacities? In one sense, questions about the initial state at the moment of birth seem arbitrary and misleading. The particular moment of birth does not seem to be particularly important and can be influenced considerably by pharmacology and apparently random environmental triggers. Moreover, children are frequently born preterm, sometimes by more than 2 months, and as the viability of younger and younger preterm infants increases, the moment of birth becomes ever more blurred. With children surviving birth at times as early as 4 months prior to the typical due date, why talk about the normal birth date of 9.5 months postconception as the “initial state”?

There are several good reasons for continuing to focus on the question of the cognitive nature of the newborn delivered at the normal due date. First, despite clear evidence that learning can occur prenatally (De-Casper & Spence, 1986; Moon, Cooper, & Fifer, 1993; Nazzi, Bertoncini, & Mehler, 1998), there is little doubt that the opportunities to learn new information expand enormously after birth. Not only are all the sensory systems suddenly bombarded with dramatically new and much richer information, the event of birth, which places the newborn outside the womb, triggers a host of new interactions and inputs from caregivers and others around the infant (e.g., Fernald, 1992, 1993). Second, birth itself may coincide with new cognitive capacities, as is illustrated by comparisons of developmental capacities of full-term and preterm infants (Rose, Feldman, & Jankowski, 2001; Roy, Barsoum-Homsy, Orquin, & Benoit, 1995; Weinacht, Kind, Monting, & Gottlob, 1998). Birth may help accelerate or trigger cognitive capacities and abilities. Finally, even newborns are capable of a wide variety of actions on their environment that bring new experiences to them and that, in their own right, constitute important areas of learning.

From the perspective of developmental psychology, questions about the initial state were vague and largely ill formed until the past decade or two, when they have become sharpened by work in other disciplines. From

linguistics, the notion of learnability has been important. From computer science, learnability and massive parallel processing have become influential, as have ideas about architectural configurations of the initial state. From neuroscience, we now have precise neural accounts in other species of initial states and their modifications through experience as well as new paradigms for how endogenous experience, as well as exogenous experience, might structure the brain. From philosophy, there has been a considerable sharpening of ideas about initial states, and from anthropology, the notion of backward convergence with decreasing age toward a common mental structure has emerged. Each of these can be considered in more detail.

In one sense, the problem of learnability is straightforward. It asks what sorts of knowledge structures are learnable given a particular form of learning, a set of environmental inputs, and some notion of what it means to successfully achieve learning (Pinker, 1989, 1995). In many cases, it is impossible to learn a unique pattern given a limited set of data. A classic example involves trying to figure out what sort of function describes the curve that goes through a finite set of points. It is not possible to derive a unique function in most such cases, and even appeals to parsimony and simplicity are often not adequate to solve these riddles of induction (Goodman, 1965). This problem became especially evident in language acquisition where Chomsky’s notion of the “poverty of the stimulus” was used to motivate the idea that many learning systems could not identify the grammar of a language given the normal “impoverished” inputs that those systems would encounter (Chomsky, 1975). Building on more formal demonstrations of the inability of some learning systems to identify a given language from a larger possible set (Gold, 1967; Wexler & Culicover, 1980), a number of scholars argued that the same formal approach could be applied to many other areas of learning and cognitive development (Jain, Osherson, Royer, & Sharma, 1999).

The learnability approach and the “poverty of the stimulus” argument, however, has not been accepted uncritically (e.g., Fodor & Crowther, 2002; Margolis & Laurence, 2002; Pullum & Scholz, 2002). It has been argued that the stimulus is far richer than previously thought and that much more convergent learning is therefore possible (Pullum & Scholz, 2002). The point here is not to evaluate what aspects of grammar in particular, and knowledge more generally, are learnable with a particular learning system. The critical message

is that the learnability debate has helped sharpen questions concerning the initial state. Psychologists now are more likely to acknowledge that some forms of knowledge may only be learnable with certain kinds of architectures and that it is therefore important to develop precise ways of characterizing the knowledge representation, the learning strategy, the information provided, and the meaning of satisfactory levels of learning.

It would be a gross exaggeration to imply that formal learning procedures are foremost in the minds of most developmental psychologists, but there is a greater appreciation of the need to specify the relevant components of a learning system. At the same time, the challenge of using formal approaches to better delimit that initial state has become much larger than initially envisioned by many. Some workers, from a computer science perspective, have argued for dramatically different architectures to get around learnability issues, such as architectures that use massively parallel processing systems and radically different learning procedures. It has been argued that many aspects of category learning and conceptual change that seemed “unlearnable” in older, simpler associationist systems can be modeled nicely by these parallel architectures (Rogers & McClelland, 2004). Thus, computer science advances, both in more traditional learning architectures and in newer parallel ones, have refocused the study of the initial state.

Rapid advances in neuroscience have made it possible to look in detail at the initial state of some portion of a neural network and then examine how it changes as the organism learns. One of the most elegant and detailed analyses along these lines has been done with perceptual motor learning in the barn owl (Knudsen, 2002). It is possible to show how the barn owl learns to auditorily localize by tuning sets of neurons to inputs from both the eyes and the ears that appear to be gated in a complex manner related to timing of input (Gutfreund, Zheng, & Knudsen, 2002). In auditory localization learning in the barn owl, it is possible to describe, at the neural level, considerable prewiring that seems necessary to enable auditory learning but also considerable plasticity to allow for dramatic tuning and recalibration, which can be demonstrated experimentally by putting prisms on the owls’ eyes or plugs in their ear holes. There is a still a long way to go from these neural models to formal learning models, but it is possible now to see potential benefits of the convergence of these different approaches. One can, for the first time, start to com-

putationally model initial states and their tuning functions based on neural data (Kardar & Zee, 2002). This a great leap forward from earlier claims that Parallel Distributed Processing (PDP) networks were modeled after the nervous system. These claims were largely based on loose analogies rather than on data-driven mappings from neural architecture to computer architecture.

Neuroscience has also helped shape questions about initial states through discoveries about how endogenous cycles of activation can create an internal experience that must be acknowledged as much as external experience. Thus, in addition to externally driven patterns of neural activity, there are endogenously driven ones that appear to be critical in guiding the tuning and sharpening of neural circuits (Zhang & Poo, 2001). For example, in both the retina and the thalamus, spontaneous cycles of endogenously generated electrical activity of neurons are thought to be causally involved in helping refine and sharpen orientation-specific circuits in the lateral geniculate nucleus and the visual cortex. These circuits then become further tuned after birth by visual experience. Apparently, molecular genetic specifications of structures must interact with these endogenous waves of activity, perhaps conserving an activity-dependent mechanism of tuning of neural architecture both pre and postnatally (Zhang & Poo, 2001). Discussions of initial states and poverty of the stimulus must now take into account the influences of internal cycles of this sort. More broadly, tremendous advances in the neurobiology of development are now helping constrain in much richer ways discussions of initial cognitive states (Marcus, 2004).

We have talked about computer science influences arising from the debates about architectures that are massively parallel versus serial. A different contrast concerns systems that are modeled by central cognitive control patterns as opposed to “behavior based” systems that are built up out of simple perception/action routines (Brooks, 2001). The idea was immortalized in an excerpt from the film *Fast, Cheap and Out of Control* (1997), in which the computer scientist Rodney Brooks waxes at length about the virtues of engaging in artificial intelligence research in a way that he sees as recapitulating phylogeny. By starting with relatively simply perception action circuits of the sort found in insects, it is possible to model behaviors in ways that seem to pay little attention to central cognitive control mechanisms (Brooks, 1997). Consider two ways of explaining the moth’s behavior of flying toward flames. One might at-

tempt to model that behavior by starting with a central cognitive system that recognizes bright light sources and then links that recognition routine to a motivational system that wants proximity to the light source and then, based on the interaction of these two systems outputs, a series of commands to a perceptual motor guidance system. Alternatively, one might ask about the crudest possible connection between the sensory inputs and actions. A simple version is shown in Figure 14.1. Imagine that the eye of the moth that is closer to, or more directly faces, a light source fires neural outputs more rapidly. Assume further that those outputs go to the wing on the opposite side of the moth from the eye, which will then flap more rapidly than the wing on the same side as the eye. As a result of this difference in wing flapping, the moth will turn toward the flame and fly toward it until both eyes receive equal stimulation; it then flies in a straight line toward the flame.

The actual story for most moths is probably considerably more complex (e.g., Hsiao, 1973); but this “toy” example illustrates the basic point: Complex goal-directed behavior may sometimes emerge from surprisingly simple noncentral perceptual motor mechanisms. The argument made by Brooks and his colleagues is that we should think of much of the complexity of human behavior as bottom-up concatenations of such insect-like routines. Analogously, one might think of learning in development as the concatenation of such routines (cf. Thelen, 2000). We may feel compelled to infer much more elaborate central control processes to certain behaviors but perhaps often inappropriately. An endearing robot known as Kismet provides an example. Kismet has several routines built into it for tracking eye gaze and body and head movement of humanoid faces and making automatic reactions back (Adams, Breazeal, Brooks, &

Scassellati, 2000; Scassellati, 2001, 2002). The circuits that make up each of these face-responding routines are all seemingly simple and distinctly nonhuman like; and yet in real time, human observers see the behaving robot as having far more cognitive, motivational, and emotional structure than it really does.

Human infants may be nothing like Kismet, but research in that tradition has influenced thinking about possible initial states and has helped psychologists realize that highly interactive social behaviors might not on their own indicate rich internal cognitive processes or the rich initial states that those processes seem to entail. As demonstrations of ever more sophisticated social tracking and contingency responding routines occur in younger and younger infants (e.g., M. H. Johnson, 2000), debates in computer science about the appropriate architectures are ever more relevant.

In philosophy as well, recent discussions of initial states and the related issue of nativism have influenced more traditional views in developmental psychology. Philosophers have focused on classic ideas in psychology such as triggering and canalization (Ariew, 1999), domain specificity (Cowie, 1999; Samuels, 2002), and modules and their precursors (Carruthers, 2005), just as advances in developmental psychology have reinforced the relevance of these topics to philosophers interested in nativism. Philosophers have pointed out the challenges of adequately describing either representations, learning, or the available information in the environment. Philosophy has also often been the first vantage point from which interconnections are apparent between psychology, computer science, linguistics, and neuroscience.

The contributions of anthropology to characterizing the initial state are more tentative but there are exciting developments in this area as well (Sperber & Hirschfeld, 1999). As cognitive science techniques are used with more sophistication in cross-cultural research, patterns of interaction between cultural structures and cognitive structures become more accurately described. One pattern that can strongly inform questions about the initial state is seen in cases where adult diversity of cultures, when considered in younger and younger ages of a culture, tend to converge on a common format in the young child or infant. This convergence starts to make suggestions about initial states (Medin & Atran, 2004). A different tactic has been to argue that the ability of information to propagate through a culture depends on all members of that culture having a sufficiently shared

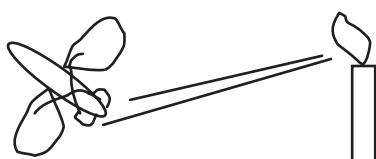

Figure 14.1 A noncognitive way to explain the moth’s tendency to fly toward light sources is to hypothesize a cross-connection between the moth’s eyes and wing muscles, such that the eye on the side of moth that is closer to a light source fires excitatory patterns to the contralateral wing, making it flap more rapidly and turn the moth toward the light source. In this manner, the moth will continually adjust its behavior until it is heading directly toward the light source.

cognitive common ground to act as a medium of transmission (Sperber & Hirschfeld, 2004). That common ground in turn leads to suggestions about initial states.

Given the complexities of characterizing the initial state, it is tempting to declare it irrelevant, just as others have declared the nativist/empiricist controversy as a nonissue. In neither case is this move correct. One of the major advances in recent years in cognitive science has been to flesh out in detail different facets of the problem of initial states across the disciplines, giving new insights to those engaged in developmental psychology research with the youngest of humans. Thus, questions about initial states have become considerably more refined as they have been considered across the disciplines.

Is There an Adapted Mind?

In one sense, the answer to this question is obviously "yes." Human brains have a large number of adaptations that all would agree on. Glial sheaths are an adaptation that occurs more prominently in organisms with complex cortices requiring transmission of larger packets of information over longer distances. Larger brains have ventricles filled with cerebrospinal fluid that help control and maintain the chemical environment of the brain. The convolutions of the cortex in primates are thought to be an adaptation to enable the packing of more cortical surface layer in a constrained volume. In all these functional and physiological senses, the brain is adapted. The more provocative question, however, is different and is at the core of evolutionary psychology (Tooby & Cosmides, 2005). To what extent are there adaptations for distinct cognitive faculties, and at what levels of processing? It is noncontroversial that there are adaptations of the sensory receptors such as the eyes and the ears, for different kinds of information. There is some disagreement, but mostly a consensus, about there being adaptations for modules that track objects (Mitroff, Scholl, & Wynn, in press), social agents (Leslie, 2000), depth (Sakata et al., 1997) and language (Hauser, Chomsky, & Fitch, 2002; Pinker & Bloom, 1990). But there is far more disagreement about whether humans or other species have evolved cognitive adaptations for detecting cheaters (Cosmides, 1989), picking attractive mates (Buss, 1994), or thinking about the living world (Atran, 1998; Bailenson et al., 2002). Although *evolutionary psychology* is a relatively new term, questions about an adapted mind were part of Darwin's thinking shortly after his proposal of the idea of evolution by natural

selection. He discussed at length the adaptive function of the early emergence of emotions and their corresponding facial expressions (Darwin, 1872).

The debate about an adapted mind is making considerable advances as considerations across disciplines start to feed back on psychological questions. One of the most intriguing has occurred in computational biology, where scholars explore the adaptive value of modular versus general structures and ask under what sorts of environments and mechanisms of architectural change modules will appear (Calabretta, Di Ferdinando, Wagner, & Parisi, 2003; Wagner, Mezey, & Calabretta, 2004). Consider a line of work that asked about the optimal way to evolve a system that performs both "what" and "where" computations on objects in the visual array. Although earlier work had shown that it was possible for a single kind of architecture with one learning algorithm to "learn" to have two distinct modules (Jacobs, 1999), later research suggested that hybrid architectures using both a genetic algorithm and a variant of learning through back propagation, show a considerable advantage in the development of functionally specialized modules (Wagner et al., in press).

Networks were designed that could change their structures in two ways, either by production of variants of the initial network through random mutations (the genetic algorithm) or through a form of instructed learning in which weights were changed as function of task performance (back propagation). It was found that a hybrid network of this sort would rapidly create distinct functional modules for "what" and "where" tasks when the genetic algorithm preceded learning through back propagation. Moreover, the advantage occurred primarily in cases where the network first learned the simpler task (where) before the complex one (what). One way of interpreting these results is to argue that the genetic algorithm mimicked evolutionary change while the back propagation learning represented learning within a single organism's life span (Calabretta & Parisi, in press).

It is far too early to conclude that hybrid architectures modeling evolved modularity and learned modularity together have an advantage over those that only incorporate learned modularity. Indeed, many continue to argue that gradually learned modularity during infancy, through a competition process between networks subserving two distinct tasks, is the way to understand the emergence of distinct domains of cognition (Dailey & Cottrell, 1999; M. H. Johnson, 2000). By such accounts, there is no adapted mind in the sense of a priori domain-specific specializations for different kinds of

information patterns corresponding to real-world categories such as social agents, living things, and faces. Instead, those specializations arise from channeling of information caused by much lower-level perceptual cues. The debate continues as other groups argue for strong evidence for evolutionarily adapted modules (Duchaine, Cosmides, & Tooby, 2001) and for a general progression in evolution of the replacement of general purpose learning systems with adaptively specialized ones (Gallistel, 2000). Either way, however, computational approaches now allow for the exploration of the relative advantages of domain-specific architectures that occur gradually and postnatally as a result of a single organism's learning experiences as opposed to those that occur through an evolutionary process across a species as whole.

There are profound problems in trying to model the richness of the environment and evolutionary processes. Researchers are forced to use highly idealized and necessarily oversimplified toy systems; but computational approaches of this sort are certainly starting to influence thought about the emergence of functional specializations and the extent to which we have adapted minds. In turn, that computational perspective has also led to new ideas about experimental research by psychologists with human infants (e.g., Munakata, McClelland, Johnson, & Siegler, 1997). As mentioned, in a broader sense, the mind is obviously adapted if one includes the structures of the sensory transducers, which do after all contain part of the nervous system. The debate revolves around whether principled boundaries limit the scope of such adaptations, such as applying only to the sensory transducers, only to lower-level perceptual input modules, or only to the highest levels of cognition. Thanks to computational perspectives, that debate is moving forward with more specificity and a greater effort to empirically support the different positions.

A related research strategy for examining the extent of the adapted mind is to use "reverse engineering." The idea is often used to describe forms of industrial espionage in which engineers take a competitor's product and, from its function, try to work backward to figure out how it works and why it was built the way it was. With respect to the mind, the idea is to consider the local functional value of a property or behavior (such as mating, child rearing, or cheating detection), frame that property as a goal, and then see what follows from such an assumption, as one tries to consider a system, its constraints, and the ways it might meet that goal. There is considerable debate about whether there are sufficient

constraints to be able to infer with some reliability the structure of the engineering solutions for the human mind (Lewens, 2002); but the strategy represents a new way of approaching questions about the adapted mind that draw on ideas in evolutionary biology.

Some have suggested that the reverse engineering strategy is empty, because it can be used to argue for the presence of anything, that is, if a pattern of thought is observed early in development and is seen in virtually all children in all cultures, it must have been selected for in evolution. Although such misleading inferences can occur, they can also occur in analyses of real engineered artifacts, which has not at all undermined use of reverse engineering as a strategy with devices (Lewens, 2002). It may well be that for more complex interconnected systems of both a biological and artificial nature, the reverse engineering strategy rarely misleads above a certain level of functional complexity. Moreover, cross-species comparisons often suggest common goals. Through broader evolutionary analyses of essential functions for social organisms, a small number of key functions may emerge, such as co-operation in groups, mating, child rearing, and self-protection (Pinker, 1997). Those functions, which are hardly controversial and have cross-species validity, can then be used to frame a wide range of questions about cognitive development.

A new look at individual differences has also arisen from questions about the role of an adapted mind in development. Traditionally, individual differences have been understood as a battleground over gene versus environment effects (e.g., Scarr, 1992); but that way of considering individual differences overlooks the ways in which patterns of variation can highlight foundational domains (Bjorklund & Pellegrini, 2000; Scarr, 1992; Segal & MacDonald, 1998). One precursor of this view comes from the work of Gardner (1983) on "multiple intelligences" that led to proposals of distinct domains of thought, such as logical, spatial, and interpersonal intelligence. Rather than ask whether the degree of manifestation of a trait, such as spatial reasoning skill, is largely a function of experience or genes, an evolutionary psychology approach to individual differences asks if, across patterns of variation among individuals, a common distinct functional architecture seems to emerge. In this way, the analysis converges with that of cross-cultural studies and developmental approaches, to ask if certain "mental organs" are highlighted by an individual-differences perspective. We are only beginning to see hints of this approach because of the large data sets

involved. If, over a wide pattern of variation across individuals, certain aspects of cognition remain both invariant and domain specific, then the cognitive abilities involved should be considered as candidates for being adapted forms of thought.

More extreme forms of individual differences—patterns of pathology—have also been used to argue for an adapted mind. These more extreme forms are distinguished by being maladaptive and likely to threaten survival of those who would have such pathologies, especially if those individuals are living in traditional environments. Thus, one argument for a cognitive faculty being adapted is that, when it is severely damaged, it threatens survival. The domain of folk psychology has been studied more in this respect than any other in individuals with autism. While there remain extensive debates about the extent to which autism is solely the result of a cognitive deficit (Birlen, 1990; Cohen & Volkmar, 1997), in a large number of cases the primary deficit seems to be a specific cognitive problem in thinking about the mental states of others, such as how beliefs and desires can lead to actions, deception, and misunderstandings (Baron-Cohen, 1995, 2004; Leslie & Thaiss, 1992). Moreover, there appears to be a continuum along which individuals can be variably handicapped in their ability to have a “folk psychology,” ranging from severely autistic individuals who have great difficulty understanding almost anything about how mental states lead to actions to more modest deficits such as Asperger’s syndrome in which individuals are able to understand the mental lives of others, but only to a limited extent and with considerable difficulty (Klin, Volkmar, & Sparrow, 2000).

Patterns of neurological impairment and their resulting deficits in specific areas of thought do not automatically mean that those areas of thought are adapted domains. There have been many demonstrations of how a generalized learning system, such as one that learns through massively parallel processing, might nonetheless show domain-specific deficits with certain kinds of lesions. Thus, differential deficits in the abilities to think about tools or animals have been simulated in such systems (Farah & McClelland, 1991; Rogers & Plaut, 2002). Low-level differences in attention to perceptual and functional features have been argued as able to account for such differences (Borgo & Shallice, 2003). In other cases, however, specific impairments in thought are much more difficult to explain in terms of problems in domain-general learning (Humphreys & Forde, 2001;

Keil, Kim, & Greif, 2002; Vinson, Vigliocco, Cappa, & Siri, 2003).

Similar controversies exist about whether humans have specific areas of the brain adapted for perceiving faces (Duchaine, Dingle, Butterworth, & Nakayama, 2004; Duchaine & Nakayama, 2005; Gauthier, Curran, Curby, & Collins, 2003; Kanwisher, 2000; Kellman & Arterberry, Chapter 3, this *Handbook*, this volume). Those debates, in turn, have often brought in key developmental arguments about the possibility that specialized brain regions that are uniquely involved in one kind of task (e.g., face perception) might not have been initially “wired” to only process faces, but because of lower-level perceptual shunts, only received information about faces and thus, over time became organized preferentially for that kind of information (Johnson & Morton, 1991). Thus, development becomes critical to understanding whether cognitive specializations in the brain were selected for in the course of evolution or in the course of learning in a single lifetime, with both possibilities being proposed in several areas of cognition (Elman et al., 1996).

The potential insights of an evolutionary perspective, however, go far beyond arguments for specialized domains of thought and modularity. Questions about an adapted mind can also lead to insights about specific developmental trajectories and rates of development. Why, for example, do the three classes of cues for depth—three-dimensional dynamic cues (e.g., motion parallax), binocular cues (e.g., binocular disparity), and pictorial cues (e.g., linear perspective)—emerge in infancy in that order? (Kellman & Banks, 1998). One appealing explanation is that it makes adaptive sense for 3-D dynamic cues to emerge first because they are most robust under conditions of degradation common in young infants, such as low acuity and weak binocular coordination. Such dynamic cues might then form feedback for other sorts of cues that are used later. Similarly, earlier emergence of some cognitive skills relative to others can be understood in adaptive terms and then considered as a largely maturational pattern.

Arguments about adaptive developmental sequences in turn raise questions about whether a sequence of development is predesigned or is an inevitable unfolding of cognitive and perceptual systems in which some components must necessarily precede other ones. Thus, although one might argue that addition precedes multiplication in the development of mathematical thought because of a maturational program, it is much more

plausible to argue that addition logically precedes multiplication and that the latter cannot be understood without a sense of the former (National Research Council, 2001). There is, therefore, a danger in being excessively promiscuous in adaptive explanations, a bias that is seen in much of biology (Gould & Lewontin, 1979). Nonetheless, although asking about developmental patterns in adaptive terms may sometimes be misleading, such a strategy often helps focus research on new sets of questions for empirical exploration.

Adaptive questions about developmental patterns can also be a fruitful way of asking about cross-species differences. Why are some organisms much more precocial with respect to some cognitive and perceptual skills than others that are more altricial with comparable or analogous skills? Why do young human infants, while clearly able to see objects in depth, show no fear or tendency to avoid the deep side of the visual cliff while other species show such a linkage at birth (Campos et al., 2000). One answer might focus on the mobility of newborns of other species and the need that mobility creates for a neonatal linkage of fear and avoidance with depth perception. That answer might further be supported by arguments for how, in the absence of mobility, it is advantageous for a fear-depth linkage to take time to develop.

More broadly, there are repeated trade-offs between the advantages of having precocious but inflexible cognitive perceptual systems as opposed to less precocious but more flexible systems. Again, adaptive explanations are not always going to inform questions about developmental sequences in the acquisition of knowledge in domains such as mathematical skills, folk psychology, folk biology, and folk physics; but they are likely to be part of the story in many of those domains and will often help frame questions that motivate more focused research. Other examples might include the use of object files and estimation skills in number knowledge before calculation-based methods (e.g., Wynn, 1998) or use of continuity, no action at distance, and solidity principles in object concepts before those of gravity and momentum/trajectory (Spelke, Breinlinger, Macomber, & Jacobson, 1992).

PATTERNS OF CHANGE

Cognitive development intrinsically involves various notions of change. It has, however, been difficult to unambiguously characterize distinct patterns of change.

Debates occur both about the representational formats involved and about the degree and kind of change involved. Work across the cognitive sciences has greatly helped to sharpen some of these distinctions.

Does Development Proceed from the Concrete to the Abstract?

Few things seem more commonsensical than the idea that development must proceed from the concrete to the abstract. This view has been discussed in different ways throughout much of the history of developmental psychology (e.g., Bruner, 1967; Inhelder & Piaget, 1958; Vygotsky, 1962; Werner, 1940). Yet, a cognitive science perspective on this question has started to raise serious questions about the ubiquity of this pattern. From the perspective of linguistic theory, a major shift in views of language acquisition was launched by Chomsky (1957, 1965, 1975). This shift was so major that it is now presupposed by most scholars in the area even as they might vigorously dispute many or all the details of how Chomsky describes the capacity for a natural language (e.g., Bresnan, 1982; Gazdar, Klein, Pullum, & Sag, 1985; Manning & Sag, 1995). The common presupposition is that there are abstract ways of characterizing language competence that are far above more concrete levels of analysis such as word tokens, simple word order patterns, or sentence size. At the concrete level, languages appear to be so dramatically different from each other as to suggest near infinite variation and little or no common structure. But with a more formal and abstract way of describing linguistic competence, as developed so powerfully by Chomsky, it was possible to see strong universals on structure that all languages share and that might be understood as guiding constraints on language acquisition (e.g., Anderson, 2004; Lightfoot, 1999; Pinker, 1994).

At an early age, children throughout the world seem to learn ordering relations based on abstract syntactic categories such as subject and object and not on number of words or word tokens. They appear to have abstract parameters that are "set" in ways that allow them to unpack the structure of a particular language (e.g., Lust, 1999; Yang, 2004). Again, this perspective can be debated (e.g., Seidenberg & Macdonald, 1999), but there is no doubt that a dominant model of language acquisition is that children start out with abstract skeletal expectations about a grammar of a language that they then fill in with more concrete

language-specific details of tense marking, subject-verb agreement, and sentence embedding.

From a computer science perspective, there has been a surge of interest in whether concrete to abstract progressions are inevitable parts of systems that learn. While such a progression might seem to be necessary in simple systems that do little more than perform first-order tabulations of feature frequencies and correlations, it is striking how more contemporary models of learning often allow for, and even vigorously embrace, systems in which more abstract representations of the environment can have developmental precedence. Consider how advances in connectionist modeling can show this seemingly paradoxical result. Since many connectionist models work by tracking feature frequencies and correlations, they might seem especially good cases of concrete-to-abstract patterns of development. It is possible, however, to design architectures in which a system quickly abstracts away from lower-level feature frequencies and correlations in a manner that does not initially emphasize concrete categories but instead gives developmental priority to more abstract ones (e.g., Rogers & McClelland, 2004). Thus, there have been arguments for developmental patterns in which children first master abstract categories such as living thing, nonliving natural kind, and artifact and then gradually differentiate downward to knowledge of more specific categories (Keil, 1979); connectionist models have been designed to model such patterns (Rogers & McClelland, 2004). Or, very young children might show category clustering by categories such as vehicle and animal before clustering by categories such as car, boat, dog, and cat (Mandler, 2004). Again, there are now computational explorations of how to model such patterns (Rogers & McClelland, 2004). A related computational approach might construct a learning system that approximates the statistical process of factor analysis (Ghahramani & Hinton, 1998), a process in which abstract factors might emerge in a computational analysis long before more local patterns have any meaning.

Abstract performance might also precede concrete knowledge in a system in which a priori weights on an architecture embody some higher-order property in a domain. Thus, some connectionist approaches augment learning algorithms and node structures with predetermined weights on some links, or “clamps,” on weight change. The aggregate structure of such clamps and weights might then embody an abstract cognitive principle such as a general principle of syntax (Yang, 2005).

There may still be profound limitations on many of these connectionist architectures (Marcus, 2001), but their evolution in recent years makes possible consideration of a wide range of patterns in which development proceeds from the abstract to the concrete. A rich array of psychological patterns that suggest abstract to concrete change (e.g., Ingaki & Hatano, 2002; Keil, Smith, Simons, & Levin, 1998; Mandler, 2004; Simons & Keil, 1995) have motivated newer computational models that now in turn feed back on and motivate further psychological questions (Goldstone & Son, in press).

In philosophy, the abstract versus concrete contrast has been a topic of active discussion in many forms. There are several levels of explanation of any system and there are complex discussions about which ones are most fruitful and how they should be characterized. As part of those discussions, it is commonly assumed the lowest level, most reductionist characterization of a process is often inappropriate and unfeasible (Fodor, 1974, 1975). Moreover, functional levels of analysis, far above levels of concrete mechanism are often embraced for their distinctive nature and importance in both science and daily thought (e.g., Block, 1980; Cummins, 1983; Lycan, 1996). Similarly, abstract notions of causal powers have been argued as more fundamental to natural science than mechanisms (Harre & Madden, 1975). All these discussions have served to provide different ways of instantiating what it means to be concrete versus abstract.

These philosophical discussions have powerful implications for developmental studies of the progression of thought. By illustrating the distinctive, and sometimes privileged, role of levels of explanation in modern science as well as in the history of science, philosophers help constrain discussion of how such structures might emerge in children.

Philosophical discourse also allows one to see more clearly not only why some patterns of abstract to concrete change might occur, but also why the opposite pattern often might seem to be more obvious. If one characterizes abstract thought in terms of the ability to explicitly describe an abstract relation in language, one is inclined to see thought as progressing from the concrete to the abstract. For reasons that may have little to do with underlying cognitive capacities (Bloom & Keil, 2001) it can be much more difficult to verbally describe a principle such as randomness than it is to label a concrete category such as dog or a concrete relation such as push. Yet, it is ever more evident that adults, children,

and even infants can be sensitive to, and cognitively employ in everyday thought, highly abstract categories and relations that they cannot verbally describe (e.g., Csibra, Biro, Koos, & Gergely, 2003; Gelman, 2002, 2003; Gergely, Nadasdy, Csibra, & Biro, 1995; Keil, 2003b; Newman, Keil, Kuhlmeier, & Wynn, 2005). Young children may be hard pressed to articulate any version of essentialism directly but appear to show assumptions about essentialism extensively in their daily cognitions (Gelman, 2003; Medin & Ortony, 1989). Similarly, young children might see certain teleological modes of interpretation as especially resonant with living kinds (Greif, Kemler-Nelson, Keil, & Guitierrez, *in press*) yet be unable to articulate that notion at all.

Philosophical discussions of language and thought and of the nature of language without thought bear closely on these issues (e.g., Fodor, 1975; Weiskrantz, 1988). They stand to help empirical researchers get a better handle on the ways in which the ability to articulate a concept in language might not be seen as the sole basis for making inferences about the presence of abstract versus concrete concepts.

Even neuroscience is relevant in such discussions. Certain patterns of brain damage resulting in difficulty in thought about categories, such as living things, might be best characterized as impairments at abstract levels of thought rather than more concrete ones (Keil, 2003c; Keil et al., 2002; Laiacona, Capitani, & Caramazza, 2003; Martin & Weisberg, 2003). A vigorous debate exists about the appropriate level of abstraction for describing the basis of a “living kinds deficit,” including discussions of how a normal ability to encode living things might be represented at a genetic level. For example, in one analysis of an individual who had a congenital deficit in thinking about living things, it was concluded:

[P]rior to any experience with living and nonliving things, we are destined to represent our knowledge of living and nonliving things with distinct neural substrates. This in turn implies that the distinction between living and non-living things, and the anatomical localisation of knowledge of living things, are specified in the human genome. (Farah & Rabinowitz, 2003, p. 408)

Although this result contrasts with other claims in the literature, it illustrates how explorations of this controversy in neuroscience are offering new refined insights into how to understand the abstract versus concrete contrast in cognitive development.

Anthropological studies are brought to bear on this question because of frequently erroneous claims that members of a certain “primitive” (and usually non-Western) culture think in more concrete terms than those of another. Such claims have time and time again been debunked by careful analyses (e.g., Cole, Chapter 15, this *Handbook*, this volume; Cole & Means, 1981). More recently, cross-cultural studies have shown how quite dramatic patterns of variation in thought might reflect different but equally abstract characterizations of a domain, such as construing biology in ecological versus more taxonomic ways (Bailenson et al., 2002; Medin et al., *in press*).

In short, the notion of concrete and abstract forms of thought and the developmental relations between the two has been a frustrating and often ill-defined problem in developmental psychology. It has been greatly informed by discussions in several other disciplines of cognitive science that converge to make sense of them.

What Is the Nature of Conceptual Change?

Psychologists have long been concerned with ways in which children’s concepts change over the course of development (e.g., Baldwin, 1895; Piaget, 1954; Vygotsky, 1962). More commonly, anyone who engages in casual conversations with a 5- and 12-year-old about concepts as diverse as density, zero, or reproduction, soon becomes convinced that typical 5-year-olds often have very different concepts of certain things than 12-year-olds, with the obvious implication that powerful patterns of conceptual change occur during that period. This much seems straightforward. Much less straightforward, however, is the question of the type of conceptual change that is occurring. We have already seen how abstract to concrete progressions, and the reverse, are one way of talking about conceptual change, but another level of analysis is more structural in manner. It is at this level of analysis that work in other areas of cognitive science has been extremely influential, especially in more recent years.

In the philosophy and history of science, there have been extensive discussions of forms of conceptual change. One of the mostly widely discussed is Kuhn’s original notion of scientific revolutions (Kuhn, 1962), a form of change in which a slowly building body of contrary evidence to a particular theory, or paradigm, ultimately reaches a critical mass that launches a dramatic shift to a new way of understanding some aspect of the

world. That notion of revolutionary change powerfully influenced views of cognitive development. For example, young children have been regarded as initially understanding much of the biological world (especially animals) in psychological terms and not biological ones (Carey, 1985). Similar arguments have been made for children's shifting concepts of weight and mass (Smith, Carey, & Wiser, 1985) and force and motion (Tao & Gunstone, 1999). This is a particular view of conceptual change with intriguing predictions. For example, concepts in a prerevolutionary system of thought might be completely incommensurable with those in a later system such that individuals from the two systems would largely be talking past each other or mistakenly think they were referring to the same things when in fact they were not. This prediction in its strongest form seemed troubling in that communication with children often does not seem to create such impasses.

Later developments in philosophical discussions of conceptual change refined Kuhn's early ideas in ways that in turn informed models of what is happening with respect to conceptual change in children. Thus, notions of local incommensurability were introduced to deal with global incommensurability and thereby allow more effective communication as well as more gradual patterns of change (Kitcher, 1978, 1993). Others more directly challenged the entire notion of conceptual revolutions (e.g., Laudan, 1990), leading to more nuanced models of conceptual change in children (e.g., Carey & Spelke, 1994).

In computer science, attempts to model conceptual change in various systems motivated quite different models that naturally arose from certain architectures. Wholesale conceptual revolutions were often more difficult to model than gradual incremental differentiation of concepts that might ultimately drift to quite different patterns of thought but not have a revolutionary flavor (Moorman & Ram, 1998; Roschelle, 1995; Shultz, Mareschal, & Schmidt, 1994; Thagard, 1992).

In psychology, other models of conceptual change have existed for many years. These might include gradual differentiation of a set of conceptual distinctions or procedures. Here, too, computer science implementations were sources of inspiration. Thus, models of children's developing understanding of tasks such as balance beams as a differentiating set of rules were closely linked to work in artificial intelligence on production systems (Klahr, Langley, & Neches, 1987; Lan-

gle, 1987; Newell & Simon, 1972; Siegler, 1976, 1981). The development of the microgenetic method in psychology (Siegler, Chapter 11, this *Handbook*, this volume) was certainly influenced by incremental logs of scientific discovery in computational systems (Newell & Simon, 1972; Simon, 2000).

Beyond differentiation and conceptual revolutions however, recent work in psychology has drawn on several other models of conceptual change, and frequently through inspiration from other fields of cognitive science. The question of whether change is qualitative versus quantitative has been informed by formal discussions of such contrasts in both philosophy and linguistics (Briscoe, 2000; Christiansen & Chater, 1999).

More specifically, several different structural models have emerged through commerce with other disciplines in cognitive science. Consider two such examples that have emerged as alternatives to the ideas of conceptual revolutions and gradual incremental change: increasing access and shifting default biases (Inagaki & Hatano, 2002; Keil, 1999).

The notion of increasing access was initially proposed in the context of comparative considerations of how development varied across species (Rozin, 1976). A cognitive routine might be largely automatized and relatively encapsulated and then gradually become more and more available for use in other domains in some species, but not others. In development, Rozin suggested that increasing access to a phonological code might be the basis for major advances in learning to read (Rozin, 1976). In philosophy, notions of increasing access during the course of development figured prominently in accounts of modularity and conceptual change (Fodor, 1975, 1983; Karmiloff-Smith, 1992). In such accounts, a cognitive capacity might be present early on, in a narrow range of contexts, but then become available for deployment in a wider and wider range of situations. In anthropology, it is common to talk about how an innovation might initially be sequestered within a small group and then spread through a culture as access increases. The notion of increasing access to a cognitive skill or competency is an account of conceptual change that is starkly different from both gradual differentiation and revolutionary change. The mental structure or computational routine might be present and unchanged throughout the relevant developmental period but simply be unavailable for use in many tasks in younger children. A sharp increase in access can look like dramatic concep-

tual change even as the underlying conceptual structure changes little.

The notion of differing default biases suggests that children might have two quite different ways of understanding a system with the primary changes being which one first comes to mind or is seen as most relevant in particular tasks. Unlike increasing access, two different forms of thought may be fully accessible throughout a developmental period, but there may be a dramatic shift in which one is normally used first. Thus rather than seeing young children as only able to understand animals in psychological terms, this view might argue that, throughout much of development, children have both biological and psychological ways of understanding organisms but that younger children tend to default more to the psychological form (Gutheil, Vera, & Keil, 1998). In some tasks, slight reframings of contexts can get young children to use the lesser default (biology) in reasoning (Gutheil et al., 1998). This idea of shifting default biases was heavily influenced by cross-cultural work in anthropology showing that people in other cultures often did not simply have a radically different way of viewing the world, but rather had multiple ways of making sense of situations that might overlap closely with people in other cultures. What differed was which ways of thinking were first elicited in certain sets of contexts. Forms of reasoning about moral situations in terms of sacred violations, or interpersonal harm, or authority conformance, might all be available to people in all cultures, but have different default hierarchies as to which is elicited first in local contexts such as family, community, or peer interactions (Haidt, 2001; Shweder, Much, Mahapatra, & Park, 1997; Turiel & Perkins, 2004).

Shifting default biases are also informed by discussions in philosophy and linguistics of relevance and how it is determined in discourse (Sperber & Wilson, 1995). In those fields, a rich discussion has focused on principles guiding inferences about the relevance of various topics and propositions to situations and prior discourse. Those discussions in turn influence how psychologists think about how children might adopt one frame of reference versus another (Keil, 2003a).

Linguistic approaches to the study of language acquisition afforded unusually specific accounts of different patterns of conceptual change. Thus, debates about whether the very young child understood ordering relations in a language in radically different ways from older children, led to vigorous debates about how the nature of

natural grammar might change over time (Brown, 1973; Ingram, 1989; Lightfoot, 1999; Pinker, 1994). The precision of those different accounts and the ways in which evidence is brought to bear on them strongly influenced models of conceptual change in psychology.

In summary, as patterns of change are considered across a broader range of disciplines than just psychology, we start to see sharply contrasting ways in which change might occur. These patterns can then be used to motivate studies that directly explore which changes are actually occurring in cognitive development. Several studies now suggest that a much greater diversity of highly explicit models of conceptual change is needed to adequately model the changes we see in children. For example, as the microgenetic method offers more fine-grained images of developmental change, it also reveals how superficially similar patterns of change can have quite different underlying bases.

What Is the Difference between Learning and Development?

It has long been a controversy in developmental psychology as to whether the patterns of learning seen in adults are of a different kind from those found in children (see chapters by Siegler, Chapter 11; Kuhn & Franklin, Chapter 22, this *Handbook*, this volume). Consider, for example, the patterns of qualitative change that occur as adults progress from novice to expert forms of knowledge and whether those patterns are essentially the same patterns as qualitative change in children (Brown, Bransford, Ferrara, & Campione, 1983; Chi, 1978). The debate has become considerably more sophisticated as a result of converging discussions in other disciplines that contribute to the cognitive sciences.

In computer science, there have been attempts to model increasing expertise in ways that have invoked both local and global aspects of cognition (Anderson, 2000; Ericsson, 1996; Gobet, 1997; Larkin, McDermott, Simon, & Simon, 1980; Schunn & Anderson, 2001). This contrast in turn informs the refined question as to whether children differ from adults primarily because they are universal novices rather than more local ones. Perhaps only those with local novice states can use analogies to grow knowledge in other domains because only they have expertise in another domain that they can use as a basis for an analogy. Adults might find it much easier to learn about computer programming by using

analogies arising from domains where they are more expert, such as recipes in cooking, whereas children may not have such domains to use as launching pads for analogies. Computer scientists and psychologists in collaboration have, in turn, built simulations of how structure mapping might allow transfer of analogical relations to a new domain (Falkenhainer, Forbus, & Gentner, 1989; Gentner, *in press*). These simulations enable researchers to assess more precisely the benefits of expertise in one domain on a novice to expert transition in another.

At the level of neuroscience, changes in anatomy and functional status of brain regions postnatally start to place constraints on the learning versus development contrast. It is commonly assumed that considerable physical and functional maturation of the prefrontal cortex might influence development of cognition in domains as diverse as moral reasoning and intuitive physics (Zelazo, 2004; Zelazo, Muller, Frye, & Marcovitch, 2003). It is always risky to infer too much about psychological change from neurological change, but as techniques become ever more sophisticated in neuroscience, at the least, loose constraints emerge that might indicate how development would differ from learning. If there are global, brain-based limitations on executive processing that apply across all domains in young children, then no amount of learning in any of those domains in childhood will be the same as a novice-to-expert transition in one of those domains as an adult.

From anthropology, the influences may be more subtle but are still present. As one considers patterns of cognition across cultures, it is common to ask how a domain that has a long cultural tradition in one culture differs from cases in which it is relatively novel in another. People in one culture might well be considered experts in an area, because of their cultural heritage, while those in a different culture without that heritage might be considered novices. When scholars ask about how a culture came to a certain set of beliefs over time, they may ask about the extent to which that pattern of historical development was analogous to the pattern of development that might occur in individuals who are going from novice to expert states in one lifetime. There has been considerable discussion of how individuals in cultures such as China and Russia are learning, as adults, about capitalism, a kind of cultural novice-to-expert transition. It is natural, then, to contrast those patterns of change with those that gradually occurred as capital-

ism developed over many generations in other cultures (Asland, 2002; Cornia & Popov, 2001; Guthrie, 1999). Are the two end states the same, or are there intrinsic differences between how a practice develops over many generations in a culture and cases in which it emerges in less than one generation? These discussions may not have yet influenced issues of learning versus development in psychology, but they are likely to do so in future years as psychologists confront many of the same issues.

In linguistics, there has been a particularly focused approach to questions of learning versus development by exploring questions about first (L1) versus second (L2) language acquisition (Bialystok & Hakuta, 1994; Ellis, 1994; Gregg, 2001). The nature of L1 acquisition may be different from that of L2. Contrasts range from the influences of L1 on L2, thus drawing parallels to the universal versus local novice issue, to issues involving maturational and critical period effects (Johnson & Newport, 1989; Newport, 1990). Detailed structural comparisons about the precise nature of the two forms of acquisition shed considerable light on how to think more broadly about the learning versus development controversy. Thus, because formal linguistics enables language-acquisition researchers to carefully track structural change over time, it is possible to document differences in novice-expert shifts in adult L2 learning and child L1 learning. A key question is whether those differences will be unique to language because of special domain-specific properties or whether some aspects of those differences will shed broader light on the learning versus developmental controversy.

REPRESENTATIONAL FORMATS

Questions about cognition often involve questions about the formats of mental representations. In considerations of the development of cognition, questions about representational formats become central, especially when considered in a cross-disciplinary manner.

What Representational Formats Underlie Developmental Change?

In some ways, questions about representational formats underlying developmental change overlap with those just considered with respect to conceptual change. Thus abstract-to-concrete shifts are partially ones about for-

mat; but they also can be considered as more concerned with questions about the kind of information (e.g., high versus low category level) that is used at various points of development. Questions more directly focusing on format ask about how we might want to best represent knowledge at various points in development. Developmental psychology has long entertained claims about representational formats and how they might change, even during the times when behaviorists frowned on such discussions in many other areas of psychology. Consider the view of children progressing from enactive, or motor-based representations, to image-based ones, to more symbolic propositional ones (e.g., Bruner, 1967). This approach attracted considerable attention and was linked to a large set of empirical studies, but benefited greatly from philosophical considerations of the plausibility of particular representational formats and the mechanisms for making transitions between them. One analysis suggested that there was no feasible mechanism available in psychology for describing how a child could progress from understanding the world largely in terms of images to then understanding it in terms of language like propositions (Fodor, 1972, 1975). That question developed into a substantial philosophical literature (e.g., Davidson, 1999; Glock, 2000) that in turn led to reevaluations of such representational shifts in psychology.

In computer science, a vigorous debate has emerged concerning the intrinsic limitations on various forms of computational architectures. Many of these early debates centered around Turing machines, Markov machines, and perceptrons with some of the most detailed applications involving models of language learning and vision (Chomsky, 1957, 1965; Minsky & Papert, 1969). In some cases, these accounts were viewed as formal descriptions of learning procedures, but in others they were viewed as having representational implications. In both philosophy and linguistics, new ideas therefore emerged about links between representations and learning. Such questions became much more prominent, however, with the emergence of connectionism, which was frequently cast as a dramatic alternative to symbolic representational systems (Churchland & Sejnowski, 1994; Smolensky, 1988). The notion of a proposition-like language of thought that manipulated symbols in the manner of classic computer architectures was rejected in favor of “subsymbolic” forms of representation (Smolensky, 1988).

There remain vigorous debates about the merits of both approaches and about the nature of the formal computational limitations of each (Marcus, 2001); but there has also been intriguing feedback from such debates to models of the representational states of children and infants. There have been connectionist models of the object concept in infants that have led to novel predictions about performance on object search and retrieval tasks (Munakata, 2001; Munakata et al., 1997). Connectionist considerations of how past tense forms and word order might be learned have led to predictions as well (McClelland & Patterson, 2002). Similarly, as discussed earlier, attempts to model abstract patterns of conceptual change in terms of connectionist architectures (Rogers & McClelland, 2004) have led to new suggestions about how conceptual change might occur.

From a different computational perspective, there has been a surge of work on computational systems based on Bayesian approaches that are designed to track causal structure in the world (e.g., Gopnik et al., 2004; Sanjana & Tenenbaum, 2002; Tenenbaum & Griffiths, 2001). These approaches have afforded powerful new insights into how causal patterns might be apprehended and then elaborated on. In cases in which such simulations are successful, they can then be used as a basis for speculations about underlying representational formats. Thus, one key question is whether certain network graphs of probability relations can do away with any explicit use of the notion “cause” in a representational system.

Finally, from neuroscience, there has been impressive progress in describing neural circuits in ways that suggest how information might be represented and modified in the course of development (Gallistel, 2000). One of the best worked-out examples is seen in discussions of the neural structures underlying pattern recognition in various regions of the visual cortex. Some visual illusions, such as illusory contours, can be found to be computationally present in the first levels of processing of the visual cortex (e.g., Ramsden, Hung, & Roe, 2001). This finding in turn has led to computational models of development that include interactions between higher-order visual processes and more feature-based ones throughout all periods of development, rather than as a sequence from feature representations to those embodying illusions (Grossberg, 2003).

Questions about representational formats are at the very heart of much of cognitive science and have been

the focus of intensive study in many different fields. Those lines of work are now intersecting more and more and, as a result, are refining views in developmental psychology of how to characterize the representational bases of developmental change.

What Is the Role of Implicit and Explicit Thought in Cognitive Development?

In one form or another, developmental psychologists have long embraced the idea that some aspects of cognition develop outside awareness while others are very much part of our phenomenal experience. Freud's discussion of unconscious thought and its role in development (Freud, 1915) has been considered an early cognitive science theory of representations in development (Kitcher, 1992). Sensorimotor (Piaget, 1952) and enactive (Bruner, 1967) representations might be thought of as examples of implicit thought in early development. It is, in fact, common to think that a major part of infancy may be dominated by implicit thought, which yields to more explicit thought with the onset of language. But these older discussions in psychology were often quite vague in defining the two forms of thought. In more recent years, work in other areas of cognitive science has helped to refine the senses of these contrasts. In neuroscience, patterns of brain damage such as the classic case of HM, who had hippocampal regions removed to cure epilepsy (Corkin, 2002; Scoville & Milner, 1957), have illustrated how implicit learning can proceed while explicit learning seems blocked. Thus, amnesics like HM can show marked improvement on many tasks, such as the tower of Hanoi, while not explicitly remembering the task at all. Other work on visual processing streams, showed that the dorsal stream seems to be involved in implicit processing of visual information while the ventral stream is involved in more explicit processing (Goodale & Milner, 2002; Goodale, Milner, Jakobson, & Carey, 1991). That neuropsychological work has in turn been invoked to explain developmental changes in how infants regard the trajectories of objects (Mareschal, 2000; Von Hofsten, Vishton, Spelke, Feng, & Rosander, 1998).

In linguistic theory, there has long been a contrast between implicit linguistic knowledge in the form of a natural language grammar, and explicit understanding of the structure of a language, which may be largely absent in most normal users. Even though children and adults can show precise and powerful intuitions about

grammaticality of sentences, they may have little or no explicit access to those grammatical rules. In some cases, perhaps the grammar of language, it is been argued that the implicit nature of the knowledge arises from it being a module that is informationally encapsulated and cognitively impenetrable (Fodor, 1983).

Philosophical work on modules (e.g., Fodor, 1983) in turn inspired newer psychological approaches asking if automatization of skills might be related to transitions from implicit to explicit and the opposite (Karmiloff-Smith, 1992). In particular, several of those psychological approaches attempted to explain how implicit domain-specific forms of representation and processing might emerge in an organism that had minimal innate biases for those forms of representations (Karmiloff-Smith, 1992). Thus, notions of implicit and explicit in developmental psychology have been considerably sharpened by philosophical proposals about how and why some aspects of cognition might work outside awareness.

Computational approaches that directly target the implicit/explicit contrast have been less prominent. Again, the rise of connectionism was accompanied by claims that processing at the subsymbolic level might also often be implicit (Churchland, 1990). It remains unclear, however, as to how explicit cognition can be best modeled as emerging from a connectionist architecture.

The emergence of research on metacognition in developmental psychology is also related to the implicit/explicit contrast. In that work, young children have complex cognitive systems involved in memory and attention yet often seem to be largely unaware of those systems (Flavell, 1979; Wellman, 1985). Many of the researchers studying metacognition turned their attention to "theory of mind" (Flavell, 1999; Wellman, 1992); they became more centrally interested in the question of how one gains an awareness of mental states in oneself and in others. That new focus brought in a rich philosophical literature on what it means to be aware of one's own mental states (Aydede & Güzeldere, in press).

More broadly, work on epistemology in philosophy has inspired psychological work asking about how children come to have an explicit awareness of their own knowledge states and of the processes of acquiring and evaluating knowledge (Kuhn, 1993, 1999; Kuhn & Franklin, Chapter 22, this *Handbook*, this volume). Naïve epistemology connects to the implicit/explicit contrast because of the clear difference between having and using knowledge and being aware of that knowledge.

Developments in philosophy in the study of social epistemology, that is how knowledge is constructed in social groups (Goldman, 2002), have also influenced psychological work on how children seem to understand the division of cognitive labor in the world around them (Danovitch & Keil, 2004; Lutz & Keil, 2002).

The implicit/explicit contrast in many respects remains a puzzle. A simple noncircular account of explicit cognition continues to elude us, perhaps not surprisingly as it is closely related to the “hard problem” of consciousness—knowing what it is like phenomenally to have a conscious experience (Chalmers, 1996). At the same time, research is moving rapidly forward regarding many of the distinctive features correlated with cases of implicit cognition (instances more like the “easy problem” of consciousness; Chalmers, 1996). Moreover, work across the disciplines is helping inform our understanding of the relations between these two modes of thought in development. One important advance has occurred in work on the development of the self-concept, which might be considered a necessary part of explicit cognition. By breaking down the notion of self-knowledge into five distinct senses, ranging from a perceptual “ecological self” to a highly propositional “conceptual self,” it is possible to see how some sense of self is present throughout development from the earliest moments of infancy (Neisser, 1988). That sort of analysis has helped foster views that no longer involve a shift from the cognitively implicit infant to a cognitive explicit child, but rather examine the ways in which a form of cognition may be manifested throughout the developmental period.

What Is the Role of Association and Rules?

For almost a century, psychologists have been concerned with two very different ways of thinking about how humans might represent reality: in terms of rule-like representations or in terms of associative ones (Sloman, 1996). Associations were traditionally thought to be frequency-based tabulations of environmental contingencies and have a legacy at least as far back as the writings of the British empiricists in the eighteenth century (e.g., Hume, 1975). In developmental psychology, there has long been a suggestion that associative ways of representing information are more developmentally basic, or foundational, and are then later supplemented or replaced by rule-based forms (e.g., Inhelder & Piaget, 1958; Klaczynski, 2001; Kuhn

& Franklin, Chapter 22, this *Handbook*, this volume). Despite the intuitive sense that there is a powerful contrast at work, this notion has been difficult to explore further in developmental psychology until quite recently when developments in neuroscience, linguistics, and computer science began to suggest more detailed ways in which the contrast might, or might not, be implemented in a representational model.

From neuroscience, there emerged claims that rule-based and association-based knowledge of linguistic forms could be dissociated through patterns of brain damage as well as through different activation patterns as revealed by imaging studies. Some people have deficits that make them do poorly with irregular past tense forms, which may be learned in largely associative ways, while doing fine with regular tense forms. Others may show the opposite pattern (Marslen-Wilson & Tyler, 1997; Pinker, 2001; Tyler et al., 2002). This pattern of findings has in turn brought in computational modelers who vigorously debate whether two computational systems are needed (McClelland & Patterson, 2002; Pinker & Ullman, 2002). Those computational debates have subsequently inspired newer psychological approaches that attempt to model the rules versus association contrast in terms of a single system of representation, such as a largely associative one in which rules are single-dimension evaluations at one end of a continuum that invokes more normal multidimensional similarity at other parts of the continuum (Pothos, in press).

The rules versus association debate has also been prominent in other ways in linguistic and philosophical discussions of the existence and nature of rules that are nonetheless implicit (Davies, 1995). One facet of this debate has been the question of whether rule-like properties (such as syntactic compositionality and productivity), can emerge from implicit architectures. For example, techniques for modeling connectionist networks as sets of vectors have been argued as embodying, through those vectors, rule-like properties (Pacanaro & Hinton, 2002; Smolensky, 1990). These modeling projects in computer science have led psychologists to ask about a richer array of representational formats that might be able to underlie behaviors that appear to be based on both rules and associations. One approach has been to argue that symbols and rules are more perceptually grounded than they might appear at first and, as such, are based on analogue representations that might be more easily compatible with connectionist networks while still being able to account for rule-like patterns in

how people acquire and use concepts (Barsalou, 1999; Prinz, 2002). This line of work has in turn been connected to theories about representations in infancy such as “image schemas” which appear to have at least some perceptual grounding (Mandler, 2004).

It is far too early to tell if abstractions, such as vectors or factors, over connectionist architectures, can fully model rule-like patterns without in the end simply becoming neural implementations of a symbolic system (Marcus, 2001). There is a major difference between views that one can model rule-like patterns without any need for rules or symbols, and whether they are very much a computational reality at the right level of description even in connectionist architectures (Chalmers, 1993; Marcus, 2001). Either way, the debate has been invaluable in sharpening the focus on the roles of rules and associations in development. A central developmental question concerns whether it is appropriate to see younger and younger children as more and more associative creatures, with rules only becoming important at later points (Klaczyński, 2001). Perhaps infants are best understood as largely associative creatures that only acquire rule-like representations after they have gained some mastery with language. Indeed, this account might be considered one facet of Vygotsky’s theory (Vygotsky, 1962). Alternatively, it may be that human cognitions are necessary hybrids of association and more rule-like structures and that both must be present throughout development for learning to ever get off the ground and proceed successfully (Keil et al., 1998). Such hybrid architectures offer a fascinating way to think about the representational basis for development and in turn raise complex questions about how the two formats interact throughout the course of development. Rather than seeing one format in competition with another, it may be much more fruitful to think of them in mutually supporting roles (Farah & Rabinowitz, 2003; Keil et al., 1998; Sun, 2001).

GENERALITY AND SPECIFICITY

Across the cognitive sciences there has been a convergence of interests on questions concerning the generality and specificity of cognitive structures and processes over the course of development. Many longstanding questions about the nature of cognitive development have been greatly informed by increased attention to the

kinds of universals and the kinds of domains that are needed to characterize the growth of the mind.

Are There Developmental Universals?

Developmental psychologists over the years have proposed that inevitable patterns of development and knowledge structures might be built on each other in a sequence largely determined by the structure of that knowledge. Thus, Piaget’s concept of epigenetic development included the idea that knowledge structures and cognitive skills developed to a point where their internal structure precipitated change to a new form. Similarly, models of conceptual change as revolutions are often described as the gradual accumulation of evidence that challenges the existing theory until that theory reaches a point when it undergoes a revolution in terms of how some aspect of the world is understood (Carey, 1985; Kuhn, 1962).

These views of development are compatible with an account involving universal patterns of cognitive growth, not because of innate universal constraints, but because there is only one way of developmentally assembling knowledge. As suggested, the knowledge itself, plus simple assumptions about learning in a normal range of environments, might be enough to account for universal patterns of developmental change. By way of analogy, with a certain set of building blocks, there may be only one sequence that enables building a structure above a certain height; with a set of functions, there may be only a certain sequence in which a computer program could be constructed. As noted, even in knowledge domains, such as mathematics, there are arguments for how certain forms of computation, such as addition, must be learned before others, such as multiplication (National Research Council, 2001).

In some cases, therefore, regardless of the instruction or the environment, a complex knowledge system or cognitive skill must be assembled in a fixed sequence. Thus, if development is to happen with respect to that system or skill, it must happen in the same way. The rate of developmental change may be heavily influenced by the environment and the child’s capacities, but not the sequence. In principle, this is an easy point to make with many analogies available in building systems in biology, computer science, and mathematics. That said, it is much more difficult in more naturalistic situations to have a sufficiently detailed and complete description of the representational and computational aspects of a skill

or kind of knowledge to know if it must follow a universal developmental sequence.

This area seems ripe for future investigation and is an area in which work in computer science, philosophy, and linguistics might be especially fruitful. Computer scientists for years have studied questions of optimality and necessity in the ordering of algorithms when designing large programs in traditional architectures. It is less clear whether the computational limitations of connectionist architectures are sufficiently constrained and shared across different versions as to suggest developmental universals, but this represents an interesting challenge for those working in such architectures. Similarly, in linguistic theory, formal models of acquisition often have a necessary order. One must have a set of parameters of different possible values before they can be set at each value. Similarly, certain abstract syntactic categories must be understood before ordering relations between them can be modeled. Philosophers, as well, frequently talk about necessary steps of an argument. It seems likely that, as work progresses in these fields on cognitive-science-related issues, it will greatly inform questions about universals in cognitive development.

In all discussions of developmental universals, anthropological and cross-cultural perspectives loom particularly large; for it is only in those more dramatic differences across kinds of environments that developmental universals can be explored. Thus, if it is claimed that a particular end-state knowledge structure must have arisen from a specific developmental sequence, the best test of such a claim is to consider the most radically different real-world environments possible and see if the same sequence repeatedly occurs.

In summary, questions about developmental universals are not as well studied as others in this chapter. However, they seem likely to be precisely the sort that will most benefit from a cognitive science perspective.

What Constitutes a Cognitive Domain?

There has been a sea change in the study of cognitive development from talk about global patterns of change to talk about domain-specific ones (Gelman & Kalish, Chapter 16, this *Handbook*, this volume; Keil, 1981; Wellman & Gelman, 1997). In many cases, development in a particular domain has its own unique path quite different from that found in other domains. Yet, despite an embrace of domain specificity in many quarters, there remains a difficult and confused issue of

how to characterize a domain. That issue may well be better understood with the benefit of a cognitive science perspective. Depending on the different ways in which knowledge and cognitive skills are used, quite different senses of domains emerge with the contrasting senses becoming clearer when considered across the disciplines involved in cognitive science. Three different senses seem most common: domains as modules, domains as areas of expertise, and domains as modes of thought (cf. Wellman & Gelman, 1997).

In the sense of modules, we can think of distinct cognitive domains that fit the criteria laid down by Fodor (1983). Modules are relatively independent cognitive and perceptual systems that show properties of informational encapsulation and impenetrability. Thus, the information in a system is bounded and operated on in a manner distinct from other areas of thought and cannot be cognitively examined by more general thought processes. Modules are thought to be activated by particular informational patterns. They then automatically run through their processing routine with little or no control by other aspects of cognition. They are also assumed to have distinct and dedicated neural architectures that are innately predetermined.

The domains of thought corresponding to modules often have a quasi-perceptual nature and, indeed, some of the best worked-out examples involve perception. A common example is the perseverance of visual illusions even as higher-level cognition might state with certainty that they cannot exist. A viewer may know full well that two lines are of the same length or two circles are of the same size but be unable to overrule the phenomenal impression of differing sizes (Pylyshyn, 1999). Comparable properties were assumed to hold for more cognitive kinds of modules such as those that were involved in syntactic processing (Fodor, 1983) and theory of mind (Scholl & Leslie, 1999, 2001). The sense of domains that emerges is one in which there is often a strong perceptual grounding and the domains are often quite small in scope or are only part of a functioning cognitive system. Thus, if there is a theory of mind module, it may only apply to certain aspects of thinking about social beings and their mental states and not others. Similarly the modular component of natural language syntax may not account for all aspects of syntactic structure and certainly not all aspects of language structure.

There have been many discussions of Fodor's version of modularity, ranging from arguments for massive modularity in which the highest levels of cognition are

modularized (Pinker, 1997; Sperber, 2002) to arguments that modularity should be strongly limited to a relatively small number of cases usually related to perceptual input systems (Fodor, 2000). A different line of criticism has been to suggest that modularity can also emerge through a process of modularization as a function of acquired expertise in a domain (Karmiloff-Smith, 1992). Domains organized around expertise, however, have a different grain and functionality from the original sense of modularity.

Expertise domains, the second possible sense of domain, can vary enormously in terms of the specificity of the domain. Quite young children can be an expert on characters in a particular video game, on dinosaurs (Chi, 1983), chess (Chi, 1978), and on any number of other topics and skills. Moreover, expertise confers cognitive advantages in terms of task performance. This sense of domain differs dramatically from that used in discussions of Fodorian modules. There is massive individual variation with respect to expertise domains, as opposed to relatively uniform performance levels for Fodorian domains. Expertise domains can, on at least some occasions, be cognitively penetrable and not automatic, although emerging automaticity can also occur with some forms of expertise such as reading, typing, and the like. Expertise domains can also be constantly evolving and changing and therefore may not have universal properties across cultures.

Finally, a third sense of domain specificity is based more on the idea of constrained frameworks of thought (Keil, 1981; Pinker, 1997). This sense of domain has sometimes been equated with having a theory (Gelman & Kalish, Chapter 16, this *Handbook*, this volume; Wellman & Gelman, 1997), but theories can vary considerably across individuals. It is useful therefore to contrast acquired theories (Gopnik & Wellman, 1994), such as those of cosmology, which can often be local and culturally specific and which are more likely to be part of a domain of expertise, with broader foundational ways of understanding the world that may be universal and often more implicit.

Advocates of radical conceptual change are more likely to embrace domains as theories that can vary considerably across individuals and cultures. By contrast, it may be that, even at the highest levels of thought, there are universal domain-specific constraints on the kinds of beliefs and conceptual systems that people develop. This last proposal is highly controversial, as some, such

as Fodor (1983), argue against any sort of domain-specific constraints on central cognitive structures. Consider how such constraints might work. There are, for example, different forms of argumentation, such as the teleological and mechanistic. If one associates the teleological with one domain and the mechanistic with another, it may be more difficult to frame arguments in the nonnatural form of argumentation. Thus, people may naturally be predisposed to make teleological arguments about living kinds (Atran, 1998; Keil, 1992) and in doing so may find it difficult to entertain arguments that are not teleological. Similarly, people may assume an essence for living kinds that they do not assume for artifacts (Gelman, 2003; Keil, 1989). That essentialist assumption powerfully constrains theory construction about living kinds versus artifacts.

Work in other areas of cognitive science has shed considerable light on domain specificity and its different senses. Thus, in philosophy and anthropology, there has been discussion of the extent to which there could be modularity at the highest levels of conceptual structure (Sperber, 2002). A particularly intriguing line of argument is that cultural transmission of knowledge may be greatly facilitated by having shared domain-specific constraints on conceptual systems, these constraints paradoxically allow for cultural diversity by providing a common ground that enables the spreading of ideas in an understandable manner (Boyer, 2001; Sperber, 1994). In computer science, a number of approaches have examined sequestering computational routines and data representations into distinct domains with their own unique principles. Thus, it is commonplace to have specialized chip architectures for processing video arrays as opposed to numeric computations. As mentioned, a fascinating series of studies has emerged in neuroscience, asking what senses of domains might be disrupted by damage to neural tissue with an interesting feedback from that work to computational modeling. That particular discussion is informative for the ways it has refined questions about what senses of domains are viable and how domains might get set up in development. In linguistics, there has been a major shift in perspectives regarding whether there are domain-specific constraints governing aspects of language learning as diverse as syntax and word meaning. In contrast to earlier work suggesting that word learning happened because of language-specific constraints on such meanings, it now appears that such constraints emerge from much broader

facets of cognition (Bloom, 2000). In light of that more recent work, the relevant sense of domain shifts accordingly.

There remains a need to refine the different senses of domains and the claims that one wants to make about each in terms of patterns of cognitive development. Further refinements in developmental psychology will almost surely be heavily influenced from work on how different senses of domains are implemented in other areas of cognitive science.

CONCLUSION

Why has the study of cognitive development become linked especially closely to the cognitive sciences in contrast to many areas of cognitive psychology that continue to function as freestanding enterprises largely unaffected by work in other disciplines? It may be because the study of change over time is such a powerful theme in so many areas of research. Whether it is the study of moral beliefs in a culture, a grammatical form in a Celtic language, the history of ideas about species, or the adaptation of a computer network to new inputs, there are interesting stories to tell about beginnings, patterns of change, representational formats, and the generality of the phenomena. These discussions have relevance for the study of cognitive development at levels far beyond those of analogy and metaphor. Repeatedly in this chapter, we have seen how highly explicit ideas in accounts of cognitive development have been inspired by work in other fields on the growth of a cognitive capacity. Developmental questions evoke converging threads from many disciplines in ways that few other questions do.

In this chapter, we have considered 10 questions that have a venerable history in developmental psychology: What is the initial state? Is there an adapted mind? Does development proceed from the concrete to the abstract? What is the nature of conceptual change? What is the difference between learning and development? What are the representational formats underlying developmental change? What is the role of implicit and explicit cognition in development? What is the role of association and rules in development? Are there developmental universals? What constitutes a cognitive domain and how does domain structure influence development? These 10 questions also have had long histories in the disciplines

of philosophy, linguistics, computer science, neuroscience, and anthropology. The striking new pattern is how researchers in psychology are starting to provide and receive benefits from work on similar versions of these questions in the other disciplines. A sense of the larger enterprise of cognitive science has fostered interactions between each of these fields in profound ways that were often unimaginable to those who originally posed these questions in their own disciplines in the past. As a result of these interactions, these questions have assumed a much greater precision and predictive value in each discipline, perhaps especially so in psychology. In many cases, the meanings of these questions are not only more precise, they have changed in ways that are different from their original form and, as a result have suggested new kinds of answers. By all indications, the decade ahead will only accelerate this trend.

This chapter is the third *Handbook* contribution devoted specifically to the topic of culture and cognitive development, although several chapters in prior editions, as well as those by Shweder and his colleagues, Chapter 11, this *Handbook*, Volume 1, and Greenfield and her colleagues, Chapter 17, this *Handbook*, Volume 4, include relevant material within the broader rubric of culture and development. In light of the increasing attention being given to culture's role in development, my goal is to complement these contributions by broadening the issue of culture and cognitive *ontogeny* (which has implicitly been the topic of all other *Handbook* chapters on culture and development) to place it in a broad evolutionary and historical framework.

This expanded analysis of culture in development seems an important task for several reasons. No one writing on this topic denies that human development is heavily constrained by our species' phylogenetic heritage. In

fact, Shweder and his colleagues (1998) explicitly state that human beings are creatures with a long, common phylogenetic past that provides constraints on development. They also invoke ideas about the influence of experience that come directly from work in developmental neuroscience. However, they do not explore how these phylogenetic factors are linked to culture and human ontogeny, restricting themselves to pointing out that whatever these primeval, shared, characteristics are, they "only gain character, substance, definition and motivational force . . . when . . . translated and transformed into, and through, the concrete actualities of some particular practice, activity setting, or way of life" (Shweder et al., 1998 p. 871). This perspective provides a good starting point, but if it is not elaborated on, it de facto places human phylogeny and cultural history so far into the background of their presentations that the ongoing relationships between these different spheres during on-

togeny go unexamined. Rogoff (2003), who also presupposes but does not analyze species-specific phylogenetic foundations to cognitive development, focuses instead on shifting modes of participation within and between practices during ontogeny and historical changes in those practices.

The approach I adopt here reflects my long-term interest in the work of the Russian cultural-historical school of psychology, for whom human development was seen as the emergent outcome of phylogenetic, cultural-historical, ontogenetic, and microgenetic processes all acting simultaneously on the developing person (Vygotsky, 1997; Wertsch, 1985). This position makes contact with increasingly popular work in the field of evolutionary developmental psychology (e.g., Bjorklund & Pellegrini, 2002), which focuses on the relationship between phylogeny and ontogeny. The evolutionary developmental perspective, however, pays little attention to the role of cultural history, particularly with respect to the issue of *cognitive* development. Consequently, one of my goals is to bring cultural history into the study of human development without abandoning a commitment to an evolutionary perspective.

DEFINITIONS: CULTURE, COGNITIVE DEVELOPMENT, AND ALLIED CONCEPTS

Since this chapter links the study of biological history cultural history and cognitive ontogeny, at least a brief discussion of the meanings of the terms *culture* and *cognition* as they appear in the different disciplines that I must draw on (e.g., anthropology, paleontology, primatology, and psychology) seems necessary.

Culture

In its most general sense, the term culture ordinarily refers to the socially inherited body of past human accomplishments that serve as the resources for the current life of a social group ordinarily thought of as the inhabitants of a country or region (D'Andrade, 1996). Several issues perennially spur debate concerning the concept of culture vis-à-vis the study of cognitive development in ontogeny. These include whether culture is a unique property of human beings, the extent to which human cultures can be ranked in terms of level of development, the relationship between mental/ideal

and material aspects of culture, and the extent to which culture can be assumed to be shared by members of a social group.

Is Culture Unique to Humans?

In recent years, many primatologists have argued that the core notion of culture is “group-specific behavior that is acquired, at least in part, through social influences” (McGrew, 1998, p. 305) or “behavioral conformity spread or maintained by nongenetic means” through processes of social learning (Whitten, 2000, p. 284). By this minimalist definition, culture is not specific to human beings. Not only many primates, but members of other species display behavioral conformities that they have acquired by nongenetic means, although precisely what those means are is widely debated.

I return to this point when discussing phylogenetic contributions to the development of human cognition. For the present, it is sufficient to note that even those who argue for the presence of culture among nonhuman primates generally agree that there is more to human culture than nongenetically transmitted behavioral patterns, just as there is more to human cognition than is found in nonhuman primates. Disagreements about precisely what this “more” is and what the differences in the nature of culture among species tell us about the role of culture in human cognitive development have produced a massive and contentious literature (Byrne et al., 2004).

Cultural History and Development

During the nineteenth century, culture was used more or less as a synonym for civilization, referring roughly to the progressive improvement of human creativity in areas such as the industrial arts, including the manufacturing techniques for metal tools and agricultural practices; the extent of scientific knowledge; the complexity of social organization; the refinement of manners and various customs; and control over nature and oneself (Cole, 1996; Stocking, 1968).

During the twentieth century, owing to the work of Franz Boas and his colleagues, the notion of culture-as-progress was gradually replaced by the idea that all cultures are the products of local adaptations to the circumstances of the social group during its history up to the present. Consequently, anthropologists have generally resisted the idea that different cultures could be scaled with respect to overall value or virtue, since such judgments are historically and ecologically contingent.

However, there remain those who emphasize that cultures can be ranked in terms of lower and higher levels of complexity, if not virtue. The question then becomes how such cultural variations are associated with variations in psychological processes (e.g., Damerow, 1996; Feinman, 2000; Hallpike, 1979).

Cultural Patterns: Shared or Distributed?

When early ethnographers such as Margaret Mead went to far-off, relatively isolated, nonliterate societies to study culture and development, their notions of culture were subsumable under the notion of “the socially inherited body of past human accomplishments that serves as the resources for current life of a social group in its historical and ecological circumstances.” In Mead’s case, parental attitudes toward adolescents and customs relating to young people’s sexual activities, or the ways the people of Manus built their houses on stilts, watched over (or failed to watch over!) their children, or engaged in animistic explanations for events constituted the “inherited knowledge” and “current resources” of interest. She also made the additional assumptions that social inheritance is highly patterned, interconnected, homogeneously experienced, and pervasive. The heavy emphasis placed on cultures as monolithic, gestalt-like configurations gave way over subsequent decades to appreciation of internal heterogeneity at both the cultural and individual levels and to the consequent need for people actively to create and recreate their culture for it to exist at all (Schwartz, 1978).

The degree to which particular cultural elements are shared has become an important topic in anthropology in general and the study of culture and cognition in particular. Kim Romney and his colleagues have proposed what they refer to as a “cultural consensus model” to characterize the degree to which users of a culture share particular understandings (Romney & Moore, 2001; Romney, Weller, & Batchelder, 1986). Medin and Atran (2004) apply this model to characterize how different subgroups within a society think differently about particular domains (e.g., how they conceive of nature and, consequently, how they act with respect to it). Such a “distributed” notion of culture finds its natural counterpart in distributed theories of cognition (e.g., Hutchins, 1995).

The Relation of the Ideal and Material in Culture

The proliferation of conceptions of culture by the middle of the twentieth century induced Alfred Kroeber and

Clyde Kluckhohn (1952) to offer a famous omnibus definition that provided greater specification to the general “social learning” approach adopted by primatologists or the “social inheritance” approach noted by D’Andrade for the human case:

Culture consists of patterns, explicit and implicit, of and for behavior acquired and transmitted by symbols, constituting the distinctive achievements of human groups, including their embodiment in artifacts; the essential core of culture consists of traditional (i.e., historically derived and selected) ideas and especially their attached values; cultural systems may on the one hand be considered as products of action, on the other as conditioning elements of further action. (Kroeber & Kluckhohn, 1952, p. 181)

Note that this definition contains a mixture of elements, some of which appear to be material things “out there in the world,” whereas others appear to be mental entities (ideas and values) that are “in here,” in the human mind. Here we see clearly the emergence of a division between the study of material culture and symbolic culture, which represents a major cleavage line in the field to this day. Moreover, Kroeber and Kluckhohn provide at least a crude evaluation of the relative importance of the ideal and material aspects of culture when they pick out ideas and values as the “essential core” of culture. This is not an innocent preference, but rather reflects the fact that in the middle of the twentieth century a steady movement began in anthropology away from definitions (theories) of culture that emphasize its behavioral/material aspects toward definitions (theories) that, following Kroeber and Kluckhohn, emphasize its ideational/mental aspects.

In recent years, it has become common to see efforts to combine the “culture is out there/material” and the “culture is in here/mental” views in definitions of culture.

For example, Shweder and his colleagues define human culture as *both* a symbolic *and* a behavioral inheritance:

The symbolic inheritance of a cultural community consists of its received ideas and understandings . . . about persons, society, nature, and divinity. . . . The “behavioral inheritance” of a cultural community consists of its routine or institutionalized family life and social practices. (1998, p. 868)

Thomas Weisner and his colleagues have developed a similar perspective. Weisner (1996) argues that the

locus for cultural influences on development is to be found in the activities and practices of daily routines that are central to family life. The relations between individuals and activities are not unidirectional, however, because participants take an active role in constructing the activities in which they participate. Consequently, “the subjective and objective are intertwined” in culturally organized activities and practices (Gallimore, Goldenberg, & Weisner, 1993, p. 541).

There are a great many suggestions about how culture operates as a constituent of human activity. In the early 1970s, Geertz cited with approval Max Weber’s image of humankind as “an animal suspended in webs of significance he himself has spun,” declaring that “I take culture to be those webs” (Geertz, 1973, p. 5). Owing to this metaphor, Geertz is often read as an anthropologist who adopts the conception of culture as exclusively inside-the-head-knowledge (e.g., Berry, 2000). It is significant, however, that Geertz (1973) explicitly rejected the strictly idealist notion of culture by suggesting that culture should be conceived by analogy with a recipe or a computer program, which he referred to as control mechanisms:

The “control mechanism” view of culture begins with the assumption that human thought is basically both social and public—that its natural habitat is the house yard, the marketplace, and the town square. Thinking consists not of “happenings in the head” (though happenings there and elsewhere are necessary for it to occur) but of traffic in what have been called, by G. H. Mead and others, significant symbols—words for the most part but also gestures, drawings, musical sounds, mechanical devices like clocks. (p. 45)

In what follows, I adopt the view that symbols and meaning embodied in, and constitutive of, historically accumulated practices constitute human culture.

Development

Because this chapter is intended for an audience dominated by developmental psychologists, the theory-laden nature of definitions of development requires far less exposition. If one thumbs through leading introductory texts on child development, it becomes clear that many of them simply don’t define the term, but assume its meaning and focus on particular content domains, or methods of analysis. Other texts offer “least common

denominator” definitions that are filled in later through examinations of theory and data: “the sequence of changes that children undergo as they grow older—changes that begin with conception and continue throughout life” (Cole, Cole, & Lightfoot, 2005, p. 2). Still others provide definitions that are theory laden; for example, “development involves age-related, qualitative changes and behavioral reorganization that are orderly, cumulative, and directional” (Sroufe, Cooper, & DeHart, 1996, p. 6).

The same problem arises when we turn to the more specialized topic of culture and cognitive development. Rogoff (2003) for example, treats the terms “learning and development” as synonymous. Others, including myself, see learning and development as interleaved, but distinct, processes involved in the cognitive change as children grow older (see Keil, Chapter 14, Kuhn & Franklin, Chapter 22; and Siegler, Chapter 11, this *Handbook*, this volume, for varying perspectives on this issue). Learning implies accumulation of knowledge and skills, whereas development implies qualitative reorganization of different constituents of such knowledge and skills and a concomitant reorganization of the relationship between persons and their environments (Cole, 1996; R. Gelman & Lucariello, 2002; Vygotsky, 1978). Diagnosis of the notion of development implied in any given treatment of culture and cognitive development is often most readily inferred from the specific tasks that are used as indexes of cognition, drawn as they are from different theoretical traditions of developmental psychology.

Culture and Cognition: A Synthetic Framework

As noted, the cultural-historical perspective from which I approach the question of culture and cognitive development requires that psychologists study not only ontogenetic change but also phylogenetic and historical change in relation to one another (Wertsch, 1985). According to the initiators of the cultural-historical perspective, each new “level of history” was associated with a new “critical turning point”:

Every critical turning point is viewed primarily from the standpoint of *something new* introduced by this stage into the process of development. Thus we treated each stage as a starting point for further processes of evolution. (Vygotsky & Luria, 1993, p. 37)

The turning point in phylogeny is the appearance of tool use in apes. The turning point in human history is

the appearance of labor and symbolic mediation. The major turning point in ontogeny is the convergence of cultural history and phylogeny with the acquisition of language. The product of these fusions of different streams of history is the distinctly human, higher psychological function.

In bringing this perspective up to date, I first review current data and speculation about the human biological, cultural, and cognitive characteristics in phylogenetic perspective. Next, I turn to research on cultural-historical change, then age-related changes in children's thinking as mediated by culture and the microgenetic changes through which ontogenies are constructed. My discussion of phylogeny is divided into two sections—one on hominization in relation to cultural and cognitive development, and the other on comparative studies of human and nonhuman primates—since each area has been the subject of intense interest in recent decades and in combination they are used to make claims about culture and ontogenetic development.

CULTURE AND PHYLOGENETIC DEVELOPMENT

I present the knot of phylogenetic issues in terms of two evolutionary lines. The first spans the several million years of human evolution beginning with the appearance of *Australopithecus* approximately 4 million years ago and ending with *Homo sapiens sapiens*, perhaps 60,000 years ago. The second focuses on the other branch of our phylogenetic tree, the great apes, especially contemporary chimpanzees and bonobos.

The logic uniting these two lines of investigation is the assumption that human beings and apes shared a common ancestor some 4 to 5 million years ago (Noble & Davidson, 1996). The successors to that common ancestor leading to *Homo sapiens* underwent massive changes not only in the brain and in physical morphology of the body (bipedalism, the structure of the arms, hands, and fingers, the vocal tract, etc.), but in physical ecology, cognitive capacities, and the accumulation of the products of the past in the form of human culture. By contrast, the anatomy, body size, physical morphology, behavior, cognitive abilities, and modes of life among nonhuman primates have not changed markedly over the past several million years. Hence, a three-way analysis of change, one that follows the hominid line, one that follows the nonhuman primate line, and a third that com-

pares the two should provide a "guesstimate" of the initial capacities of archaic human predecessors, the processes of hominid physical and mental evolution, and in particular, the role of culture in those processes. The results of this analysis then provide the essential context within which to consider human ontogeny and its relationship to human culture in evolutionary context.

Culture and Hominization

According to the general view summarized in Figure 15.1 and Table 15.1, there are a few relatively uncontroversial facts that serve as anchors for more detailed accounts of hominid evolution prior to the advent of modern human beings.

First, there is the evident increase in size of the brain in the sequence of species leading to *Homo sapiens sapiens*. There are various ways of calculating this growth in brain size but since the work of Jerison (1973), brain size has in some way been treated in relation to overall body size, which he referred to as an encephalization quotient (EQ; Falk & Gibson, 2001). Jerison demonstrated that the EQs of species from the great apes through the hominid line increase markedly, so that the EQ of modern humans is almost three times that of the chimpanzee and other great apes. Bickerton (1990) created a graph that arrayed EQs as a percentage of that of *Homo sapiens sapiens* across the presumed sequence of major landmark species in the hominid line that indicates an accelerating rate of change across time.

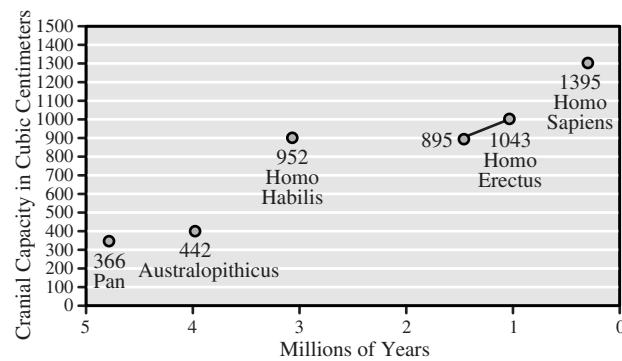

Figure 15.1 Evolutionary milestones for the hominid line, with divergence from chimpanzees at about 5 million years. Data represent cranial capacity in cubic centimeters associated with each new member of the hominid line. *Source:* From *The Human Primate* (p. 110), by R. Passingham, 1982, San Francisco: Freeman. Reprinted with permission.

TABLE 15.1 The Chronology of Anatomical and Cultural Change

Approximate time-line for the succession of hominids, in years before present.
5 million years: Hominid line and chimpanzee line split from a common ancestor:
4 million years: Oldest known australopithecines:
—Erect posture
—Shared food
—Division of labor
—Nuclear family structure
—Larger number of children
—Longer weaning period
2 million years: Oldest known <i>Habilines</i> :
—As above, with crude stone-cutting tools
—Variable but larger brain size
1.5 million years: <i>Homo erectus</i> :
—Much larger brain
—More elaborate tools
—Migration out of Africa
—Seasonable base camps
—Use of fire, shelters
0.3 million years: Archaic sapient humans:
—Second major increase in brain size
—Anatomy of vocal tract starts to assume modern form
0.05 million years: Fully modern humans

Source: From *Origins of the Modern Mind: Three Stages in the Evolution of Culture and Cognition*, by M. Donald, 1991, Cambridge, MA: Harvard University Press.

Although, as indicated in Table 15.1 and Figure 15.1, the overall and relative brain size of later hominids increased following the line from *Australopithecus* to *Homo sapiens sapiens*, this growth appears to have been especially pronounced in the frontal, prefrontal cortices, hippocampus, and cerebellum, all heavily implicated in cognitive changes both in phylogeny and ontogeny. Of special interest has been the appearance, derived from endocasts (moldings of the inside of skulls) for increased brain volume in Broca's area that appears with the advent of *Homo erectus* because of the relationship of Broca's area to language in normally developing modern humans.

There have also been many studies of morphological changes in other parts of the body associated with species changes following divergence from a common ancestor. These include bipedalism and various changes in anatomy with significance for hominization such as changes in the hand implicated in fine motor control (especially the opposable thumb), the pelvic region (which is crucial to the timing of birth and the length of infancy) and the vocal apparatus necessary for rapid and fluent speech (see Lewin & Foley, 2004, for a summary).

Data relevant to the cultural sphere, particularly the evidence of changes in material artifacts, are perhaps the second most reliable source of evidence concerning cognition-culture relations (Foley & Lahr, 2003). The first crude tools are often said to have appeared with *Homo habilis*. These tools were made of stone and, according to most interpreters, were probably made by shattering small rocks to make sharp-edged implements (choppers) and additional tools, such as knives, by chipping off flakes from the remaining stone core. With *Homo erectus*, there is generally believed to have been a quantum increase in size and the complexity of the tool kit. According to this line of interpreting the fossil record, tools now included hand axes with two cutting edges that required a much more complex manufacturing process. While initially change in the hominid tool kit was exceedingly slow, lasting perhaps a million years, the rate of change, the variety, and the complexity of tools increased in the course of human evolution, although the timing of changes is disputed (Foley & Lahr, 2003; Lewin & Foley, 2004).

With respect to behavior, which is inferred from the tools and the uses to which they were presumably put (e.g., cutting up large animals for meat, later for skins to be used as clothing) as well as evidence of group size and patterns of food consumption, *Homo erectus* appears to have been a critical turning point. For the first time there is evidence of creatures who lived in relatively permanent base camps, had stone tools that differed from any claimed for other species, and ventured out to hunt and gather; later in their 1.5 million years of existence, the use of fire makes its appearance. It is also *Homo erectus* that ventures out of Africa and migrates to Asia and Europe.

When we get to *Homo erectus*, the increased complexity of the tool kit (in particular, the symmetrical, crafted implements) provides evidence of greater cultural complexity and implies more complex cognitive abilities although it is uncertain what this increased cognitive complexity comprised. Some scholars argue that language was one such constituent (Bickerton, 1990; Deacon, 1997); special selective pressures for language development began early in evolution along the line to *Homo sapiens*, perhaps resulting from the need for increased cooperation in larger social groups, as with the appearance of *Homo sapiens* (Dunbar, 2004). Others argue that language came very late, with the advent of *Homo sapiens sapiens* owing to the development of a specialized vocal tract that could produce rapid speech (Lieberman, 1984). Whether early or late in hominization, symbolic language is agreed to be essential to the emergence of modern humans.

Suggestions for important cognitive changes that may or may not have accompanied language include increased ability to coordinate motor and spatial processing (Stout, Toth, Schick, Stout, & Hutchins, 2000; Wynn, 1989), increased ability to cooperate with others over extended periods to produce standardized products (Foley & Lahr, 2003), and an increased ability to imitate the behavior of others (Donald, 1991, 2001). (For discussion of Donald's views, pro and con, see Renfrew & Scarre, 1998.)

In some ways, the most well documented developmental change, from *Homo sapiens* to *Homo sapiens sapiens* is the most mysterious. Except for continued brain growth and some development in tools, there appears to be no clear reason for the sudden flowering of symbolic culture and the rapid expansion of human culture that is now clearly documentable, including sometimes elaborate burial with clear symbolic content, cave art, and ornamentation, not only of tools but for purposes that appear to have no direct utilitarian significance. The apparent discontinuity some 40 to 60 thousand years ago has led some to suggest a genetic mutation controlling the operation of a language module as the event leading to the appearance of modern humans (Berlim, Mattevi, Belmonte-de-Abreu & Crow, 2003). But this discontinuity position has been challenged by evidence of a great many species whose remains have been found in Africa that bespeak the presence of various elements of the "human revolution" (new technologies, long-distance trading, systematic use of pigment for art and decoration) tens of thousands of years earlier than previously thought but never fully developed in one place (McBrearty & Brooks, 2000). By this latter account, the human revolution was simply human evolution, in which many isolated changes in different species, combined with the changes in climate and population, brought disparate peoples together 40,000 years ago in Europe as it emerged from the latest Ice Age. The harsh climate had served to keep human groups apart, blocking the conditions of cultural and biological interaction among groups from which modern humans emerged.

If we seek to rise above the myriad disagreements among those who seek to synthesize processes at the phylogenetic level of analysis, the most important conclusion for our purposes is that the relations between biological, cultural, and cognitive change are reciprocal. The "virtuous circle" that the evidence most strongly supports is that changes in anatomy (increased relative

brain volume) resulted from a change in diet, in particular greater intake of protein from the killing and ingestion of animals. The ability to kill and eat animals was the result of concomitant anatomical changes (the ability to run long distances that evolved following the evolution of the ability to walk upright, which also freed the hands and was accompanied by greater dexterity of the fingers) (Bramble & Lieberman, 2004). These biological changes were both cause and result of increased sophistication of the cultural tool kit, including the control of fire (clearly a cultural practice, but one whose origins are disputed across a million-year margin). This richer diet and the way of life associated with it enabled the growth of cognitive capacities that further enriched the cultural tool kit, which in turn further supported growth of the brain, and so on. In Henry Plotkin's (2001) felicitous phrasing, "biology and culture relate to each other as a two-way street of causation" (p. 93).

Living Primates

Virtually all attempts to arrive at plausible speculations about cognitive change in phylogeny incorporate information from currently living species of nonhuman primates as an indirect way to make educated guesses about all the questions that arise when one is dealing solely with archeological evidence (see Joulian, 1996, for a discussion of this approach). Collectively, a number of remarkable events linking evolutionary biology, primatology, and developmental psychology in recent decades have revolutionized our ideas about the relationship between chimpanzees and bonobos (our closest primate kin) and modern humans (de Waal, 2001; Parker & McKinney, 1999).

In the middle of the twentieth century, those who considered culture a significant contributor to human development maintained that in many crucial respects, human beings are not just quantitatively, but qualitatively, different from other species in their cognitive abilities and in their use of culture as a medium of human life. At the time, DNA had not been decoded and the human genome project had not begun. Various hallmarks of human cognition and culture such as language, tool making, self-awareness, and intentional teaching were considered either nonexistent or extraordinarily underdeveloped in nonhuman primates. In short, there was something special about humans over and above their obvious morphological features associated with language and culture, which, in turn, were seen as co-

constituted. Human beings were considered exceptional not just because they have more brain cells, or differently organized brain cells, but an experiential way of life in which culture is both cause and effect of that experience.

The antiexceptionalism (continuity) side of this controversy, Darwinian saltation of cognitive capacity or cultural characteristics (producing a change in degree not kind), was revolutionized by DNA comparisons between humans and chimpanzees (Marks, 2002) and the ethnographic/ecological observations of communities of chimpanzees pioneered by Jane Goodall (1968). Together, the results of these landmark achievements make it more manageable to think of bonobos and chimpanzees as genetically very similar to humans. Matt Ridley (2003) sums up the shifting conceptions of chimpanzee mental, social, and cultural capacities when he refers to Goodall's descriptions of chimpanzee behavior in the wild over many years as "simian soap operas." Reading and then seeing videotapes of Goodall's chimpanzees, he wrote, their behavior seemed "like a soap opera written about the Wars of the Roses written by Jane Austin—all conflict and character." (p. 13). Goodall's chimps deceived each other, cheated on each other, and even killed each other. They also used leaves and sticks to fish for ants, and their children seemed to learn from seeing them do this.

I first examine current evidence concerning cognitive achievements and then the presence of culture among nonhuman primates before turning to the question of culture-cognition relations in these species and what issues those relations pose for scholars interested in culture-cognition relations in human ontogeny.

Cognitive Achievements

Some of the primate literature supporting a continuity perspective grows out of, or is conducted in connection with, ontogenetic studies of such processes as imitation, enumeration, self-awareness, attributions of intentionality, active teaching, and tool use, all of which have been implicated in the acquisition of cognitive capacities and the acquisition of human culture (Parker, Langer, & McKinney, 2000; Tomasello & Rakoczy, 2003; see also Boysen, & Hallberg, 2000).

Language

The study of language in nonhuman primates has been one of the most visible lines of research pushing the envelope of continuity theory (Savage-Rumbaugh, Fields,

& Taglialatela, 2001). Current enthusiasm for the idea that chimpanzees have the capacity to understand and produce language has been inspired by the work of Duane Rumbaugh & Sue Savage-Rumbaugh (Rumbaugh, Savage-Rumbaugh, & Sevcik, 1994). They provided their chimpanzees with a "lexical keyboard" whose keys bear symbols that stand for words, and they used standard reinforcement learning techniques to teach the chimpanzees the basic vocabulary symbols (e.g., "banana," "give"). In addition, the people who worked with the chimpanzees used natural language in everyday, routine activities such as feeding.

The Rumbaughs' most successful student has been Kanzi, a bonobo who initially learned to use the lexical keyboard by being present when his mother was being trained to use it. Kanzi is able to use the keyboard to ask for things and he can comprehend the meanings of lexical symbols created by others. He has also learned to understand some spoken English words and produce phrases of his own (Rumbaugh & Washburn, 2003).

Kanzi correctly acted out the spoken request to "feed your ball some tomato" (he picked up a tomato and placed it in the mouth of a soft sponge ball with a face embedded in it). He also responded correctly when asked to "give the shot [syringe] to Liz" and then to "give Liz a shot": in the first instance, he handed the syringe to the girl, and in the second, he touched the syringe to the girl's arm.

Kanzi's ability to produce language is not as impressive as his comprehension, however. Most of his utterances on the lexical keyboard are single words that are closely linked to his current actions. Most of them are requests. He uses two-word utterances in a wide variety of combinations, and occasionally makes observations. He produced the request "car trailer" on one occasion when he was in the car and wanted (or so his caretakers believed) to be taken to the trailer rather than to walk there. He has created such requests as "play yard Austin" when he wanted to visit a chimpanzee named Austin in the play yard. When a researcher put oil on him while he was eating a potato, he commented, "potato oil."

At present it appears that bonobos and chimpanzees can produce many aspects of language roughly at the level of a 2-year-old child using the lexical keyboard. In their productions, they form telegraphic utterances that encode the same semantic relations as young children (e.g., a two-symbol combination relating an agent to its action—"Kanzi eat"). These telegraphic

utterances can either combine visual symbols or combine gesture with symbol (Savage-Rumbaugh, Murphy, Sevcik, & Brakke, 1993).

Piagetian Developmental Milestones

An extensive line of work yielded evidence modeled on sensorimotor tasks favored by Piagetians to make the case for evolutionary continuity (e.g., Parker & McKinney, 1999). This research indicates that chimpanzees go through the same sequence of sensorimotor changes as human children, passing Piagetian sensorimotor tasks in various domains up to, and sometimes into, substage 6, the achievement of representational thought. Further evidence that substage 6 Piagetian understanding provides a meeting point of chimpanzee and human ontogenetic development comes from the work of Kuhlmeier and Boysen (2002) who have shown that that chimpanzees can recognize spatial and object correspondences between a scale model and its referent at a level of complexity roughly equivalent to that of 3-year-olds.

Acquisition of Tools Use

At least from the time of Kohler's classic studies of problem solving, a great deal of attention has been focused on chimpanzee tool use and tool creation. McGrew's (1998) summary regarding tool use is worth quoting at length because it indicates current claims for chimpanzee tool use and tool-making capabilities:

Each chimpanzee population has its own customary tool kit, made mostly of vegetation, that functions in subsistence, defense, self-maintenance, and social relations . . . many have tools sets, in which two or more different tools are used as composites to solve a problem. . . . The same raw material serves multiple functions: A leaf may be a drinking vessel, napkin, fishing probe, grooming stimulator, courtship signaler, or medication. . . . Conversely, a fishing probe may be made of bark, stem, twig, vine, or the midrib of a leaf. An archeologist would have no difficulty classifying the cross-cultural data in typological terms, based on artifacts alone; for example, only the far western subspecies . . . uses stone hammers and anvils to crack nuts. . . . Given this ethnographic record, it is difficult to differentiate, based on material culture, living chimpanzees from earliest *Homo* . . . or even from the simplest living human foragers. (pp. 317–318)

In line with McGrew's views, in at least one case it has been claimed that chimpanzees carry different tools with them to accomplish different goals (Boesch &

Boesch, 1984). The chimpanzees in question lived in the Ivory Coast. They encountered two kinds of nuts in their foraging, one with hard shells, the other with softer shells. For the hard nuts, they transported harder, heavier hammers (mostly stones) from their home base. They seemed to remember the location of stones and to choose the stones so as to keep the transport distance minimal.

Boesch and Boesch concluded that these chimpanzees possess a representation of Euclidian space that allows them to measure and remember distances; to compare several such distances so as to choose the stone with the shortest distance to a goal tree; to locate a new stone location with reference to different trees; and to change their reference point to measure the distance to each tree from any stone location. Overall, they appeared to combine the weight and the distance, leading Boesch and Boesch to infer these wild chimpanzees possess concrete operation abilities in the spatial domain. In a study with Kanzi, Savage-Rumbaugh and her colleagues obtained a similar result using lexigrams for location (Menzel, Savage-Rumbaugh, & Menzel, 2002).

Theory of Mind

The domain of social cognition has received special attention because it appears to indicate that chimpanzees interpret correctly the state of mind of conspecifics. This work is thoroughly reviewed by Harris (Chapter 19, this *Handbook*, this volume) and does not bear detailed recapitulation here. Just a few points deserve highlighting to maintain continuity in the current context.

I find it significant that Boesch and Tomasello (1998), who used to be on different sides of the exceptionalism issue, have come to agree that chimpanzees acquire some parts of theory of mind, but not others (they understand some things about what others see or have seen in the recent past, and some aspects of others' goal-directed activities, but do not appear to distinguish gaze direction from attention or prior intentions that are no longer perceptually present). Most recently, Tomasello and his colleagues (Tomasello, Carpenter, Call, Behne, & Moll, 2005) have argued that the key cognitive difference is the adult human ability to engage in *shared* intentionality that permits engagement in complex collaborative activities and requires powerful skills of intention-reading as well as for a motivation to share psychological states with others. The intermingling of these abilities in human ontogeny, they argue,

“produce[s] a unique development pathway for human cultural cognition, involving unique forms of social engagement, symbolic communication, and cognitive representation. Dialogic cognitive representations, as we have called them, enable older children to participate fully in the social-institutional-collective reality that is human cognition” (p. 16).

Additional examples of cognitive domains could be reviewed in which it has been claimed that chimpanzees exhibit at least the rudiments of cognitive abilities once believed to be the sole possession of human beings (myriad examples are provided by Bekoff, Allen, & Burghardt, 2002, and by de Waal, 2001). Extending such examples still leaves us with the question of how such cognitive similarities are related to the issue of central concern in this chapter—the relation of culture and cognition in development. To address this issue we need to look more closely at treatments of culture among the great apes and then return to examine the relation of culture to cognition in nonhuman species and humans.

Culture among Apes

Belief in a narrow, quantitative gap between humans and nonhuman primate cognition is paralleled by belief in a narrow gap with respect to culture (Wrangham, McGrew, de Waal, & Heltne, 1994). Recall that in approaching the issue of primate culture, researchers define culture as behavioral traditions spread or maintained by nongenetic means through social learning. This kind of definition does not presuppose characteristics that are themselves arguably specifically human (e.g., religious beliefs, aesthetic values, social institutions). Hence, the analyst can remain agnostic with respect to culture-cognition relationships in different species (Byrne et al., 2004). At the same time, the definition allows examination of the extent to which cognitive characteristics claimed to be necessary for acquisition of human culture are present in displays of nonhuman primate behavioral traditions (cultures), such as deliberate teaching or tool making and use. I will focus here on chimpanzees, for which the most extensive evidence is available, but will include other well-researched examples as well (see McGrew, 1987, 1998).

The textbook example of a social tradition for which we know the origin and have data on its spread comes from sweet-potato-washing by Japanese macaque monkeys on Koshima Island (Matsuzawa, 2001). In 1953, a juvenile female monkey was observed washing a muddy sweet potato in a stream. This behavior first spread to

peers and then to older kin. Ten years later it was observed among more than 50% of the population and 30 years later by 71%. A few years later, the same monkey invented a form of “wheat-sluicing,” in which wheat that had been mixed with sand was cast upon the sea so that the floating bits of wheat could be easily sorted from the sinking sand. Within 30 years, 93% of this group engaged in this behavior.

McGrew (1998) draws attention to other important characteristics of Japanese macaque cultural traditions. First, they do not remain entirely static. Koshima monkeys began by washing their potatoes in fresh water, but later adopted washing in seawater (presumably to add to the taste). A group of monkeys living in the far north adopted the tradition of bathing in warm springs in winter; initially the mothers left their offspring on the edge of the pools, but the young monkeys can now be seen swimming underwater. Second, cultural traditions develop with no discernible relation to subsistence activities; several groups of macaques routinely handle small stones in a variety of ways (rolling, rubbing, piling) that are not related to any identifiable adaptive function. These observations blunt attempts to find restrictions of the observed cultural behaviors to subsistence constraints.

The behavioral traditions involved have included the use of probes for termites and ants, nut cracking with sticks and stones, hunting strategies, nest building, and styles of grooming behavior (Matsuzawa, 2001; McGrew, 1998; Whitten, 2000; Wrangham et al., 1994). In light of their importance in discussions of both primate language and cognition, bonobos in the wild appear to display no evidence of tool use. This species difference should serve to block any simple equation between tool use and either cognitive development or the nature of social traditions.

Culture, Cognition, and Nonhuman Primate Development

With respect to both cognition and culture considered separately, evidence appears to support the idea that members of the great ape family, particularly chimpanzees, attain levels of cognitive development that bring them to the threshold of the corresponding human domains. In the cultural realm, they form within-group social traditions through processes of social learning; these traditions include elementary kinds of tool use. In effect, nonhuman primates attain levels of cultural and cognitive development that terminate at

approximately the transition from infancy to early childhood among human children. This brings us to the question of how cognition and culture are related among nonhuman primates.

Attempts to answer this question have focused on the cognitive mechanisms of social learning. The general answer given is that social learning requires some form of mimesis broadly interpreted as a process in which the behavior of one individual comes to be like another through some form of contact. But this broad understanding of mimesis is little more than restating what one means by a social tradition, since many different processes can lead to behavioral conformity. Consequently, the task of further specifying the processes of mimesis has garnered the bulk of scholarly attention (Byrne, 2002; Meltzoff & Prinz, 2002; Tomasello & Rakoczy, 2003; Whitten, 2000).

At the most elementary level, groups of the same species living in different locales may behave differently from each other, but in conformity with each other, because of differences in their local ecology. Each animal may be discovering the solution for itself, by this account.

In addition, situations may arise when members of a group are attracted to the location of conspecifics and, on their own, learn the behaviors that others have learned in the same circumstances. They may learn that grubs are located in the area, and learn to find the grubs and eat them, without any special orientation to the behavior of others. This source of social learning is termed *stimulus enhancement*.

A slightly more complex form of social influence is referred to as *emulation learning*, which occurs when, for example, an infant chimpanzee observes its mother turn over a log and sees that there are grubs under the log. Although the infant is not focused on the mother's goal-directed intentions (strategies), it learns something about objects in the environment and can then, on its own, learn about attaining such objects.

The most complex (and most controversial) claims about the source of acquiring social traditions in nonhuman primates are *imitation*—when the infant attempts to copy the goal-directed strategies of the mother. There is as yet no consensus on whether nonhuman primates raised in the wild engage in this form of mimesis (Byrne, 2002).

For those who believe that true imitation is present among the great apes, there is little to distinguish the re-

sulting forms of culture and their cognitive underpinnings among species (Parker & McKinney, 1999; Russon & Begun, 2002). We are again faced with a "threshold" phenomenon: Whether the threshold involves the presence of symbolic representation arising in substage 6 of Piaget's sensorimotor period or the extent to which chimpanzees are interpreting the intentions of conspecifics, the resulting culture may meet the minimal definition of culture as a socially acquired behavior pattern, but it does not involve either symbolic mediation of thought. It is also noteworthy that there are no claims for the ways in which chimpanzee culture influences chimpanzee cognition. The most that has been claimed is that chimpanzees raised by humans are likely to be poorly adapted to life in the wild, a perfectly reasonable conclusion that implicates learning of various kinds, but no cultural influences on the development of chimpanzee thought processes.

The only circumstances in which immersion in culture reveals clear consequences for the cognitive and linguistic development of nonhuman primates is where they are raised by human beings who seek to promote their cognitive development using all the (human) cultural means at their disposal. This point has been emphasized by Tomasello (1994), who has suggested that "a humanlike social-cognitive environment is essential to the development of human-like social-cognitive and imitative learning skills. . . . More specifically, for a learner to understand intentions of another individual requires that the learner be treated as an intentional agent" (pp. 310–311). As might be expected, those who attribute more mental capacities to nonhuman primates than does Tomasello dispute this idea and, to buttress their argument, point to observational evidence that primates raised by humans undergo hardships when introduced into their natural environment precisely because they have not been exposed to the appropriate culture (Parker & McKinney, 1999; Russon & Begun, 2002).

Unusual evidence concerning the influence of humans on primate culture/cognition comes from the work of Savage-Rumbaugh and her colleagues, who have worked for many years with a group of bonobos at their Language Research Center (Savage-Rumbaugh et al., 2001). For many years, these researchers have engaged in joint, mediated, activity with a group of bonobos and refer to the behavioral customs that have emerged in the process of these interactions as "*Pan/Homo*" culture. They readily admit that a variety of behaviors that ap-

pear in bonobos under these cultural conditions (e.g., tool use) would not evolve in the wild. But the message they take away from this state of affairs is, “These findings render moot old questions regarding limits of the ape brain. They raise instead more productive questions about the form and function of the perpetual dance that is constantly taking place between plastic neuronal systems and their external culturally devised ways of being” (p. 290).

Ironically, given the strong preference of these authors for a continuity perspective, the requirement that bonobos become enculturated into a unique, hybrid, ape/human culture in order to develop the more human-like forms of behavior at the upper range of their ability simultaneously provides support for the important cognitive differences between humans and apes and the role of human culture as both consequence and cause of that difference.

CULTURAL HISTORY

Although there are innumerable differing explanations for the causes of the transition to *Homo sapiens sapiens* (a genetic change, a change in climate, a change in interactivity among *Homo sapiens* creating a critical mass of cultural isolates, some combination of the above, etc.), there is reasonable agreement that something special emerged in the hominid line between 40,000 to 50,000 years ago, the “high Paleolithic” period of paleontology. The following set of changes are among those widely believed to have occurred (Cheyne, 2004):

- *Semeiosis—the act of creating signs that stand for objects.* The production of figurative and nonfigurative marks on stones, bones, plaques, cave walls and so on.
- *Production of second-order tools.* This refers to the production and use of tools to work bone, ivory, antler, and similar materials into a great variety of new tools such as points, awls, needles, pins, and spear-throwers.
- *Production and use of simple machines that exploited mechanical advantage (e.g., the spear-thrower and perhaps the so-called baton de commandement).*
- *An ability to visualize the complex action of tools or simple machines.* The production and use of fish hooks and harpoons appeared at this time. The me-

chanics of these devices required that the makers be able to visualize and understand or predict the sequence of remote events such as those of penetration, withdrawal, and secondary penetration of a barb.

- *Spatial structural organization of living sites.*
- *Long-distance transport of raw materials such as stones and shells over tens or even hundreds of kilometers.*

These psychological and cultural developments were associated with other changes of enduring significance. These included:

- A rapid expansion of human populations into all territories previously occupied by earlier developed forms of humans and the extremely rapid replacement of the indigenous populations
- Further expansion into territories not previously inhabited by humans
- An increase in population densities to levels comparable to those of hunting-and-gathering societies of historical times (Cheney, 2004)

Here, it appears, is the beginning of modern humans, the cavemen and hunter-gatherers of anthropological, paleontological, and historical lore.

I assume the following common story of change following the emergence of biologically modern humans to be roughly true (c.f. Diamond, 1997; Donald, 1991; Gellner, 1988). Some of the hunter-gatherers who inhabited many parts of the earth and lived in small bands went on to engage in sedentary agriculture. From that way of life there emerged in some places conglomerations of people larger than the small groups that preceded them; older ways of life disappeared or continued in very much the same way for millennia. In others there was a marked increase in sociocultural complexity (Feinman, 2000).

As a number of scholars interested in culture and cognitive development in prehistory have emphasized, a defining characteristic of the Paleolithic era was the appearance of external systems of symbolic, representational cave art, statuary, and perhaps elementary counting devices (Donald, 2001). While the symbolic nature of such artifacts and their probable incorporation in symbolically mediated rituals including burial practices is generally agreed to provide convincing proof of

the evolution of symbolic activity among *Homo sapiens sapiens*, researchers have not yet agreed on the precise cognitive mechanisms involved. According to Damerow (1998), it seems most reasonable to consider the many millennia between the beginning of the Paleolithic period and the Neolithic period around 8000 B.C. (when people began to domesticate plants and animals and live in permanent villages) as a historical equivalent of the transition from sensorimotor to preoperational thinking. If, as McGrew (1987) argues, such societies approximate the level encountered in small face-to-face societies during the European age of exploration, it provides evidence in favor of the assumption that the cognitive processes of such peoples are best characterized as preoperational (Hallpike, 1979).

According to both Damerow (1998) and Donald (2001), it is with the urban revolution coinciding with the elaboration of tools, agricultural techniques, the smelting of copper and then bronze that one sees the transition from preoperational to operational thinking in human history. Two important lessons for the study of contemporary studies of culture and human ontogeny are emphasized by this literature. First, when concrete operational thinking begins to make an appearance, it is tightly bound to particular domains of culturally organized activity. Cuneiform writing, Damerow writes, represented mental models of the administrative activities that they mediated. Although they involved protonumerical systems, such systems did not embody principles of concrete operations and did not conclusively imply that their users could engage in reversible mental operations. Second, the causal relations between the development of culture and the development of cognition were reciprocal. Like Plotkin, quoted earlier, who was referring to a much earlier period of hominization, Donald (2001) is emphatic in his conclusion that the brain and culture "have evolved so closely that the form of each is greatly constrained by the other." Moreover, with the advent of literacy especially, "Culture actually configures the complex symbolic systems needed to support it by engineering the functional capture of the brain for epigenesis" (p. 23).

The difficulty with using prehistoric and even historical materials that have survived only in writing is that we have too little information about their contexts of use to make refined inferences about culture and cognitive development in ontogeny. For this reason, psychologists especially value studies enabled by rapid cultural-his-

torical change in most parts of the world over the past several decades. Conditions of rapid change make it easier to tease apart relations between cultural-historical and ontogenetic change because there are coexisting generations close to each other in age who engage in markedly different culturally organized activities.

Cross-Sectional Cultural-Historical Comparisons

Perhaps the best known study on the relation of rapid cultural-historical change to cognitive change was carried out by Alexander Luria in the early 1930s, although the work was not fully published in Russian or any other language until the middle of the 1970s (Luria, 1976). Luria studied a cohort of people under conditions of rapid change in remote parts of the Kirghizia and Uzbekistan.

The historical occasion was the collectivization of agricultural labor under state control, which brought with it changes such as formal schooling and exposure to bureaucratic state agencies, during what can fairly be described as a revolutionary period in that part of the world. Luria concluded that the new modes of life deeply affected the dominant modes of thought, such that the "premodern" group was restricted to a form of "graphical/functional" reasoning based on common experience, whereas modernization brought with it access to scientific concepts that subsumed and dominated the everyday modes of thought, replacing graphical/functional thinking.

Luria's research was not developmental in the sense of studying the impact of the historical changes on people of different ages. He relied primarily on psychological test data collected from adults with different degrees of exposure to Soviet collectivization. His conclusions are open to a series of criticisms, two of which are most important. First, data from tests and clinical interviews were generalized very broadly to activity-dependent experience, but there was no in-situ evaluation of such connections. The interview situation was an alien form of activity to the traditional pastoralists who served as subjects in Luria's experiments; their responses may have reflected as much the alien nature of the modes of discourse as the influence of their own cultural experience employed in indigenous activities. Second, this same abstraction from the theoretical site of change, the activities themselves, both made it difficult to grasp the

processes at work in the course of change and made it appear that the changes from concrete-graphic to theoretical thinking were of a general nature. In this respect, Luria's research was typical of cross-cultural work. It is still valued, however, for its clever use of interview methods similar to those used by Piaget, rather than settling for simple, unchallenged test responses, and for Luria's use of a broad range of tests ranging from perception, through classification, logical reasoning, to reasoning about oneself.

Modern research by King Beach in an area of Nepal undergoing rapid historical change used methods that appear to overcome some of the shortcomings of Luria's work (Beach, 1995). Beach studied changing forms of arithmetic calculations in a Nepalese village that underwent rapid socioeconomic and cultural change in the 1960s and 1970s. Roads from India moved closer to the village, schooling was introduced for the first time and continued to expand over ensuing decades, and shops that exchanged merchandise for money appeared during the same period and rapidly increased in number. At the time the research was initiated in the late 1980s, two coexisting generations of men experienced different relations between their experience of traditional farming, shopkeeping, and schooling. What all groups shared was some experience with subsistence agriculture and the need to buy and sell in the shops using traditional nonmetric units to measure a given length of cloth and then calculate price in terms of meters and centimeters, to which the monetary price was linked. The traditional system relied on using the length from the elbow to the tip of the middle finger while the newly introduced system involved use of a ruler and the metric system.

Senior high school students were apprenticed to shopkeepers in the village, and shopkeepers who had never had the opportunity to attend school were enrolled in an adult literacy/numeracy class. Farmers who had never attended school and had never worked in a shop also completed a shopkeeping apprenticeship or were enrolled in the adult education class. The transitions between education and work activities that were induced as a part of the study simulated larger scale changes taking place in rural Nepali society. Some of the problems posed by Beach to track changes in arithmetic during the shop apprenticeship involved purchases requiring translation and calculation between the two measurement systems. Problems presented to those enrolled in the adult education class were arith-

metic problems of the kind typically encountered in school mathematics classes.

Traditionally, shopkeepers used arithmetic forms based on indigenous systems that bear little surface relationship either to metric measurement (arm lengths versus a metric measuring stick) or to the methods of calculating amounts and prices (the use of objects and other artifacts and decomposition strategies versus the use of paper and pencil to write equations and calculate with column algorithms). Those students becoming shopkeepers continued to use the written form they had learned in school after they entered the shops, even though reliable traditional methods long in use were prevalent there. Over time and with much pressure from the shopkeeper and customers, the students adapted the written form for use with the calculation strategies championed by the shopkeepers. Those who began as shopkeepers and were studying in the adult education class used their arms and traditional measurement objects to carry out their calculations, but eventually adopted a flexible approach of sometimes using traditional measurement units and calculation strategies and other times doing written calculations adapted to the problem at hand. Why?

From interviews with the participants, Beach was able to determine that students who were becoming shopkeepers viewed themselves as engaged in two activities, displays of school learning and shopkeeping that were initially in contradiction with each other. The status of schooling and of "being educated" made it difficult for them to give up the written form of calculation, though the speed and adaptability of the shopkeeper's calculations eventually induced them to adapt the written form to the shopkeeper's calculation strategies. In this way, their status as formally educated adults was retained, marked by their use of the written form, but they could use the written form to do the calculations as quickly and accurately as shopkeepers. The shopkeepers, however, even though they were in an evening school, always thought of themselves as engaged in their own shopkeeping activities and did not shift over to the school-based system except when they saw it as facilitating their ongoing work. Both by virtue of the tasks he presented and the way in which he presented them, Beach verified the linkage between cultural-historical and ontogenetic change that depended on both the history of relations between the activities and the individuals' developmental history at the point of participation

in those activities. This leads to a process of ontogenesis that is much more variable and more content/artifact-specific than Luria's results would suggest.

Longitudinal Studies of Cultural-Historical Change

Despite differences in methods, the research by Beach and Luria involved people with different amounts of exposure to new cultural practices.¹ A common feature of the two studies discussed in this section is that the same developmentalist returned after many years to the same place, using the same general methods, so that it is possible to document the cognitive development under changed sociocultural conditions for the same people at two disparate times.

Each of the studies reviewed here covers three generations: adults and children 30 to 40 years ago and grandparents, parents, and children recently. This relatively long time scale (in ontogenetic terms) meant that children in earlier studies could be studied as parents in the second, and the children-to-be in the first study replace the children-now-parents in the contemporary study.

Historical Change and Cognitive Change in Zinacantan

In the late 1960s, Patricia Greenfield and her colleagues went to the Zinacantan, a Mayan group living in the state of Chiapas, Mexico, where they began to study the cognitive and social consequences of learning to weave (Greenfield & Childs, 1977). Their work included experimental tests of categorizing ability by both boys and girls, careful descriptions of the apprenticeship of young girls into weaving and of the weaving process, and analysis of the products produced. In the 1990s, they returned to the same village and conducted parallel observations of parents (former child subjects) inducting their children into weaving and the products of this work (Greenfield, 1999; Greenfield, Maynard, & Childs, 2000).

In her recent writing comparing the relation between cultural change, modes of weaving, and modes of weaving instruction, Greenfield has emphasized the interconnectedness of historical change in economic activity,

¹ Beach's students were in their early 20s, his shopkeepers in their 40s, but this age difference was not the object of his research and all were treated as adults.

exposure to new products and practices from contact with people from the modern sector of Mexican society, socialization practices (in particular, modes of socializing girls into weaving), and cognitive processes involving the mental representation of the patterns in woven cloth (Greenfield, 2002, 2004; Greenfield et al., 2000). These changes are viewed as interconnected.

Historical Changes

The analysis begins with historical changes in general modes of living. In contrast to the late 1960s, in the mid-1990s this Mayan community shifted from an economy based primarily on subsistence agriculture and relative seclusion from the modern state to one based more heavily on involvement in the money economy, trade, and much more frequent interaction with people and trade from outside the village and the local region.

Socialization

The instructional mode characterizing the mother-child weaving sessions in 1970 emphasized a long process of gradual apprenticeship involving many roles preparatory to weaving itself. When children first began to weave, mothers hovered close by and guided children with their own hands and bodies, using little verbal instruction. The entire system appeared to focus on maintenance of tradition and is characterized as "interdependent cultural learning."² In the 1990s, mothers who were more involved in the modern economy (e.g., by weaving products for sale) instructed their children verbally from a distance, sometimes using older siblings to take over instruction, and the children learned by a process that Greenfield and her colleagues characterize as "independent cultural learning" which involves a good deal more trial and error and self-correction of errors.

The variety of products changed. In the late 1960s, the products were limited, reflecting a very small set of "right ways to weave cloth." By the 1990s, there was no longer a small set of simple, "correct" patterns, but an efflorescence of patterns, indicating the increased

² The importance of getting an early start on learning to weave reveals itself in the problems that American psychologists such as Greenfield and Rogoff experienced when attempting to master this skill. A major hurdle was the difficulty they had in maintaining the postural position required. This pervasively experienced fact is a reminder of how cultural practice shapes biological capacity during ontogeny.

respect paid to individual innovation that comes with a trial-and-error approach to learning. This proliferation in turn depended on, and contributed to, changes in weaving practices.

Changing Modes of Mentally Representing Patterns

Accompanying the historical changes were changes in the way children represented weaving patterns in an experimental task that used sticks of varying width and color that could be inserted into a rack to reproduce model patterns from woven models. Instead of using, for example, three white sticks to represent a broad band of white cloth, a single broad white stick was more likely to be used in the later historical period and those who attended school were more likely to be able to create novel patterns. Importantly these historical changes were accompanied by an unchanging pattern of representational development related to age: older children in both historical periods were more able than younger children to represent more complex visual patterns, a fact that Greenfield et al. interpret as an indication of universal developmental processes accompanying culturally contingent ones. (I return to examine other results from this extensive research program in the section on ontogenetic developmental change.)

Based on her decades-long involvement with a Mayan community in the Yucatán, Suzanne Gaskins (1999, 2000, 2003) notes the same economic changes observed by Greenfield and her associates but provides a different, although compatible, explanation of the causal factors involved. Gaskins focuses on how the changing economic circumstances change maternal work patterns, suggesting that reduced time spent on traditional chores (e.g., not hauling water because there is running water, or having a longer day because of electricity) and time spent in the commercial sector outside the home, shift the division of labor inside the house in ways that reduce direct parental involvement with children's socialization in general, not just with respect to weaving. She also suggests that the efflorescence of weaving patterns may arise as much from copying models and parts of models imported by truck and the availability of money for foreign cultural goods as from any individual increase in creativity engendered by different modes of teaching.

Differences in interpretation of underlying process notwithstanding, the Greenfield et al. multigenerational

study brings a whole new range of data to bear on mechanisms of cultural change and accumulation, suggesting a strong link between cultural change resulting from the interaction of cultures and the new means of teaching and learning that accompany the shift to more intensively commercially mediated forms of life.

The Cultural Evolution of Arithmetic in New Guinea

A second "longitudinal cultural-historical" study was begun from 1978 to 1980 by Geoffrey Saxe and his colleagues, who conducted developmental studies among the Oksapmin in the remote highlands of central New Guinea (Saxe, 1982, 1994). His initial research followed the cross-cultural Piagetian tradition. He found that Oksapmin children acquired the ability to use counting strategies before they acquire conservation of number, which they acquire more slowly than their counterparts in New York (Saxe, 1981). But it was the number system that caught his attention. Traditionally, the Oksapmin use a 27-digit counting system that is based on body parts, beginning with the pinky of the right hand and ending at the pinky of the left hand, with stops in between for the elbow, biceps, eyes, nose, and so on.

When Saxe arrived, he found the traditional number system in wide use, but he also found that people who had traveled to earn money at nearby tea and copra plantations for 2 years at a time were likely to bring back a taste not only for some of the goods they encountered there, but also for money (a heretofore unknown phenomenon), which could be exchanged for those desirable consumer goods. Moreover, the outside world had penetrated Oksapmin life sufficiently to establish schools that taught in an English-related pidgin language in which children learned base 10 arithmetic and standard calculation procedures.

On the basis of ethnographic data, Saxe was convinced that traditionally the Oksapmin used their number system to count things such as pigs, identify the ordinal position of a house in a small hamlet, or to measure the length of an object. However, they did not habitually engage in arithmetic operations such as addition. Instead, for example, they would establish 1:1 or 1:N relations between objects being traded in economic exchanges.

So when Saxe asked people to use this system to engage in arithmetic operations, he expected performance to improve as a function of engagement in the use of

money for everyday transactions. True to his supposition, the more people had been exposed to the use of money, the more complicated strategies for addition and subtraction they manifested and the more they were able to carry out such strategies when there were no coins present to serve as a tool for counting and adding (Saxe, 1985). He also found that Oksapmin children attending school both used their traditional system to help them solve problems (instead of counting on their fingers) and developed more of the same sort of complex strategies exhibited by the adults with the most exposure to transactions involving money.

More than 20 years later, Saxe and his colleagues returned to the Oksapmin. He had, in the meantime, carried out studies of the development of mathematical abilities among nonschooled children working in various occupations in Brazil that involved mathematical operations and put forth a general theory of how arithmetical forms and functions (means and ends) develop in ontogeny (Saxe, 1994). He had also studied the microgenesis of arithmetic knowledge in specially designed games involving arithmetic operations intended for use in school. This work helped him to focus on the microgenesis, the moment-to-moment changes, in the dance of form and function that produces developmental change (Saxe, 2002). During this same period, he was interacting with scholars interested in cultural practices as the proximal medium of cognitive development in any culture, and he began to take an interest in how cultural-historical development, or cultural evolution, comes about.

Consequently, the research he conducted when he returned to New Guinea was both more ambitious and more historically oriented than his prior work had been. He also had his prior work in the same villages to provide a benchmark for plotting the course of cultural change—in particular, changes in cultural practices (such as schooling that involves direct instruction in arithmetic using a foreign system and trade that involves the use of money).

As a means for studying population variations associated with varying experience of schooling or in the use of money (which was now much more prevalent in the area, associated with a high volume of trade in agricultural products and the introduction of mining in not-too-distant areas), Saxe and Esmonde (in press) traced the cultural history of a single lexical item, “fu,” which they show underwent a number of changes during the

period between 1978 and 2001. When Saxe first went to New Guinea, traditional Oksapmin, who had not yet learned pidgin, used *fu* to refer to the completion of counting a set of objects, as in, “1 . . . 27, done.” During the ensuing 20 years, the English system of 20 shillings to the pound, which was relatively new to the Oksapmin when Saxe was first there, was replaced by a national Papua New Guinea (PNG) base-10 system in which 10 units that functioned like shillings summed to one PNG denomination called a *kuan*. People referred to a 2-*kuan* note by the same term they used to refer to a pound. In both cases, the number 20 is of exceptional importance. Saxe and his colleagues found that the number 20, which is at the left elbow, became a privileged site in the body-counting system, and at the same time, *fu* took on the new function of referring to completion of a count of shillings/2PNG *kuan*.

As a result of taking developmental change over a cultural-historical epoch as a focus of interest, Saxe and Esmonde were faced with the possibility that the changing meanings of *fu* were not the result of conscious human effort to create a more powerful arithmetic as a general cultural tool, but rather, arose as a by-product of the mixture of ways of using language and the body to represent number in conjunction with the ever-changing, and ever-more-commercialized, social and economic exchange practices that people engaged in.

History, Social Differentiation, and Education

The historical development of formal schooling based on literacy and numeracy is an example of change at the cultural-historical level with implications for cognitive development (Cole, 2005; Rogoff, Correa-Chávez & Cotuc, 2005). Among academics, policymakers, and the general public, it is widely believed that education makes one more developed cognitively, either generally (United Nations Educational, Scientific, and Cultural Organization [UNESCO], 1951) or with respect to some more specific range of cognitive skills (Rogoff, 1981; Serpell & Hatano, 1997). Hence, historical changes in this form of culturally organized activity are an especially important example of the relationship between cultural change and cognitive development.

Although it is sometimes argued that the term, *education*, applies equally across all societies at all times because all human groups must prepare the next generation if the social group is to continue (Reagan, 2000), I

find it more helpful to think of education as a particular form of schooling and schooling as a particular form of institutionalized enculturation. Tracing the process of education thus interpreted over historical time serves to concretize this ordering from enculturation (induction into the cultural order of the society), to schooling (deliberate instruction for specific skills), to education (an organized effort to “bring out” [educe] the full potential of the individual).

Small, Face-to-Face Societies

Reminiscent of arguments that arise in the literature on culture formation in nonhuman primates, Jerome Bruner, in an influential monograph on culture and cognitive development, remarked that in watching “thousands of feet of film (about life among the Kung San Bushmen), one sees no explicit teaching in the sense of a ‘session’ out of the context of action to teach the child a particular thing. It is all implicit” (Bruner, 1966, p. 59). Elsewhere in the same essay, he comments that “the process by which implicit culture is ‘acquired’ by the individual . . . is such that awareness and verbal formulation are intrinsically difficult” (p. 58).

Similarly, Meyer Fortes, in his well-known monograph on education in Taleland emphasized that “the social sphere of the adult and child is unitary and undivided. . . . As between adults and children, in Tale society, the social sphere is differentiated only in terms of relative capacity. All participate in the same culture, the same round of life, but in varying degrees, corresponding to the stage of physical and mental development . . .” (Fortes, 1938, p. 8).

Reagan (2000) supports these descriptions of small, face-to-face societies in a recent review of ethnographic evidence from 76 societies in sub-Saharan Africa leading him to conclude that in the African setting, education “cannot (and indeed should not) be separated from life itself” (p. 29).

Rudimentary Forms of Separation between Enculturation and Schooling

Even granting such a starting point, one encounters small societies where agriculture has displaced hunting and gathering as the mode of life, but they remain small in size and relatively isolated from each other. In such conditions, one witnesses the beginnings of differentiation of child and adult life involving forms of deliberate teaching that usually include a good deal of training. In

many societies in rural Africa, what are referred to casually as *rites de passage* may be institutionalized activities that last for several years and teaching is certainly involved. For example, among the Kpelle and Vai peoples of Liberia, where I worked in the 1960s and 1970s, children were separated from their communities for 4 or 5 years in an institution referred to in Liberian pidgin as “bush school.” There, children were instructed by selected elders in the essential skills of making a living as well as the foundational ideologies of the society, embodied in ritual and song. Some began there a years-long apprenticeship that would later qualify them to be specialists in bone setting, midwifery, and other valued arcane knowledge.

Social Accumulation, Differentiation, and the Advent of Schooling

It appears that it is primarily, if not only, when a society’s population grows numerous and it develops elaborate technologies enabling the accumulation of substantial material goods, that the form of enculturation to which we apply the term *schooling* emerges. As a part of the sea change in human life pattern associated with the transition from the Bronze Age to the Iron Age in what is now referred to as the Middle East, the organization of human life began a cascade of changes, which while unevenly distributed in time and space, appear to be widely, if not universally, associated with the advent of formal schooling. In the Euphrates valley, the smelting of bronze revolutionized economic and social life. With bronze, it became possible to till the earth in more productive ways, to build canals to control the flow of water, to equip armies with more effective weapons, and so on. Under these conditions, one part of the population could grow enough food to support large numbers beside themselves. This combination of factors made possible a substantial division of labor and development of the first city-states (Schmandt-Besserat, 1975).

Another essential technology that enabled this new mode of life was the elaboration of a previously existing, but highly restricted mode of representing objects by inscriptions on tokens and the elaboration of the first writing system, cuneiform, which evolved slowly over time. Initially, the system was used almost exclusively for record keeping, but it evolved to represent not only objects but the sounds of language, enabling letter writing and the recording of religious texts (Larsen 1986; Schmandt-Besserat, 1996).

The new system of cuneiform writing could only be mastered after long and systematic study, but record keeping was so essential to the coordination of activities in relatively large and complex societies, where crop sizes, taxes, troop provisioning, and multiple forms of exchange needed to be monitored for the society to exist, that these societies began to create a new institution and devote resources to support selected young men for the explicit purpose of making them scribes, people who could write. The places where young men were brought together for this purpose were the earliest formal schools.

Not only the interactional patterns of the activities that took place in these schools, but the architecture, the organization of activities, and the reigning ideologies within them were in many respects startlingly modern. The classrooms consisted of rows of desks, facing forward to a single location where a teacher stood, guiding students in repetitive practice of the means of writing and calculating as well as the operations that accompanied them. Instead of inkwells, the classrooms contained bowls where students could obtain wet clay to refresh clay tablets. In many such schools, the compiling of quantified lists of valued items (not unlike listing states of the United States or capitals of the world) was a major pastime, although some letter writing also occurred. These lists were often viewed as evidence of extraordinary cognitive achievements (Goody, 1977).³

Evidence concerning early schooling indicates that more than socially neutral, technical, literacy and numeracy skills were thought to be acquired there. Learning esoteric lists and the means for creating them were imbued with special powers such as are currently ascribed to those who are civilized, and it was recognized that socioeconomic value flowed from this knowledge.

In the Middle Ages, the focus of elementary schooling shifted to what LeVine and White (1986) refer to as "the acquisition of virtue" through familiarity with sacred texts, but a certain number of students were taught essential record-keeping skills commensurate with the forms of economic and political activity that needed to be coordinated through written records. Such is the state of schooling in many Muslim societies to this day, although there is great variation in Islamic schooling de-

pending on whether the local population speaks Arabic and how formal schooling articulates with the state and religion in the country in question (see Serpell & Hatano, 1997, for a discussion of these variations and their implications).

As characterized by LeVine and White (1986), the shift from schools in large agrarian societies to the dominant forms found in most contemporary industrialized and industrializing societies manifests the following common features:

- Internal organization to include age grading, permanent buildings designed for this purpose, with sequentially organized curricula based on level of difficulty
- Incorporation of schools into larger bureaucratic institutions so that the teacher is effectively demoted from "master" to a low-level functionary in an explicitly standardized form of instruction
- Redefinition of schooling as an instrument of public policy and preparation for specific forms of economic activity—"manpower development"
- Extension of schooling to previously excluded populations, most notably women and the poor

Serpell and Hatano (1997) have dubbed this form of schooling "institutionalized public basic schooling" (IPBS). They point out that this European model evolved in the nineteenth century and followed conquering European armies into other parts of the world (LeVine, LeVine, & Schnell, 2001; LeVine & White, 1986; Serpell & Hatano, 1997). Local forms of enculturation, even of schooling, have by no means been obliterated, sometimes preceding (Wagner, 1993), sometimes coexisting with (LeVine & White, 1986) the more or less universal "culture of formal schooling" supported by, and supportive of, the nation-state. Often these more traditional forms emphasize local religious and ethical values (Serpell & Hatano, 1997). Nonetheless, these alternatives still retain many of the structural features already evident in the large agrarian societies of the Middle Ages.

As a consequence of these historical trends, the institutional form referred to as IPBS has become an ideal if not a reality in most of the world (the Islamic world providing an alternative in favor of adherence to religious/social laws, as written in the Q'uran, a word which means "recitation" in Arabic). The IPBS approach operates in the service of the secular state, eco-

³Although some features differ, a similar story could be told for China, where bureaucratized schooling arose a thousand or so years later, and for Egypt, as well as for many of the civilizations that followed.

nomic development, and the bureaucratic structures through which rationalization of this process is attempted, and exists as a pervasive fact of contemporary life. According to a survey conducted by UNESCO in 2003, during the 1990s more than 80% of children in Latin America, Asia (excluding Japan), and Africa were enrolled in public school, although there are large disparities among regions and many children only complete a few years of schooling. Nonetheless, experience of IPBS has become a pervasive fact of growing up the world over (Serpell & Hatano, 1997).

With these considerations as background, I now turn to the consequences of this pervasive form of educational experience for the development of individual children, their communities, and humanity more generally, in the contemporary world. I pay special attention to the role of culture and cultural variations in shaping any such consequences.

The Consequences of Formal Schooling in the IPBS Mode

The reader interested in a comprehensive survey or the intellectual and social consequences of school is referred to summaries by Rogoff (1981), Rogoff et al. (2005) and Serpell and Hatano (1997). For present purposes, I focus on three strategies for assessing the consequences of participation in the kind of formal schooling that has been dominant in the twentieth and twenty-first centuries. Each strategy has its advantages and its shortcomings.

The School-Cutoff Strategy

In many countries, school boards require that children must be a certain age by a particular date to begin attending school. To enter Grade 1 in September of a given year, children in Edmonton, Alberta, Canada, for example, must have passed their sixth birthday by March 1 of that year. Six-year-olds born after that date must attend kindergarten instead, so their formal education is delayed for a year. Such policies allow researchers to assess the impact of early schooling while holding age virtually constant: They simply compare the intellectual performances of children who turn 6 in January or February with those who turn 6 in March or April, testing both groups at the beginning and at the end of the school year. This procedure is known as the school-cutoff strategy (Christian, Bachman, & Morrison, 2001).

Researchers who have used the school-cutoff strategy find that the first year of schooling brings about a

marked increase in the sophistication of some cognitive processes but not others. Frederick Morrison and his colleagues (Morrison, Smith, & Dow-Ehrenberger, 1995), for example, compared the ability of first graders and kindergartners to recall pictures of nine common objects. The first graders were, on average, only a month older than the kindergartners. The performances of the two groups were virtually identical at the start of the school year. At the end of the school year, however, the first graders could remember twice as many pictures as they did at the beginning of the year, whereas the kindergartners showed no improvement in memory at all. Significantly, the first graders engaged in active rehearsal during the testing, but the kindergartners did not. One year of schooling had brought about marked changes in the children's strategies and performance on this task.

The same pattern of results was obtained in recognition of the names of the letters of the alphabet, in standardized reading and mathematics tests, and in a variety of deliberate remembering tests. But *no effects* of attending a year of school were found when children were administered a standard Piagetian test of conservation or assessed for the coherence of their storytelling or for the number of vocabulary words they understood (Christian et al., 2001). Performance in these latter tasks improved largely as a consequence of children's more general experience. These findings both confirm the importance of schooling in promoting relatively specific cognitive abilities and support Piaget's belief that the ability to understand the conservation of quantity develops without any special instruction sometime between the ages of 5 and 7.

Comparing Schooled and Nonschooled Children

Although the school-cutoff strategy provides an excellent way to assess the cognitive consequences of small amounts of schooling, it is, by definition, limited to only the 1st year. For a longer-range picture of the contribution of formal education to cognitive development, researchers have conducted studies in societies in which schooling is available to only a part of the population. We summarize evidence from three cognitive domains that have received a good deal of attention in studies of cognitive development: organization of word meaning, memory, and metacognitive skills.

1. Organization of word meaning: Donald Sharp and his coworkers studied the potential impact of

schooling on the way Mayan Indians on the Yucatán peninsula of Mexico organize their mental lexicons (Sharp, Cole, & Lave, 1979). When adolescents who had attended high school one or more years were asked which words they associated with the word "duck," they responded with other words in the same taxonomic category, such as "fowl," "goose," "chicken," and "turkey." But when adolescents in the same area who had not attended school were presented with the same word, their responses were dominated by words that describe what ducks do ("swim," "fly") or what people do with ducks ("eat"). Such word associations are often used as a subscale on IQ tests, with duck-goose accorded a higher score than duck-fly. In addition, a good deal of developmental research shows that in the course of development, young children are more likely to produce duck-fly than duck-goose. The results of this study and findings from other parts of the world (Cole, Gay, Glick, & Sharp, 1971) suggest that schooling sensitizes children to the abstract, categorical meanings of words, in addition to building up their general knowledge.

2. Spatio-temporal memory: A meticulous study by Daniel Wagner suggested that children who attend school gain memory-enhancing skills (Wagner, 1974). His methods replicated those of Hagen, Meacham, and Mesibov (1970), who had demonstrated a marked increase in children's ability to remember the locations of cards after they reached middle childhood. But was this increase a result of universal maturational changes or participation in IPBS? To find out, Wagner also conducted his study among educated and uneducated Maya in the Yucatán, where the amount of schooling available to children varied from 0 to 16 years depending on whether the government had built a school with 3, 6, 9, 12, or 16 years of instruction available in the locale where they lived. Wagner asked a large number of people varying in age from 6 years to adulthood who had experienced different levels of schooling to recall the positions of picture cards laid out in a linear array. The items pictured on the cards were taken from a popular local version of bingo called *lotería*, which uses pictures instead of numbers, so Wagner could be certain that all the stimuli were familiar to all his subjects. On repeated trials, each of seven cards was displayed for two seconds and then turned face down. As soon as all seven cards had been presented, a duplicate of a picture on one of the cards was shown and people had to point to the position where they thought its twin was located. By selecting different duplicate pictures, Wagner in effect

manipulated the length of time between the first presentation of a picture and the moment it was to be recalled.

Wagner found that the performance of children who were attending school improved with age, just as in the earlier study by Hagen and his colleagues. However, older children and adults who did not attend school remembered no better than young children, leading Wagner to conclude that it was schooling that made the difference. Additional analyses of the data revealed that those who attended school systematically rehearsed the items as they were presented, leading to the improvement in their performance.

3. Metacognitive skills: Schooling appears to influence the ability to reflect on and talk about one's own thought processes (Rogoff, 2003; Tulviste, 1991). When children have been asked to explain how they arrived at the answer to a logical problem or what they did to make themselves remember something, those who have not attended school are likely to say something like "I did what my sense told me" or to offer no explanation at all. Schoolchildren, on the other hand, are likely to talk about the mental activities and logic that underlie their responses. The same results apply to metalinguistic knowledge. Scribner and Cole (1981) asked schooled and unschooled Vai people in Liberia to judge the grammatical correctness of several sentences spoken in Vai. Some of the sentences were grammatical, some not. Education had no effect on the interviewees' ability to identify the ungrammatical sentences; but schooled people could generally explain just what it was about a sentence that made it ungrammatical, whereas unschooled people could not.

Questioning the Validity of the Evidence

Findings such as those cited previously, despite some residual concerns about selection artifacts, make it appear that at least with respect to some cognitive abilities, schooling helps children to develop a new, more sophisticated, cognitive repertoire to use in their everyday lives. In the case of word associations, a more mature, scientifically organized lexicon comes into being. In the study of memory, it appears that schooling promotes strategies for remembering. In the case of metacognitive awareness, schooling seems to enhance the ability to reflect on one's own reasoning processes (in this case, reasoning about language). Had this research been conducted in the United States, older children or adults who responded in the less sophisticated

ways would have been suspected to have some form of developmental delay or retardation.

Yet there are serious reasons to doubt that differences obtained with standard psychological testing methods provide any logical evidence at all for *generalized* changes in classical categories of cognitive functioning. It is not plausible to believe that word meaning fails to develop among children who have not attended school. The nonliterate Mayan farmers studied by Sharp and his colleagues knew perfectly well that ducks are a kind of fowl. Although they did not refer to this fact in the artificial circumstances of the free-association task, they readily displayed awareness of it when they talked about the kinds of animals their families kept and the prices brought by different categories at the market. Similarly, when materials to be remembered were part of a locally meaningful setting, such as a folk story or the objects in a diorama of the subjects' town, the effects of schooling on memory performance disappear (Mandler, Scribner, Cole, & DeForest, 1980; Rogoff & Waddell, 1982). And the ability of nonschooled people to deploy language in strategic, self-conscious ways for their own advantage has long been documented in the anthropological literature (Bowen, 1964).

Consequently, such demonstrations using more-or-less standard cognitive tasks imported from Euro-American psychological traditions led some to conclude that when schooling appeared to induce new cognitive abilities, it might well be because the entire structure of standardized testing procedures served as covert models of schooling practices (Cole, 1996; Rogoff, 1981). Virtually all the experimental tasks used in such research, modified or not, bear a strong resemblance to the tasks children encounter in school, but bear little or no relation to the structure of the intellectual demands they face outside school.

The logic of this sort of comparative work appeared to demand the identification of tasks that schooled and unschooled children from the same town encounter with equal frequency, followed by demonstration that children who go to school solve such tasks in more sophisticated ways than their nonschooled peers and that these are tied specifically to their schooling. Failure to find tasks of equal familiarity, in effect, meant that we were treating psychological tasks as neutral with respect to their contexts of use, when this was patently false. But identifying cognitive tasks in everyday life circumstances not constructed by the research is a problematic undertaking (Cole, 1996).

At the same time, the finding of school/nonschool differences on more or less standard psychological tasks, if treated as specific forms of skill acquisition, does not mean that schooling exerts no significant impact on children. First, as many have noted, schools are places where children's activity is mediated through print, not only adding a new mode of representation to the child's repertoire, but also introducing a whole new mode of discourse (Olson, 1994) that has counterparts in everyday life. At a minimum, practice in representing language using writing symbols improves children and adults' ability to analyze the sound structure and grammar of their language (Morais & Kolinsky, 2001), a finding that Peter Bryant and his colleagues have made good use of in the design of programs for the teaching of reading (Bryant, 1995; Bryant & Nunes, 1998). But these effects, while not necessarily trivial, do not indicate that education produces any general influence on children's mental processes that can be considered superior to the kind of enculturation that has existed in all societies throughout human history.

Investigators have studied how children and adults who attend school versus those who engage in some other activity make various calculations using mathematically equivalent tasks (such as selling candy on the street, or measuring cloth, or calculating the area of a building site) (Nunes, Schliemann, & Carraher, 1993; Saxe, 1994). Such research has repeatedly shown that groups differing in their amount of school-based experience or everyday, work-related experience approach the same task (logically speaking) in different ways. The schooled subjects' reliance on written algorithms often led them to make egregious errors, whereas the mathematical activities arising in the course of selling candy or calculating the ratio of one board length to another were both quantitatively superior and free of nonsensical answers. Moreover, in many cases, the procedures acquired informally in the course of work were more adequately generalized, undermining the oft-repeated idea that such knowledge was somehow bound to particular contexts of use. Rather, it has turned out that it is knowledge acquired in school that is most vulnerable to becoming encapsulated.

Intergenerational Studies of the Impact of Schooling

As noted, the difficulty with cross-sectional studies comparing schooled and nonschooled people is that the logic of comparison requires that we identify situations

equally experienced by both groups, with the cognitive skills and modes of discourse (such as those learned in elementary school) finding application outside school. Although they did not pursue this issue in their monograph on the consequences of education in the Yucatán, Sharp and his colleagues suggested an answer that has been followed up subsequently:

the information-processing skills which school attendance seems to foster could be useful in a variety of tasks demanded by modern states, including clerical and management skills in bureaucratic enterprises, or the lower-level skills of record keeping in an agricultural cooperative or a well-baby clinic. (Sharp, Cole, & Lave, 1979, p. 84)

In recent decades, Robert LeVine and his colleagues have pursued this path in a program of research that provides convincing evidence of the cognitive and social consequences of schooling. These researchers focused on the ways in which formal schooling changes the behavior of mothers toward their offspring and their interactions with people in modern, bureaucratic institutions, as well as the subsequent impacts on their children (LeVine & White, 1986; LeVine, LeVine & Schnell, 2001). These researchers propose a set of plausible habits, preferences, and skills that children acquire in school, retain into adulthood, and apply in raising their own children. Raising one's children can reasonably be considered a task with many cognitive elements that are common to schooled and nonschooled adults. These changes in parenting behavior include, in addition to use of rudimentary literacy and numeracy skills:

- Discourse skills using written texts for purposes of understanding and using oral communication that is directly relevant to negotiating interactions in health and educational settings involving their children
- Models of teaching and learning based on the scripted activities and authority structures of schooling, such that in subordinate positions schooled women adopt and employ behaviors appropriate to the student role, and in superordinate positions, adopt behaviors appropriate to the teacher role
- An ability and willingness to acquire and accept information from the mass media, such as following health prescriptions more obediently

As a consequence of these changes in the maternal behavior of young women who have attended school at least through elementary school, LeVine and his col-

leagues find that the children of women who have attended elementary school experience a lower level of infant mortality, better health during childhood, and greater academic achievement. Hence, while schooling may or may not have produced measurable cognitive effects at the time, such experience produces context-specific changes in behavior that have general consequences in child rearing, which in turn produce general consequences in the next generation.

The work of these researchers has been supported by direct observations of the teaching styles of Mayan mothers who have, or have not, been to school. Pablo Chavajay and Barbara Rogoff found that mothers who had experienced 12 years of schooling used school-like teaching styles when asked to teach their young children to complete a puzzle, while those with 0 to 2 years of schooling participated *with* their children in completing the puzzle and did not explicitly teach them (Chavajay & Rogoff, 2002). There is nothing inherently wrong with the unschooled mothers' teaching style, but it does not prepare their children well for schools, which rely heavily on the recitation script as the mode of instruction.

In sum, when the effects on health-related behaviors that affect the child's biological well-being are combined with changes in maternal ability to use modern social welfare institutions and to adopt new ways of interacting with their children, the effects of schooling appear to go well beyond cognitive effects to become general in the society.

Cultural-Historical Change in IQ Scores

An interesting example of cultural-historical change in cognitive abilities that is probably related in various ways to the social complex of which universal formal school is a part has been referred to as the "Flynn effect." It is named after James Flynn (1987), a political scientist working in New Zealand, who observed that the standard intelligence test scores of adults from 14 different nations had consistently increased in recent decades. Since then, the "Flynn effect" has been confirmed by numerous studies (Daley, Whaley, Sigman, Espinosa, & Neumann, 2003; Nettlebeck & Wilson, 2004). An average increase of several IQ points per decade was found for several intelligence tests. At present, this pattern has been found in more than 20 countries including the United States, Canada, different European nations, and Kenya. One might expect that the Flynn effect would be clearest for tests that empha-

size cultural knowledge or education. The opposite is true, however: the increase is most striking for tests measuring the ability to recognize abstract, nonverbal patterns (e.g., Raven Matrices), while tests emphasizing traditional school knowledge have generally shown less increase.

Since publication of Flynn's paper, there has been an ongoing debate about the meaning of the results (Daley et al., 2003; Neisser, 1998). In his initial paper, Flynn was unwilling to believe that his generation was significantly more intelligent than that of his parents. And when one extends the time span of the changes, the results are even more difficult to credit. Extrapolating Flynn's results would mean that the average African American adult in 1990 had a higher IQ than the average European-American adult in 1940, and that the average English person in 1900 would score at the level currently considered to indicate mental retardation.

Noting that compared with the previous generation, the number of people who score high enough to be classified as "genius" has increased more than 20 times, Flynn argued that we should now be witnessing a cultural renaissance. Because he found this conclusion implausible, he suggested that what has risen is not intelligence but some kind of "abstract problem-solving ability."

Quite apart from raising again the issue of what IQ tests measure, the Flynn effect has given rise to explanations that include improvements in nutrition and health, increased environmental complexity (e.g., advanced technology, mechanical toys, video games, as well as ubiquitous exposure to television with its special conventions of interpretation and information-processing demands), decreased family size and concomitant changes in family structure (e.g., a higher percentage of children are firstborns), and increased parental education and literacy.

What is significant for present purposes is that all these factors, even if their proximal effect is biological (e.g., improved nutrition) are cultural in origin and speak to the importance of studying culture and cognitive development in relation to its cultural-historical context (for a similar argument, see Greenfield, Keller, Fuligni, & Maynard, 2003).

ONTOGENY

When we come to the issue of the relationship of culture and cognitive development against the background of ev-

idence concerning hominization, primatology, and cultural history, several basic points stand out. First, the development of human beings at the beginning of the twenty-first century is but the most recent manifestation of life processes that at a minimum trace their origins back several million years (assuming that we begin with consideration of the common ancestor of *Homo sapiens sapiens* and the great apes).

Second, cultural resources and constraints have coevolved with the biological structure of *Homo sapiens* "from the beginning." Culture is, quite literally, a phylogenetic property of human beings.

Third, while biological changes may have been minimal in the "eyeblink" of phylogenetic time separating the Paleolithic period from the twenty-first century, cultural historical change, driven in significant measure by the invention and deployment of cultural artifacts, especially externalized symbol systems, has markedly increased the complexity and power of the human cultural tool kit, thereby changing the conditions of ontogenetic (and particularly) cognitive development in ways that reconfigure phylogeny-ontogeny relations.

Fourth, claims for marked discontinuities between human beings and near neighbors among the great apes must be tempered with respect to views that ascribe entirely unique cultural and cognitive processes to human beings. Rather, the achievements of our near-kin among other species offer important constraints on our theorizing about the process of culture and cognitive development that need to be exploited in development of a more powerful theory of human cognitive development. (At the same time, it would be an equally egregious error to assume that despite our close kinship to chimps and bonobos, modern human beings are merely highly talented apes, or that human culture, thought, and social organization are mere quantitative extensions of the behavioral and social patterns inferable among *Homo habilis* or observable in *Pan troglodytes*. Our phylogenetic and cultural history provide the fundament for contemporary human ontogeny, not an explanation of its emergent properties.)

Although these points are currently receiving wide acceptance, research that incorporates them into the study of human ontogeny is relatively sparse and concentrated within a few parts of the vast domain of culture and cognitive development. Overall, research on cognitive development in recent years has tended to focus on younger and younger age groups so that, for example, middle childhood, which received the lion's

share of attention 20 years ago is sparsely represented in contemporary research, while the opposite situation holds for infancy (see also Kuhn & Franklin, Chapter 22, this *Handbook*, this volume). At the same time, research on infancy that considers cultural influences is more likely to be concentrated on socioemotional and physical than cognitive development, particularly research that uses cross-cultural methods. Even in cases where the same topic (e.g., the development of concept formation or memory) continues to yield new evidence, psychologists' theoretical preferences and the specific methods they use to gather evidence have changed, so that it is not possible to report the results of further research on topics formulated at an earlier period.

These circumstances make it difficult to maintain continuity with the previous chapters on culture and cognitive development. They also restrict the relevant data on which I can draw to summarize current knowledge (in the sense of research conducted in recent years).

I have adopted two strategies in response to these difficulties. First, at certain points I summarize culture-development relationships that spill beyond the cognitive domain, narrowly conceived, but that illustrate phylogeny-culture-ontogeny relationships with clear implications for cognitive development. Second, when dealing with cultural variations and cognitive development, I concentrate my attention on two areas of research where there has been relatively dense interest and hence a good deal of new data—conceptual development and autobiographical memory. Current research on conceptual development is particularly rich in implications for the intertwining of phylogenetic and cultural constraints in cognitive development. Autobiographical memory, by contrast, connects the study of cognitive development to presumed society-wide contrasts in broad cultural themes, thereby making contact with both earlier and contemporary research on culture and cognitive styles.

The Proximal Locus of Development: Activity Settings and Cultural Practices

An important lesson from the primate literature on the process of acquiring culture is that to acquire cultural patterns during postnatal development, the young must be in close enough proximity to older members of the community who engage in those commonly patterned forms of behavior. Human beings are notable for the ex-

tremely immature state of their young at birth. They require many years of extraordinary support from their parents and community to survive into adulthood and acquire the cultural knowledge necessary for the social reproduction of the group (Bogin, 2001; Bruner, 1966).

As noted, developmentalists who study culture and development have highlighted the idea that the arrangements made in all societies to support the postnatal development of young children be conceived of as a “developmental niche” that merges practices to support physical care with parental beliefs about future requirements. This emergent sociocultural system, as Super (1987) commented, implies that “environments have their own structure and internal rules of operation, and thus, . . . what the environment contributes to development is not only isolated, unidimensional pushes and pulls but also structure” (p. 5).

Moreover, the nature of this niche within societies changes with the age of the child. Whiting and Edwards (1988), following Mead (1935), early on suggested periods of childhood that corresponded with the physical constraints on children's behavior. She referred to early infancy as the period of the “lap child,” the period between 2 and 3 years as “knee children,” who are kept close at hand but not continuously on the mother's lap or in a crib; 4- to 5-year-olds as “yard children” because they can leave their mothers' sides but are not allowed to wander far. In many modern, industrialized countries, children between 3 and 5 or 6 years of age spend part of the day in an environment designed to prepare them for school, which has led this time of life to be called the “preschool period,” after which they become neighborhood children, free to roam, but not beyond the confines of the community.

In the early years of the study of culture and development, heavy emphasis was placed on the way in which the organization of this proximal developmental environment served as a locus within which the behavior of parents and older kin molded the child's behavior. Beatrice Whiting (1980, p. 97) extended this idea to suggest that the mother and father's greatest effect is in the assignment of the child to settings that have important socializing influences. Whiting's work was directed primarily at the development of social behavior and personality, but her insight has subsequently been influential in redirecting the focus of researchers' attention beyond the family and local community to the settings that children inhabit, the people to be found there, their changing forms of participation, and the part that activ-

ties within those settings play in the overall process of development—what Super and Harkness refer to as the child's developmental niche (Göncu, 1999; Rogoff, 2003; Super and Harkness, 1986, 1997).

Cultural differences in the organization of children's developmental niches are almost certainly more variable than the physical environments in which they live; there are many ways to achieve survival in a given ecological niche. Infants among the Aka foragers in the Central African Republic are held by their parents while the parents hunt, butcher, and share game (Hewlett, 1992). Quechua infants high in the Andes spend their early months wrapped in layers of woolen cloth strapped to their mothers' backs. The cloth forms a "manchua pouch" for the infants, who must survive the exceedingly cold, thin, dry air surrounding them, greatly restricting their vision and movement. Ache infants living in the rain forests of eastern Paraguay spend 80% to 100% of their time in physical contact with their parents and are almost never more than 3 feet away because these hunter-gatherers do not make permanent camps in the forest, but only clear an adequate space leaving stumps and roots that are hazardous for the children (Kaplan & Dove, 1987). Contrast these niches with those of American children with their own bedrooms and play areas, time spent in day care or preschool among many children the same age and one or two stranger-caretakers, while *Sesame Street* is playing on the television; or other American children living two families to a room in a crowded slum, reality TV playing on the television, and single unemployed mothers trying to keep order and their sanity. The range of developmental niches in contemporary human development is obvious.

As researchers have pointed out, these variations in developmental niches create experiential patterns making it difficult to reduce them to a single dimension, although clusters of attributes are discernible. According to Morelli and her colleagues, the Efe of the Democratic Republic of Congo (formerly Zaire) live in small groups of one or more extended families who forage with bow and arrow and work for members of nearby farm communities. Children are free to wander where they wish around their small camp to watch adults make tools and cook. Young children entertain themselves and may enter, uninvited, into most huts. From the age of at least 3 years, they accompany their parents to gather food, collect firewood, and work in gardens. Although they were only 2 to 4 years of age, Efe children were at least

present when adults were working in 74 of the observation periods and participated in specialized child-focused activities by adults only 5% of the time. A similar pattern was observed in San Pedro, an agricultural town in Guatemala, where people engage in agriculture and small business, family sizes are larger, the total number of the community members is far greater, and older children spend part of their time in school (Morelli, Rogoff, & Angelillo, 2003).

As different as they are from each other, in many ways these two traditional, rural communities exhibited relatively similar patterns of adult arrangement of 2- to 4-year-old children's activities. In contrast, children were present when adults were engaged in work only during 30% of the observations of two middle-class communities in the United States (one in Utah and one in Massachusetts, so they also differed in many ways). When Efe and San Pedro children were observed playing by themselves, their play almost always consisted of emulation of adult activities, but the play of the American children rarely emulated that of adult activities. In the two American samples, children were often engaged by adults in specialized child-focused activities including lessons or play that often mimicked schooling. The American adults also engaged their young children as conversational partners on child-focused topics in approximately 15% of the interactions observed, a category that was very rare in either of the other two communities.

These observations were complemented by Gaskins (1999, 2000, 2003) during her ethnographic work among rural Mayan children in the Yucatán. Her observations extended across a broad age range from a few months to 17 years. Gaskins, used a method of "spot observations" similar to that used by Morelli and her colleagues, supplemented by repeated discussions with Mayan adults. She identified four kinds of activities:

1. Maintenance activities (eating, bathing, grooming, dressing)
2. Social orientation (observing and keeping track of what others are doing or interacting with them directly)
3. Play
4. Work

Three cultural principles appear primary in interpreting Mayan children's behavior in these four basic kinds of activities:

1. *The primacy of adult work:* Mayan economic production occurs primarily in the family setting and adults believe that children should not be allowed to interfere with this priority. This means that they do not try to amuse children and allow them to enter into adult activities only in so far as they make a contribution. In their parental role of socializing agent, they believe they can have the most influence in teaching their children the particular skills and attitudes they need to be productive workers and members of their community. It is also expected that children will obey parental authority unquestioningly in these areas, and parents will use the threat (or the act) of force to ensure a child complies.
2. *The importance of parental beliefs:* First of all, parents have health concerns that they attend to in terms of local beliefs about the sources of threats to health, so they organize children to minimize perceived health risks. Second, they believe that development is internally programmed and it just “comes out by itself.” Consequently, adults show little interest in promoting or even monitoring children’s development, so long as they do not get in the way. As a result, parents do not take much initiative to influence the child’s psychological characteristics nor responsibility for how the child turns out.
3. *The independence of children’s motivation:* Children are expected to take care of themselves and interact with siblings, and adults do not spend time structuring when the children do what. This extends even to such issues as when to start school and how much to sleep or eat.

Gaskins reports that maintenance and social orientation activities are highest with 0- to 2-year-olds and diminish until the ages of 15 to 17, when interactions in work settings increase in frequency. Play peaks at 3 to 5 years old but decreases throughout childhood and is rarely seen after 12 years of age. Play almost always involves adult activities. Work is already a significant activity among 3- to 5-year-olds and grows steadily as children begin the passage from childhood to adulthood. No comparable research has been conducted in a highly industrialized society, but it is clear that the pattern of activities arranged for children at each age would be quite different, with pretend play replacing mimicking of adult activities and involvement in work with adults being replaced by schooling until a much later age.

Those engaged in the study of children’s development in the activity settings they inhabit in nonindustrialized

societies have accrued evidence to show that such children develop a special proclivity or ability for learning through keen observation, although it is not entirely clear if such skills involve higher order forms of imitation, motivation to emulate others, or some combination of such factors. Bloch (1989) reports that Senegalese children 2 to 6 years of age observed other people more than twice as much as European-American children in the same age range. Chavajay and Rogoff (1999) found that Guatemalan Mayan mothers and toddlers were more likely than middle-class European-American counterparts to attend simultaneously to several ongoing events, a practice that, they argue, supports learning by observing.

Rogoff and her colleagues (Rogoff, Paradise, Arauz, Correa-Chavez, & Angelillo, 2003) include observational learning in their notion of “intent participation,” in which keen observation is motivated by the expectation that at a later time, the observer will be responsible for the action in question. Intent participation may involve more experienced participants facilitating a learner’s participation and participating along with the learner, or it may involve direct verbal instruction (Maynard, 2002). But it places a heavy role on observation relative to verbal instruction of the sort characteristic of developmental processes that are prominent in formal schooling. Studies indicate that intent participation is a special form of learning by observation that has cultural roots and contributes to ongoing activities.

For example, Mejia-Arauz, Rogoff and Paradise (2005) arranged for Mexican-and European-heritage children whose parents had either a relatively high or low level of education to observe an “Origami lady” make two origami figures, after which they made figures of their own to keep. They found that all the children keenly observed the Origami lady’s demonstration, but the children whose parents had little education completed their own origami figures without asking for further information while those whose parents had experienced more education were likely to ask for help.

I will not repeat here the material on the influences of schooling sketched out in the earlier section on cultural-historically organized forms of activity. Suffice it to say that, in study after study, mothers who have experienced higher levels of schooling are more likely to organize children’s activities in ways that place less emphasis on intent participation and more emphasis on verbal explanation. Both the content of what children gain deep knowledge about and the way they attain that knowledge are influenced by the range of activities that

adults arrange for them and the way that those activities are carried out. Further, these contents and ranges are strongly affected by the physical and social ecology of the groups in question.

The Intertwining of Biology and Cultural Practices in Conceptual Development

For many years, the dominant line of cross-cultural research employed tasks in which children of different ages and backgrounds were presented sets of objects or drawings that could be classified along various dimensions (color, form, number, function, and taxonomic category were most frequently studied). This work was directly influenced by stimulus-response learning theories which assumed that concepts are built up from associations between specific attributes of stimuli brought about by some form of reinforcement (which, in the case of human beings, could be a simple designation of a response as correct or incorrect). It was further assumed that beyond the ability to perceive the stimuli, development or identification of the relevant categories was entirely a matter of experience; consequently, interest focused on what kinds of experiences different cultures provided. (See Cole and Scribner, 1974; Laboratory of Comparative Human Cognition, 1983 for reviews.)

During the past 2 decades, this line of work has withered away. In part, the evidence suggested that difficult-to-pin down factors are closely associated with the particular stimuli and experimental procedures that differentially influenced the performance of schooled and nonschooled populations in uncontrolled and uninterpretable ways; and in part, the general approach to concept development that it represented fell from favor. One of the new lines of research that arose to take its place focused on the categorization of natural kinds. Categorization of natural kinds was presumed to be constrained to a great extent by phylogenetically based cognitive predispositions. In addition, inductive judgments about new instances rather than sorting by similarity became the essential criterion of categorical knowledge (see S. A. Gelman and Kalish, Chapter 16, this *Handbook*, this volume; R. Gelman & Williams, 1998, for relevant reviews).

The concepts that have been featured in this recent work are often identified with cognitive domains, where domain is defined as “a body of knowledge that identifies and interprets a class of phenomena assumed to share certain properties and to be of a distinct and general type” (Hirschfeld & S. A. Gelman, 1994, p. 21).

Current disagreements focus on what these initial constraints are and how they limit or shape the role of experience (including culturally organized experience) in conceptual development. There is a rough scale that can be used to describe the particular theory of how phylogenetic constraints and culturally organized experience during ontogeny combine (see S. A. Gelman and Kalish, Chapter 16, this *Handbook*, this volume, for a more extensive account focused on ontogenetic change).

At one end of the scale is the view that gained popularity in connection with Chomsky’s (1959, 1986) theory of language acquisition, which included the claim that while the specific surface forms of a language depend on cultural experience (e.g., French is different from Cantonese), the underlying deep structure is innately specified. Language is not acquired through environmental learning contingencies, as learning theorists had claimed (Skinner, 1957).

Chomsky’s view was generalized to a broad range of intellectual domains by Fodor (1985), who coined the term *mental module* to refer to any “specialized, encapsulated mental organ that has evolved to handle specific information types of particular relevance to the species” (Elman et al., 1996, p. 36). In this view, knowledge acquisition in a modularized domain does not require extensive experience for its development; the role of the environment is merely to trigger the corresponding module. Particularly important for considerations of culture and development is the assertion that modular systems are “encapsulated,” meaning that they rapidly produce mandatory outputs from given inputs. (An example would be the perceptual illusion that a stick half submerged in water is bent, even when the perceiver knows full well that it is straight.) Often, modularity theories are accompanied by the assumption of prespecified brain areas as the locus of the module in question (e.g., Broca’s area is taken to be the brain locus of language).

Many developmentalists who have been convinced of the existence of domain-specific, biological constraints on conceptual development resist the notion of modularity, preferring instead to speak of “core” or “privileged” domains of knowledge, where biological constraints may provide “skeletal principles” that constrain how developing children attend to relevant features of the domain, but are not entirely encapsulated; rather, they require the infusion of cultural input and continued learning to develop past a rudimentary starting point (Baillargeon, 2004; Chen and Siegler, 2000; S. A. Gelman & Kalish, Chapter 16, this *Handbook*, this volume; R. Gelman & Lucariello, 2002; Hatano,

1997). Theorists in this camp differ from each other in precisely how to construe the role of environmental factors and the ways in which they operate.

Among those who argue that the role of experience in concept development goes beyond the triggering of modularized processes, some argue that environmental contingencies not dissimilar to those proposed by S-R (stimulus-response) theorists of earlier generations are essential (Elman et al., 1996), while others argue that domain-general cognitive mechanisms such as analogizing are key mechanisms in moving beyond initial states to more mature forms of conceptual thought (Springer, 1999).⁴

To further complicate matters, it appears plausible that the degree to which “highly specific innate constraints + minimal experience,” versus “skeletal constraints + a good deal of culturally organized experience,” are needed to account for development may differ with the domain in question. In the domain of physics, within months after birth children have some grasp of at least a few very basic physical principles, including expectations that two objects cannot occupy the same location at the same time or cannot pass through physical obstructions (Spelke, 1994). As a result of such findings, Spelke has argued that knowledge in the domain of physics is innate, domain-specific, encompasses constraints that apply to all entities in the domain, forms the core of mature knowledge, and is task specific. Similar claims have been made for the domains of number (Feigenson, Dehaene, & Spelke, 2000), agency (Gergeley, 2002; Gopnik & Meltzoff, 1997), biology (Atran, 1998), and theory of mind (Leslie, 1994), although in each case there are others who argue for hybrid positions that include domain-general reasoning abilities (Astuti, Solomon, & Carey, 2004; Springer, 1999).

Research on the influence of the environment, particularly cultural variations in environmental influence, have not been evenly distributed across the full range of conceptual domains that have preoccupied developmentalists. There is apparently no research on cultural differences in the development of naïve physics, although

even those who favor strong nativist claims have an interest in determining whether development beyond initial, core principles does in fact continue to adhere to the initial constraints they hypothesize on the basis of research with very young infants. There is, however, some cross-cultural research in the domain of number (the work of Saxe reviewed earlier with respect to cultural-historical change is relevant in this regard), and there is a good deal of research on the domains of psychology and biology. Consequently, my review focuses largely on these three domains.

Number

In recent decades a good deal of evidence has been accumulated for elementary numerical abilities involving small quantities, including counting, addition, and subtraction, in both very young human infants and in primates, although there is controversy about the precise processes involved (Boysen & Hallberg, 2000; R. Gelman & Gallistel, 2004; Hauser & Carey, 1998). R. Gelman and Williams (1998) conclude that the pattern of errors evidenced by young infants asked to perform numerical operations on set sizes of three or less objects may indicate the presence of a “common preverbal counting mechanism similar to the one used in animals” (1998, p. 588). Hauser and Carey go somewhat further, concluding:

Early primate evolution (and probably earlier), and early in the conceptual history of children, several of the building blocks for a representation of number are firmly in place. [These include] criteria for individuation and numerical identity (the sortal object, more specific sortals like cup and carrot, and quantifiers such as one and another). Furthermore, there are conceptual abilities . . . such as the capacity to construct one to one correspondence and the capacity to represent serial order relations . . . (p. 82)

Studies of numerical reasoning in early childhood indicate that it builds on these early starting conditions in an orderly fashion. Thus, Zur and R. Gelman (2004) report that when 3-year-olds who had not attended preschool viewed the addition or subtraction of N objects from a known number and were asked to predict the answer and then check their prediction, they provided reasonable cardinal values as predictions and accurate counting procedures to test their predictions. Such rapid learning in the absence of explicit instruction, they argue, supports the idea that there are “skeletal mental

⁴ As S.A. Gelman and Kalish (Chapter 16, this *Handbook*, this volume) point out, even those who deny the need to posit strong phylogenetic, domain-specific constraints assume that phylogenetic factors play a role in cognitive development, including concept formation. The disagreements center on how to characterize those phylogenetic constraints and the extent to which they are domain specific.

structures that expedite the assimilation and use of domain-relevant knowledge" (p. 135). Data such as these, despite uncertainties about mechanism, support the argument for number reasoning as a core domain, and hence a human universal.

Evidence from number development in other cultures appears, at least at first glance, to cast doubt on the universality of elementary number reasoning and leaves little doubt that Hatano and Inagaki (2002) are correct in arguing that, because innately specified knowledge is still skeletal, it is essential to study the ways in which cultural experience interacts with phylogenetic constraints to produce adult forms of numerical reasoning.

To begin with, a good many societies in the world appear to have at most a few count words on the order of "one, two, many" (Gordon, 2004; Pica, Lerner, Izard, & Dehaene, 2004). While no research has been conducted with infants in such societies using procedures comparable to those used by modularity and core-domain theorists, it is not clear how such impoverished systems could be considered evidence of a universal set of numerical knowledge. R. Gelman and Williams (1998) argue that this appearance may be deceiving. They cite evidence from a South African hunter-gatherer group which has only two numerical lexemes but report that this does not stop them, for example, from counting to ten by using the additional operation to generate successively larger cardinal numbers, so that the word corresponding to eight translates as $2 + 2 + 2 + 2$. However, Gordon (2004) has recently reported that while Pirahã adults living in a remote area of the Amazon jungle display elementary arithmetic abilities for very small arrays, their performance quickly deteriorates with larger numbers. But Pirahã children who learn Portuguese number words do not display the same limitations as their parents. Similar results are reported for another Amazonian group by Pica et al. (2004).

While number reasoning beyond the level achieved by some nonhuman primates and infants may be in doubt for some hunter-gatherer groups, this same evidence underscores how important cultural influences are for the elaboration of core numerical knowledge. A key factor appears to be the appearance of lexicalized arithmetic knowledge when economic activities begin to produce sufficient surplus to necessitate record keeping and trade. Recall that traditional Oksapmin number practices appear to have been at the very beginnings of such reasoning because, according to Saxe (1982), small amounts were traded and one-to-one correspondence often sufficed as a mechanism to mediate exchange.

Taking an example from two societies, both of which engaged in agricultural production, Jill Posner (1982) compared children from two neighboring groups in the Ivory Coast. The first she characterized as farmers using primitive agricultural methods to eke out a subsistence living; the second also farmed, but in addition engaged in trades such as tailoring and peddling that required frequent participation in the money economy. The children in both groups displayed knowledge of relative quantity, a skeletal principle, but the children from the subsistence farming group displayed far weaker counting skills and calculation skills than those from the group with more involvement in the money economy, a difference that was compensated for by schooling.

Research comparing the development of numerical knowledge and skills among middle-class and working-class children in the United States also supports the idea that culture elaborates core domain knowledge to different degrees, and perhaps in different ways but still within the framework of the core domain (Saxe, Guberman, & Gearhart, 1987). These researchers, observed children and their mothers in their homes, presented a variety of tasks to the children, and also observed mothers present prespecified problems to their children. They found that children from both social classes were regularly engaged with activities involving number, but by 4 years of age, children from middle-class homes displayed greater competence on more complex numerical tasks than did their working-class peers. During mother-child interactions, all mothers adjusted the goals of activities to reflect the child's ability, and children adjusted their goals to their mothers' efforts to organize the activity; but the working-class mothers were more likely to engage in greater simplification and to profess lower expectations for their children in conversation with the interviewer.

Overall, the research on development in the domain of number provides strong support for the "core domain plus cultural practice" perspective proposed by Hatano and Inagaki (2002). (See also the discussion of cognitive development in Chapter 11 by Shweder et al., this *Handbook*, Volume 1, and the position adopted by S. A. Gelman and Kalish in Chapter 16, this *Handbook*, this volume, although they do not speak of culture as the source of empirical input.)

Research in two other domains where there is greater disagreement about their status as core domains and the experiential factors that may affect development offer a more challenging picture in which phylogenetic and

cultural contributions to development may not dovetail so neatly.

Naïve Psychology and Theory of Mind

As applied to humans, the term *theory of mind* “refers to the tendency to construe people in terms of their mental states and traits” (Lillard & Skibbe, 2005). It is referred to as a theory because people use these inferences based on invisible entities (desire, beliefs, thoughts, emotion) to guide their action, and to predict the behaviors of others.

As indicated in the earlier section on chimpanzee cognition, Tomasello, Call, and Har’s (2003) assertion that there is no evidence that chimpanzees or bonobos can think about the beliefs of others can stand as an agreed-on point of differentiation, because there is no doubt that human children growing up in industrialized countries where the requisite research has been done develop a “belief-desire” psychology of mind by about 4 years of age. The question then becomes one of whether this ability is universal in both its timing and nature. Again, because the role of culture on the ontogenetic course of theory of mind is extensively reviewed by Harris (Chapter 19, this *Handbook*, this volume), I simply summarize his thorough treatment to maintain continuity in the present discussion.

Research conducted in industrialized countries indicates that in the transition from infancy to early childhood, and all during early childhood, children gain a more comprehensive idea about how other peoples’ desires and beliefs are related to how they act in the world. Even at the age of 2, children can distinguish between their own desires and those of others. From studies of American children’s spontaneous speech in many settings, it has been established that by the age of 2 years, children are already capable of using terms such as *want* and *like* correctly (Wellman, Phillips, & Rodriguez, 2000; Wellman & Woolley, 1990). As discussed by Harris, the favorite experimental method for diagnosing the development of the ability to think about other people’s beliefs and the relations of their beliefs to their actions is the “false belief” task which is presented in various ways.

By the time they are 3 years old, children can engage in deception in collaboration with an adult. As Lillard and Skibbe (2004) summarize the matter, “mentalizing abilities thus appear to begin during infancy.” By the age of 5, children master the ability to reason about a false belief and mental representations in tasks that apply to

others. Later, their theory grows to encompass secondary emotions such as surprise and pride.

This sequential, developmental progression of theory of mind capabilities led quickly to the suggestion that such a theory is a mental module (Leslie, 1994), which is part of the common inheritance of some nonhuman primates. Among humans, it appears to develop within a narrow age range, 3 to 5 years, and it appears to be a kind of rapid, unconscious, inference-generating device. Links between the asocial nature of autistic children and modularity are used as evidence favoring the nativist argument.

If theory of mind were modular, one would expect it to be impervious to cultural variation; it would develop on a universal time scale, much as does losing one’s baby teeth. This expectation has not been tested for the full set of relevant age ranges, but there is reasonable consistency in how children deal with a key test of achieving a more adult-like form of thinking—the false-belief task.

The result has by no means yielded a foregone conclusion. There is ample evidence from cultures around the world that there is enormous variety in the extent and ways that mental states and actions are spoken about and presumably how they are conceived (Lillard, 1998a; Vinden, 1996, 1999). In terms of sheer number, English is at one extreme of the continuum, possessing more than 5,000 emotion words. By contrast, the Chewong people of Malaysia are reported to have only five terms to cover the entire range of mental processes, translated as *want*, *want very much*, *know*, *forget*, *miss* or *remember* (Howell, 1984). Anthropologists have also reported that, in many societies, there is a positive avoidance of talking about other people’s minds (Paul, 1995).

At present, opinion about cultural variation using locally adapted versions of theory-of-mind tasks is divided (Harris, Chapter 19, this *Handbook*, this volume; Lillard & Skibbe, 2004). As Harris notes, ambiguities arise because people in some cultures are unlikely to talk in terms of psychological states in the head, and in some cases success on the theory-of-mind tasks was absent or partial (Vinden, 1999, 2002). But was performance poor because people lacked the vocabulary or inclination, or was it that they could not describe their intuitive understanding in words?

Callaghan et al. (n.d.) conducted a study that sought to avoid the issue of language by using a minimally verbal procedure where it was unnecessary to use difficult-to-translate words such as belief and emotion. With two

experimenters present, they hid a toy under one of three bowls. Then one experimenter left and the other induced the child to put the toy under a different bowl before asking the child to point to which bowl the first experimenter would pick up when she returned. Notice that the procedure uses language at the level of behavior (picking up a bowl) with no reference to mental terms, so the prediction that the absent experimenter would look where the toy had been when she left would indicate ability to think about others' beliefs without using the term.

Under these conditions, a large number of children 3 to 6 years of age were tested in Canada, India, Samoa, and Peru. Performance improved with age, with 4 to 5 years of age being the point at which 50% of the children performed correctly, and 5 to 6 years of age the point at which all the children responded correctly. Here is a case where careful standardization of the precise, same procedure conducted in such a way that performance does not depend on the ability to communicate about mental language with people who do not use such terms produces universality (in line with a modularity view). This invariance taps into the most skeletal core of theory of mind behavior, devoid as it is of enrichment by the local vocabulary of any information about how the children would respond if they were asked to reason about beliefs. Thus, for example, Vinden (1999) found that while children from a variety of small scale, low technology groups in Cameroon and New Guinea were able to understand how belief affects behavior, they had difficulty predicting an emotion based on a false belief.

Using a different task, in which children were asked to explain the bad behavior of a story character, Lillard, Skibbe, Zeljo, and Harlan (2003) found culture, regional, and class differences in whether children attributed the behavior to an internal, psychological trait or external circumstances, a plausible element in any theory of mind a person uses to predict and interpret someone else's behavior. Lillard (2006) makes the important point that "cultural differences are usually a matter of degrees, of different patterns and frequencies of behaviors in different cultural contexts" (p. 73), a view put forward early on by Cole et al. (1971). Children in all groups gave both kinds of responses, internal and situational; it was the frequency and patterns of use that differed. They attribute the average results in this case to language socialization practices in different communities, noting that low socioeconomic status (SES) children or rural children are more likely to have parents

who make situational attributions of behavior and model this form of interpretation for their children, whereas high SES or urban parents are more likely to use an internal model of interpretation that they embody in their interactions with their children. It has also been shown that children's theory of mind appears more rapidly if they have older siblings, who presumably provide them with extensive experience in mind-reading and mind-interpreting talk (Ruffman, Perner, Naito, Parkin, & Clements, 1998).

Both universality and cultural specificity appear to characterize the development of theories of minds. Given evidence that many (but not all) elements of a human theory of mind can be found, using suitable procedures, among chimpanzees (Tomasello et al., 2003), it should not come as a surprise that when a carefully stripped-down version of false-belief tasks is presented to people of widely different cultural backgrounds, they perform the same, while cultural variations appear when language and explanation are made part of the assessment. This pattern of results supports the idea of Hatano and Inagaki (2002) that both phylogeny and cultural history are necessary contributors to the development of an adult mode of thinking about the thoughts and situations of oneself and others.

The Biological Domain

Among the domains considered here, the possibility of a core domain of biological knowledge has generated special controversy about the degree to which biology is a core domain and the extent to which the development of biological understanding is influenced by culturally organized experience. In an influential book, Carey (1985) argued that children's understanding of biological phenomena grows out of a naive psychology. Children interpret other living things by reference to, and by analogy with, human beings whose behavior is governed by their intentional beliefs and desires. They do not accept the idea that our bodily organs function independent of our intentions, and insofar as other entities are similar to humans, the same intentional causality should apply to them. Carey used a technique in which children are asked to judge whether a particular kind of entity shares a property with a target stimulus (e.g., if humans breathe do dogs breathe? do plants breathe? do rocks breathe?). According to her results, it is not until after the age of 7 that children begin to develop a theory that treats humans as one of many kinds of living things sharing many causal principles (in particular, a mechanistic causality

of bodily organs). This change gives rise to a naive biology, which is a derivative domain.

In their work on the domain of biology, Hatano and Inagaki (2002) argued that biology is a core domain that does not arise from psychology but uses the human body as a cornerstone for interpreting other biological entities. According to their view, naive biology uses a mode of explanation (a naive theory) of living things in terms of their similarity to human beings (personification) and the idea that living phenomena are produced by a special form of causation—vital principle—as distinct from a purely chemical or physical force (vitalism). This form of domain-specific reasoning is based on a three-way relationship between food/water, activeness/liveliness (actively taking in vital power from food), and growth in size or number (the ingestion of vital power produces individual growth and production of offspring). This mode of reasoning is also assumed to be universal across cultures. Although the cross-cultural data are somewhat sparse, evidence in favor of this proposition has been found in Australia and North America, as well as Japan, where children exhibit such reasoning by 6 years of age (see Hatano & Inagaki, 2002, for more details).

However, Hatano and Inagaki also believe that participation in local cultural practices is important to development of biological thinking beyond the most skeletal knowledge. This kind of developmental process is illustrated by Inagaki (1990), who arranged for some 5-year-old Japanese children to raise goldfish at home while a comparison group had no such experience. The goldfish raisers soon displayed far richer knowledge about the development of fish than their counterparts who had not raised fish. They could even generalize what they had learned about fish to frogs. If asked, “Can you keep the frog in its bowl forever?” they answered, “No, we can’t, because goldfish grow bigger. My goldfish were small before and now they are big” (quoted in Hatano & Inagaki, 2002, p. 272).

Additional evidence in favor of cultural involvement in the development of biological knowledge comes from the work of Atran and his colleagues on the growth of biological classifications. Atran (1998) once adopted the view with respect to biological categories that the taxonomy of living kinds is universal because it is a product of “an autonomous, natural classification scheme of the human mind” (p. 567). At present, however, he and his colleagues acknowledge that factors such as density of experience and local ecological sig-

nificance contribute to the development of biological understanding beyond early childhood (Medin, Ross, Atran, Burnett, & Blok, 2002; Ross, Medin, Coley, & Atran, 2003). Moreover, they demonstrate that biological thinking does not universally begin by using one’s own body as the foundation of reasoning.

In some of their studies, Atran, Medin, and their colleagues used a version of the procedure developed by Carey. For example, the child might be shown a picture of a wolf and asked “Now, there’s this stuff called andro. Andro is found inside some kinds of things. One kind of thing that has andro inside is wolves. Now, I’m going to show you some pictures of other kinds of things, and I want you to tell me if you think they have andro inside like wolves do.”

This questioning frame was then used with a number of “inferential bases” (in this case, human, wolf, bee, goldenrod, water) and a larger number of “target objects” from each of the taxonomic categories represented by the bases (e.g., raccoon, eagle, rock, bicycle) to see if the child believes that andro (or some other fictitious property) found in the base will also be found in the target object. Two questions were of primary interest: Does inference of the presence of a property (andro) decrease as the biological similarity of the target object decreases, and do children appear to use human beings as a unique base of inference when judging biological similarity (is personification a universal feature of the development of biological classification)?

This group of researchers conducted one such study with populations they term “urban majority culture children” and “rural majority children,” and rural Native American (Menominee) children between the ages of 6 to 10 years. With respect to the first question, they found, like Carey, that the urban majority children generalized on the basis of the similarity of the comparison entity to human beings. But even the youngest rural children generalized in terms of biological affinity according to adult expert taxonomies (they did not use humans as a unique foundation of their reasoning). In addition, all ages of Native American children and the older rural majority culture children manifested ecological (systems) reasoning as well; they inferred the relations between the entities being compared on the basis of their relationships in an ecological system, such as a pond or forest.

With respect to the second question, they found that urban children displayed a bias toward using humans as a base of comparison, but the rural children, and partic-

ularly the rural Menominee children, did not, contradicting Carey's claim of anthropomorphism as a universal characteristic of folk theories of biology. Such results show that both culture and expertise (exposure to nature) play a role in the development of biological thought. Such evidence fits well with the views of Hatano and Inagaki, as well as Geertz (1973), that culturally organized experience is essential for completing the work of phylogeny.

The same experimental paradigm was used to study the development of biological induction among Yucatek Mayan children and adults (Atran et al., 2001). Adults decreased their inductions from humans to other living kinds and then to nonliving kinds, following the pattern predicted by standard biological taxonomies. But when bee was the base, they often made inferences of shared properties not only to other invertebrates, but to trees and humans. According to Atran et al., this pattern of inference is based on ecological reasoning: Bees build their nests in trees and bees are sought after by humans for their honey. Adults often explicitly used such ecological justifications in their responses.

Most important with respect to the issue of cultural influences on development, the Yucatek children's responses were similar to those of adults. Whatever the base concept, inductive inferences decrease as the target moves from mammals to trees. And, like Yucatek adults, the children showed no indication of personification: Inferences from humans did not differ from inferences beginning with animals or trees and they did not appear to favor humans as a basis of inference. If anything, the children preferred dogs as a basis of inference, perhaps based on their affection for and familiarity with this common household pet. Again, the evidence speaks to the importance of culturally organized experience in the development of inferences in the domain of biology.

A recent, extensive, and instructive study of phylogenetic and cultural influences on the development of biological understanding comes from a series of studies conducted in Madagascar by Rita Astuti and her colleagues (2004). Astuti and her colleagues assert that a core domain of biological knowledge should include concepts of birth, birth parent, biological inheritance, and innate potential. As these authors point out, claims for a core domain of biology are contentious. For example, evidence in favor of a core domain of biology comes from evidence obtained from preschool children, not infants. And cross-cultural evidence from North Ameri-

can and Nigerian children indicated that before the age of 7 to 9 years, children would not agree that if a raccoon (in the American case) gave birth to a certain animal and that this animal then gave birth to more raccoons, then the newborn animal was a raccoon, even if it looked like and acted like a skunk (Keil, 1989). Madagascar is a strategically interesting place to study biological understanding because it is one of the places in the world where people emphasize the importance of postnatal experience in determining kinship and similarity among people. When adults are asked why some babies appear or behave as they do, they give reasons such as "the mother spent a lot of time with a person who looks just like the baby" or that the baby was tampered with by a wandering spirit. Consequently, according to Astuti and her colleagues, it is difficult, from a Malagasy point of view, to differentiate between the baby as a biological organism and the baby as a social being.

These researchers carried out studies among three groups of people. The first two groups were the Vezo, who live on the coast and make their livelihood as fishermen, and the Masikoro who live inland, farm, and raise cattle. Both of these groups are ethnically Malagasy, having arrived on the island a thousand or more years ago. They share traditional religious beliefs, a form of ancestor worship, as well as a common language. The third group, the Karany, are descendants of Indo-Pakistani immigrants who are town dwellers; they are generally shopkeepers and moneylenders who are relatively wealthy and well educated. At birth, Vezo and Masikoro babies are indistinguishable, but Karany babies are easily distinguished by their lighter skin and straighter hair. The major questions were whether people of different ages would attribute similarities between a child and its parents to biological inheritance or social circumstances. Comparisons were made when the birth and adopted parents in the hypothetical problems were from the same group, or one of the other two groups. Three types of traits were queried: bodily traits (e.g., wide feet or narrow feet), beliefs (do cows have stronger teeth than horses), and skills (knows how to be a carpenter or a mechanic). The specific questions differed depending on whether the adoptive and birth parents were from the same or a different group to tease out conditions under which biological or social inference modes would display themselves.

When Vezo adults answered questions about the babies' bodily characteristics, they overwhelmingly chose biological inheritance as the crucial factor.

When asked about what social group the child would belong to, the children were judged to be members of the groups into which they were adopted, whether Masikoro or Karany—group identity depends on what people do, not on the biological identity of their parents. When asked about beliefs and skills, Vezo adults again selected the adoptive parents' group as the one that the child would acquire.

In two follow-up studies, Astuti and her colleagues presented the same task to groups of children (6 to 13 years old) and youths (17 to 20 years old). Contrary to the adults, the children were likely to say that the children's bodily characteristics, beliefs, and skills would all be determined primarily by their adoptive parents. The adolescents were most likely to follow the adult pattern, ascribing bodily characteristics to birth parents, while beliefs and skills were more like the adult pattern that ascribed bodily characteristics to biology while beliefs and skills were ascribed to cultural experience.

In a final study, children and adults were asked to make judgments about properties of baby birds that were adopted by a new mother bird. In this case, both adult and children ascribed the characteristics of the birds to their birth parents and gave biological inheritance reasons for doing so.

There are many other interesting findings in this set of studies, but for present purposes they raise two key issues. First, under some conditions (e.g., when reasoning about birds) young Malagasy children, like young children in Tokyo or Boston appear to understand basic biological principles of inheritance. Second, when reasoning about humans, Malagasy adults show that they understand these laws of inheritance, but in their everyday lives, they staunchly deny their significance.

Such results greatly complicate conclusions one can draw about biology as a core domain. While it seems reasonable to conclude that understanding of basic biological principles is universal when probed in an appropriate manner, it is difficult to understand how adults can elaborate a complex set of cultural beliefs which have great influence in people's everyday lives, yet contradict this same core biological knowledge. That Malagasy children should be slow to acquire the (universal) adult system of core biological understanding is easy enough to understand: They are constantly exposed to adults whose interpretations of their everyday experience deny principles of naive biology. But how does it come about that adults acquire that same knowledge

while at the same time acquiring the cultural knowledge about kinship, ancestors, and sources of group similarity that contradict the skeletal principles of the core domain?

There is more to the organization of culturally organized belief and action than is captured by evidence of a core domain of biology. Astuti and her colleagues suggest that because the highest value of Malagasy society is to reach old age surrounded by a vast number of descendants, Malagasy systematically devalue and deemphasize biological ties in favor of social ties that make children the descendants of the entire village, not the birth parents alone. Whatever the case, the effect of this research is to emphasize the complex interweaving of biological constraints and cultural practices on the development of reasoning.

Beyond Core Domains

As R. Gelman and Lucariello (2002) note, a great deal of knowledge that children must master does not fall within any recognized core domain. With respect to objects in the world, a major class of such objects is the class of artifacts defined earlier as aspects of the material world that have been transformed to carry out some goal-directed human action.

Ample evidence indicates that American children differentiate between artifacts and natural objects at an early age, although the conditions under which they differentiate these two categories of objects may vary (Kemler Nelson, Frankenfield, Morris, & Blair, 2000; Keil, 1989). When children were told that an item was a kind of food and taught a name for it and then shown a novel item and told it was a kind of food, they generalized the name they had learned on the basis of color. However, if they were told that the original object was a tool and the new object a tool, they generalized the name for it based on its shape. Another line of evidence for differentiation of artifacts and natural kinds comes from, among other places, studies in which the object in question undergoes a transformation of some kind and the child is asked whether it is the same or a different object, and why. If, for example, a young child is told about a goat that has had its horns removed and its hair curled and has been trained to say "baaahbaaah" like a sheep, and is shown a picture of this transformed animal, very young children will maintain that it remains a goat because its insides haven't changed. Chil-

dren assume there is something essential about it as goat that cannot be changed by changing its external appearance (S. A. Gelman & Opfer, 2002). This is the sort of response we would expect given the data on the development of knowledge in core domains, such as biology. Moreover, it is also well established that very early in life, children distinguish animate and inanimate objects, a central criterion distinguishing natural and artificial kinds.

When it comes to categorizing artificial objects, resort to essential, inner properties as indicators of an object's category membership no longer hold. A coin that is melted down and made into an ice pick no longer remains a coin. Faced with such transformations, young children are unlikely to say that the object retains its identity. Consequently, interest has focused on the criteria that children use to judge whether two artificial objects belong to the same category or not. Some believe that before the age of 3 to 4 years, most children categorize such objects according to a perceptual criterion: How similar do they look (in particular, are they the same shape or the same color)?

According to this view, at about 4 years of age the criterion changes to one of function, which is the criterion ordinarily used by adults, since by definition, an artifact is an object designed to achieve some goal. Under some conditions, American children as young as 2 years have been shown to generalize names learned for one artifact to another of the same function (e.g., two dissimilar looking objects that both functioned as a hinge) (Kemler Nelson et al., 2000); and reasoning based on categories of artifacts continues to develop over childhood and probably beyond (R. Gelman & Lucariello, 2002).

As Keil (2003, p. 369) comments, "most people seem to live in worlds of the artificial," which immediately poses a problem. While people may be able to make inferences about function from observing someone using an artifact and making inferences about their intentions, there appear to be no straightforward, domain-specific core principles that will help them draw proper inferences about the categories of artifacts involved and the functions they fulfill. R. Gelman and Lucariello make this same point using examples such as learning to play chess, "history, algebra, economics, and literature, and so on," that learning in the absence of support from core domains presents considerable challenges:

because there is no domain-relevant skeletal structure to start the learning ball rolling. The relevant mental structures must be acquired *de novo*, which means that learners acquire domain-relevant structures as well as a coherent knowledge base of domain-relevant knowledge about the content of the domain. . . . It is far from easy to assemble truly new conceptual structures and it usually takes a very long time. Something resembling formal instructions is often required and still this is not effective unless there is extended practice and effort on the part of the learner. (2000, p. 399)

Within the framework presented here, as indicated, formal instruction is a subset of the general category of historically evolved cultural practices. Consequently, the constraints that arise from the patterned forms of interaction that structure a great variety of cultural activities may enable concept formation in noncore domains. Unfortunately, to date, relatively little developmental research has been conducted with these issues in mind although some relevant research can be gleaned from what has come to be known as the study of "everyday cognition" (Rogoff & Lave, 1984; Schliemann, Carraher, & Ceci, 1997). The acquisition of concepts involved in learning to weave provide one example.

I have already presented some information about the acquisition of weaving in Zinacantan in considering research that integrates the study of cultural history and ontogenetic development. Here I return to a portion of that research project, headed by Patricia Greenfield, which focuses on contemporary cultural practices involved in weaving. These practices involve artifacts that include the production and dying of thread, the backstrap loom and its constituents (e.g., the warping frame), dowels that hold threads in place, and so on.

Whereas previously I highlighted changing interpersonal interactions in the organization of learning to weave over recent decades and changes in the products of weaving, here the focus changes to the closely related issue of the organization of the artifacts provided children at different ages and the way in which they reveal an implicit, indigenous theory of how to promote knowledge of the functions of the artifacts and skills in their use during ontogeny. What makes this story especially interesting is that the implicit ethnotheory embodied in the artifacts and their deployment is well aligned with a Piagetian stage theory of cognitive development.

Maynard and her colleagues (Maynard, 2002, 2003; Maynard, Greenfield, & Childs, 1999) report that before

they begin to engage in the adult practice of weaving (perhaps at the age of 9 or 10), young girls are provided with simplified weaving tools of two levels of complexity. The simpler of the two is a tool for winding thread that maintains the orientation of the threads that will later be used in weaving the cloth; the more complex tool involves doubling the long (warp) threads around a dowel. This more complex approach requires the weaver to visualize the extended warp (undoubled) rather than simply seeing it. Threads on opposite sides of the dowel will end up at different ends of the loom, and the length of cloth produced is twice the length of the frame.

These researchers argue that the complex warping frame requires the ability to engage in mental transformations while the simplified winding frame does not ("the weaver simply winds the warp from top . . . to bottom of the loom . . . : What you see is what you get."). They note that parents and weaving teachers assign the simpler tool to 3- to 4-year-old children, and the more complex tool to 7- to 8-year-old children, corresponding to the canonical ages for Piagetian preoperational and concrete operational stages.

To test out this correspondence, the researchers compared performance on a task requiring children to match patterns on looms to patterns of cloth and in addition asked them to perform a perceptual matching task based on Piaget and Inhelder's (1956) research on the development of spatial thinking. The task involved six different colored beads strung as a necklace that were laid out as a necklace (requiring only a simple perceptual match), or as a figure eight, such that when the figure eight was unfolded as a circle, two pairs of beads in the middle of the figure were reversed, requiring a mental transformation to arrive at a match between a necklace laid out as a necklace or as a figure eight. These tests were presented to both boys and girls ranging in age from 4 to 13 years in both Zinacantan and Los Angeles.

Among the many interesting results of this study, most germane to this chapter are the following:

- Both Zinacantecan and North American children showed a developmental progression on both tasks that corresponded to expectations from Piagetian theory.
- While the progressions were the same in the two cultural groups, the American children had higher average scores on the bead matching/transformation tasks while the Zinacantecan children outperformed the

American children on weaving tasks. This is the pattern of results that one would expect on the basis of local familiarity.

- Correspondingly, Zinacantecan girls outperformed Zinacantecan boys on the weaving tasks and the Zinacantecan boys, who were at least familiar with the cloth patterns used and had seen weaving occur although they did not participate, outperformed the same-age children in Los Angeles.

Overall, these results fit well with Greenfield's theoretical claim that cultural practices build on species-wide patterns of maturation. They also provide evidence of the way in which cultural practices can provide the necessary constraints on learning in noncore domains.

Culture and the Ontogeny of Autobiographical Memory

Although the topic of cultural influence on the development of remembering has a long history, the kinds of studies carried out at the time of prior reviews, like those on concept development, appear to have gone out of fashion (see Pressley & Hilden, Chapter 12, this *Handbook*, this volume). This earlier research was divided into studies for coherent stories and memory for arbitrary word lists which were then fashionable in experimental psychology.

Those approaches that focused on memory for coherent stories converged on the conclusion, consistent with theoretical claims made by Bartlett (1932) that people would remember parts of the story consistent with important local cultural themes, but inconsistent with Bartlett's idea that nonliterate people would be prone to remember events in a rote, serial order. In addition, cultural variations in overall amount of remembering for coherent stories were found to be minimal or absent. Studies that used lists of words or objects to be remembered often produced wide variations among populations, but when such differences appeared, they seemed to be associated with amount of schooling (for a review, see Cole, 1996, ch. 2). No substantial body of work has followed up on either of these traditions.

Coincident with the decline of interest in story recall and such questions as the influence of literacy on the way people remember arbitrary word lists has been a marked increase in studies that examine cultural in-

fluences on the development of autobiographical memory which is defined as an explicit memory of an event that occurred at a specific time and place in the person's past (Fivush & Haden, 2003; C. A. Nelson & Fivush, 2004).

In addition to there being a relatively substantial amount of research to make it worth reviewing in this venue, other reasons motivate discussion of culture and the development of autobiographical memory. First, people are asked to remember events in their own lives that are likely to be of significance to them rather than verbal or pictorial materials imported by researchers. Second, the topic of autobiographical memory makes theoretical links to the currently fashionable research on comparisons of societies characterized as independent or interdependent. I have chosen not to include this research here because little of it is developmental (see, however, Greenfield et al., Chapter 17, this *Handbook*, Volume 4, for a discussion of independence-interdependence in relation to schooling).

Three additional reasons motivate discussion of research on autobiographical memory in the context of this chapter. First, the onset as well as developmental increases in the quantity and quality of autobiographical memory have repeatedly been linked to ways that adults engage children in talk about the past, in particular past events experienced by the child (and usually, by the parent as well). Second, there have been several studies (unfortunately involving only a few distinctively different cultures) that indicate cultural variations in parental reminiscing practices and onset of autobiographical memories. Third, in contrast with earlier research on culture and memory linked up most distinctively with questions of literacy and schooling, the study of autobiographical memory links up most distinctively with questions of the development of the self and personality, providing a bridge to areas of research on culture and development that ordinarily fall outside the purview of cognitive development (see Shweder et al., Chapter 11 this *Handbook*, Volume 1, for a view of the landscape on the other side of this bridge).

In C. A. Nelson and Fivush's account of the development of autobiographical memory it is assumed that there is a species-general set of basic memory processes for events, people, and objects that are supported by species-general neurocognitive maturation. These basic processes enable the acquisition of understandings of intentionality and of others with regard to the self that

were discussed earlier in terms of core domains. Language is added to these early infantile processes along with the new forms of culturally mediated, social experiences that are required for its emergence and which in turn enable further cognitive development. Especially important in this regard is the emergence of genres of narrative, especially talk about personal episodes that come enmeshed in emotions and the entanglement of each child with those among whom the child develops. C. A. Nelson and Fivush summarize the centrality of narrative to autobiographical memory in these terms:

Narrative adds layers of comprehensibility to events above and beyond what is available from direct experience by linking events together through causal, conditional, and temporal markers. Narratives are structured around meanings, emphasizing goals and plans, motivations and emotions, successful and failed outcomes, and their meaningful relation to the teller as well as to the other players. . . . Perhaps most important, through the use of evaluative devices, narratives provide for the expression of and reflection on personal meaning and significance that in turn allows for a more complex understanding of psychological motivation and causation. (p. 494)

In short, narratives constitute important general-purpose tools for thinking, acting, and feeling in the world.

For purposes of thinking about autobiographical memory and culture, the first central compelling line of evidence is that there are significant individual differences in the ways that U.S. parents organize conversations about the past with their young children and that these differences significantly influence the children's autobiographical memories. In their review of this literature, C. A. Nelson and Fivush differentiate maternal styles of reminiscing about past events in terms of "elaborativeness," by which they mean the frequency and degree of embellishment in their reminiscing conversations with their children. (It is important to note that elaborativeness is not the same as talkativeness: highly elaborate parents may not be talkative in other circumstances.) The major finding of their review, which includes longitudinal as well as cross-sectional evidence, is that greater parental elaborativeness produces better autobiographical remembering (measured by amount and coherence). This effect is found as much as 2 years after a particular reminiscing episode. Over time, the relationship between maternal and child remembering in these episodes shifts as

children begin to contribute as much as what the parents recall in the conversations.

When we turn to research on cultural variation, a number of interesting findings have been reported. As summarized by Leichtman, Wang, and Pillemer (2003), a number of studies have reported cultural variations in the dominant forms of parent-child conversations about the past. These variations occur both in the degree to which parents engage in elaborative conversational patterns and the cultural values that they emphasize. Moreover, for Korean, Chinese, and Indian societies, where the bulk of the cross-cultural research has been carried out, these two aspects of parent-child discourse covary; compared with middle-class Americans, parents in these cultures, where low-elaborative styles dominate, are more likely to emphasize hierarchy, proper social relations, and good behavior. Also, consistent with results concerning the relation between conversational style and autobiographical memory, the earliest memories in the three non-U.S. societies were significantly later than those obtained in U.S. samples. This result was particularly striking in India, where only 12% of rural adults and 30% of urban adults reported *any* specific events about their childhoods and for a subset of those who did report events and the age at which they occurred, the range was between 6 and 11 years of age, far later than is characteristic in U.S. samples.

Researchers engaged in this work have linked such results to the distinction between cultures that privilege an interdependent versus an independent social orientation. The latter encourages a focus on oneself or others in construing one's self in relation to others (Markus & Kitayama, 1991; see also Shweder et al., Chapter 13, this *Handbook*, Volume 1). Without pretending to do justice to this line of theorizing, in the present context the distinction is captured by Mullen and Yi's (1995) idea that in interdependently oriented societies children are taught to see themselves as a collection of roles in a social network, whereas in independent societies children are taught to see themselves as a collection of individual attributes. The elaborative reminiscing style and relative lack of emphasis on social hierarchy with which it is associated thus promote the construction of coherent autobiographical narratives while the nonelaborative style blurs the distinction between self and group, in effect, diminishing the "auto" in the term autobiographical.

Research by Hayne and MacDonald (2003) reveals another cultural factor that influences autobiographical

memory—the extent to which a society values narrative accounts of its own past. These researchers compared the autobiographical memories of Maori and European-descent New Zealanders, as well as the discourse styles of mothers from the two groups when talking with their children about the past.

The first interesting finding was that Maori adult women's earliest memories occurred at just under 3 years of age, while their European-descent counterparts' earliest memories occurred a year later, on average. This difference led the authors to the assumption, based on the work previously cited, that the Maori mothers would use a more elaborative style than European-descent mothers. But they found instead that the European-descent mothers were more likely to use an elaborative style that focused on the larger context of the event and salient details about people and objects present, while the Maori mothers were more likely to focus on a limited aspect of the event and repeatedly ask the same questions about it as if they were trying to elicit a particular response. It thus appears that early autobiographical memory can follow more than one path. These results provide strong support for K. Nelson's (2003b) "functional systems" approach to development "wherein memory is seen not as a singular structure but as a set of functions that employ similar processes to achieve different ends" (p. 14).

CONCLUSION

I believe it is fair to say that never before have the chapters in the *Handbook of Child Psychology* reflected as great an interest in the role of culture and development as do the chapters in the present edition. Not only is the role of culturally organized experience examined in two other chapters that have the word *culture* in the title, but also in chapters that are focused on more or less traditional categories such as concept development and social cognition (and perhaps others to which I have not had advance access).

Most heartening from my perspective is that there seems to be a growing number of scholars who are genuinely rejecting the bedeviling nature-nurture controversy and beginning to treat culture as a phylogenetically evolved property of human beings. To be sure, programmatic statements of such a position have been discernible for many decades. To take two prominent

examples from anthropology and psychology, consider the following:

[M]an's nervous system does not merely enable him to acquire culture, it positively demands that he do so if it is going to function at all. Rather than culture acting only to supplement, develop, and extend organically based capacities logically and genetically prior to it, it would seem to be ingredient to those capacities themselves. A cultureless human being would probably turn out to be not an intrinsically talented, though unfulfilled ape, but a wholly mindless and consequently unworkable monstrosity. (Geertz, 1973, p. 68)

Recall Sir Peter Medewar's *bon mot* about nature and nurture: Each contributes 100% to the variance of the phenotype. Man is not free of *either* his genome *or* his culture. (Bruner, 1986, p. 135)

What has changed since these lines were written is that they have begun to resonate far beyond anthropology. I have already quoted the psychobiologist, Henry Plotkin's remark that there is bidirectional causation between biology and culture. Even more pointed are the assertions of neuroscientists Steven Quartz and Terrence Sejnowski (2002), who write that culture "contains part of the developmental program that works with genes to build the brain that underlies who you are" (p. 58). They emphasize, especially, that the prefrontal cortex, which is the latest brain structure to develop in both phylogeny and ontogeny, and which is central to planning functions and complex social interaction, depends crucially on culture for its development. They refer to the emerging discipline required to bring these ideas to fruition as "cultural biology." As indicated earlier, I arrive at the same perspective from the broad theoretical framework referred to as cultural-historical activity theory, which traces its origins back to Lev Vygotsky and his students.

Whether approaching the task of developing a view of human ontogeny as the emergent process of development resulting from the intertwining of culture and phylogeny, from the perspective of cultural biology, or cultural-historical activity theory, one is driven to take seriously the need to conduct such an inquiry in light of the different "streams of history" or "genetic domains" that have organized this chapter.

To initiate this task, I note the conclusions suggested by my review of the literature on hominization, comparisons of human and nonhuman primates, and cultural

history. Against this backdrop, it should be possible to evaluate the new lines of research on conceptual and memory development reviewed earlier and to suggest other lines of research that appear to hold promise for theoretical progress.

Overall Lessons from Phylogeny and Cultural History Relevant to Human Ontogeny

My reading of the literature on the paleological and primatological branches of human phylogenetic research suggests that each has a special contribution to make in thinking about culture and cognitive development in humans. In the literature on hominization, the features that stand out are the reciprocal relations between anatomical changes, changes in behavior that involve the creation and use of culture, and relations of individual organisms to each other and their environment. In particular, the influence of culture on biological change, seemingly so obscure in the case of modern humans, is particularly clear.

Several points stand out in the research on modern nonhuman primates. First, this work renders it plausible that who-or-whatever the common ancestor of contemporary humans and apes was, there was a small gap indeed between that progenitor and the earliest human beings. Nonetheless, that tiny difference was (to use Bateson's, 1972, phrase) "a difference that made a difference"—it started a complex dialectic of change in which biological, cultural, cognitive, and behavioral changes accumulated to produce *Homo sapiens sapiens* and made development through culture a defining characteristic of the species. Second, current research with nonhuman primates has contributed materially to deeper appreciation of such basic psychological mechanisms as imitation in the process of cognitive development of human beings.

In addition, research on culture understood as group-level social traditions turns attention to new questions about human culture. Now the question becomes: Why did culture appear to accumulate among early hominids and why has it become so central to humans, dominating their worlds, intertwining with their thinking, while it does not appear to do so at all in chimpanzees in the wild (Boesch & Tomasello, 1998)? It appears characteristic of human cultures that, except in unusual circumstances (Tasmania being cut off from Australia and isolated), there is a proclivity for cultural accumulation and increased complexity among human beings, both in the

sphere of tool manufacture and design and the complexity of social practices and institutions. Tomasello (1999) has termed this tendency the “ratchet effect” and has argued that innovation, true imitation (e.g., imitation based on understanding others’ intentions), and perhaps deliberate instruction are essential in this process. But the ratchet effect does not always work and it certainly does not always work rapidly. Boesch and Tomasello (1998) attribute this failure to slippage, but aside from the issue of specifying what makes a cultural ratchet durable or subject to slippage, there seems to be more to the issue of the conditions of (relatively pervasive) cultural evolution among *Homo sapiens sapiens*.

Two factors, often working together, appear essential. One is the use of external symbol-systems and the other is group interaction (both within groups and between groups). Each promotes vertical and horizontal cultural transmission. The case for the centrality of external symbol systems has been made persuasively by Donald (1991) and does not require review here. The Tasmanian case, as well as the flowering of modern *Homo sapiens sapiens*, point to intergroup interaction as an important factor in cumulative human cultural change because the frequent interaction of human groups provides rich opportunities for exogenously introduced innovation, a process that nineteenth- and early twentieth-century anthropologists referred to as diffusion. Such intergroup exchanges were infrequent during the Ice Age that preceded the appearance of modern humans and are infrequent among non-human primates.

Study of the phylogenetic and cultural-historical foundations of contemporary human cognitive abilities requires us to remember the cardinal importance of trying to keep in mind the *scale* of time involved in the processes of organic and cultural change. It is a difficult task. I can write *4 million years*, but I cannot, in any deep sense, comprehend it. Yet the evidence indicates that cultural changes along the hominid line over the past 4 million years have been staggering in their accelerating rate and their transformation of the environment, for better and for worse.

Even in the case of the study of cultural change among anatomically modern humans, the injunction to “study behaviors over time to see how they change” is easier said than done because culture among anatomically modern humans dates back at least 40,000 years and existing cultures characteristic of entire social

groups ordinarily exceed the lifetime of the researcher. These circumstances motivate research on those rare cases where it has proven possible to study changes in human cognition associated with rapid cultural changes occurring during specific historical circumstances.

The research by Beach, Greenfield, Luria, and Saxe provides a much closer look at the dynamics relating individual ontogenetic and microgenetic change to society-level collective cultural-historical change. So long as one studies such processes using tests of presumably general psychological functioning, or relies on the broad historical record, it is difficult if not impossible to gain access to the uneven, historically contingent interplay between microgenetic, ontogenetic, and cultural-historical levels of analysis that seem so central to the process of developmental change. But as soon as one focuses in on specific culturally organized activities and traces the changing location of these activities within the ways of life of which they are a part, processes of change appear to be linked proximally to specific forms of interaction involving people seeking to achieve their goals, or discovering new goals, under specifiable conditions using specifiable combinations of artifacts.

The cultural-historical line of research also highlights the importance of specialized institutions for the propagation of culture. These include modern schools and the specialized cognitive artifacts, written language and notation systems in particular, that mediate activities within those institutions and the society at large.

Cultural Variation in Ontogeny

Serious consideration of culture-cognition relations in phylogeny and cultural history brings us to the study of cognitive development in ontogeny prepared to assume that maturational factors constrained heavily by phylogenetic history will be closely intertwined with cultural factors that are essential in the organization of social life in the society into which each child is born. However, given the relatively short duration of a single life (all the more so, a single childhood) relative to the long duration of a society’s cultural history, let alone the unimaginably long time span of human evolution since the appearance of *Homo sapiens*, there is a strong, and almost irresistible, tendency of psychologists to treat phylogeny as invariant, and hence irrelevant, and to use cross-sectional studies (culturally speaking) of children

growing up in different cultures as a means of understanding culture-ontogeny relationships.

The historical obstacles that cross-cultural research has posed are well summarized in the Laboratory of Comparative Human Cognition (1983) *Handbook* chapter and elsewhere (e.g., Berry, Poortinga, & Pandey, 1997) and entered my earlier discussion of the difficulties of determining the impact of schooling on cognitive development in this chapter, so they need no review here. It is thus interesting that with some exceptions (to be noted), two lines of ontogenetic research reviewed in this chapter—concept development and memory—use methods that minimize those difficulties. With respect to the issue of the role of culture in conceptual developments, the key seems to be that instead of seeking directly to establish category membership or similarity relations by asking people to engage in sorting artificially constructed objects according to pre-set criteria, the experimenter gets at similarity relations by asking people to make inductions using question-asking discourse frames that are reasonable in local terms. Questions aimed at revealing conceptions about the causes of growth such as “Can you keep the frog in its bowl forever?” can pass as natural for young Japanese children who have been given frogs and other creatures to raise. To give another example from the concept formation work, children in all cultures are used to hearing words they do not understand, so when told that a wolf has andro inside and asked if a bird also has andro inside, the question can “pass as reasonable.”

In an analogous manner, questions about memory for early events do not have the odd characteristic of being “known answer questions” that pervades so much of the research on memory development (and schooling). Researchers (and as a rule parents) have no idea what children will claim to be their earliest memories. While not totally immune to misinterpretation owing to features of the local language and culture, this verisimilitude that locates the crucial questions in a familiar cultural context helps establish their cultural-ecological validity. In like manner, the work of Greenfield and Saxe gains plausibility to the extent that they embed procedures in familiar cultural activities, modified only in sufficient degree to isolate crucial comparisons of theoretical interest.

Unsurprisingly, then, it is when experimental procedures have the “feel” of artificiality that controversies arise about the validity of cross-cultural comparisons.

With respect to the data on cultural variations in development of core domains, this is what occurs in efforts to use false-belief tasks where questions of language ordinarily play a large (and, many would argue, a key role) in children’s performance. It is only when the procedure used is reduced to its behavioral core that cultural invariance appears but at the cost of being unable to explore important concomitants of children’s theories of mind, such as the connections between false beliefs and emotions. It appears that decades of effort to satisfy the demands of cross-cultural comparison and ecological validity are beginning to yield some evidence of success.

Less progress has been made, however, in demonstrating the role of culture in forms of cognitive development that are assumed to have a strong biological foundation. The most promising arena for pursuing this kind of research may be with children who experience brain insults early in life and then undergo culturally organized environmental intervention by adults, operating on evidence of the activity-dependent nature of many forms of brain development. Antonio Battro (2000), took advantage of functional magnetic resonance imaging (f-MRI) technologies and computer programs to provide a child who had undergone a right hemisphereectomy at the age of 3 years with dense, culturally organized, experience designed to build compensatory functional brain systems in the remaining cortex. He reports that the child attained a high level of cognitive accomplishment as a result of this “neuroeducation.” In light of our current discussion, he also demonstrated the important role of culturally organized experience on brain development.

Other data combining variations in culturally organized activities that correspond to differences in the brain organization of behavior have been reported for adult abacus experts (Hanakawa et al., 2003; Tanaka, Michimata, Kaminaga, Honda, & Sadato, 2002). In tests of digit memory or mental arithmetic, f-MRI recordings of abacus experts show right hemisphere activation of the parietal area and other structures related to spatial processing. The f-MRI activity in nonexperts engaged in such tasks is in the left hemisphere, including Broca’s area, indicating that they are solving the task by language-mediated, temporally sequential processing. When compared while engaged in verbal tasks, experts and nonexperts display the same forms of left-hemisphere-dominated f-MRI activity.

Although research that traces shifting brain localization of psychological processes is only beginning, existing cases nicely illustrate the ways in which cultural artifacts, incorporated into cultural practices, react back on the human brain so that nurture becomes nature.

In sum, a perspective on culture and cognitive development that takes seriously the simultaneous relevance of phylogenetic history, cultural history, and culturally organized activity during ontogeny promises to bring culture into the mainstream of developmental research without forcing us once again into the untenable bifurcation of nature and nurture. Our way of nurturing is our nature. The sooner we embrace this reality and begin to use it to organize our environments and ourselves, the brighter the future of human development.

Ontology	703
Causation	705
Nonobvious Properties	706
Summary	708

Concepts organize experience. When an infant smiles at a human face, a 2-year-old points to the family pet and says “Doggie!”, a 10-year-old plays a card game, or a scientist identifies a fossil, each is making use of concepts. One of the hallmarks of human cognition is that we organize experience flexibly, at many levels of abstraction, in many competing ways, identifying and reasoning about categories, individuals, properties, and relations. Therefore, the study of concepts is untidy, crosscutting many traditional subfields of psychology.

In this chapter, we take a broad view of concepts. Many theorists equate concepts and categories: Concepts are the mental representations that correspond to

Preparation of this chapter was supported by NICHD grant RO1 HD36043 from NICHD to the first author. We thank Sandra Waxman for helpful discussions and Deanna Kuhn for detailed comments on an earlier draft.

categories of things in the world (Margolis, 1994; Oakes & Rakison, 2003; Smith, 1989). Examples include *dog*, *toy*, or *physical object*. We agree that categories are fundamental and one of the most important and well-studied conceptual structures. Nonetheless, they are not the only kind of concept available to adults or children. Concepts also include properties (*red*, *happy*), events or states (*running*, *being*), individuals (*Mama*, *Fido*), and abstract ideas (*time*, *fairness*). Concepts are generally understood to be the building blocks of ideas. To form the thought, “Fido is a happy dog,” a child must possess the constituent concepts. At the same time, concepts are embedded in larger knowledge structures, and so cannot be understood wholly as isolated components. One of the goals of this chapter is to provide a framework for thinking about the full range of concepts available, what is currently known about their early emergence and development, and questions that remain for the future.

BACKGROUND AND OVERVIEW

Although human concepts deeply reflect our experiences of structure in the world, concepts do not reduce fully to world structure. Certainly there is structure to the world, and there are important perceptual clues that correlate with concepts. Rosch (1978) showed that object categories capture feature clusters; for example, the distinction between birds and mammals is over-determined: Birds (generally) have wings, feathers, claws, and beaks, whereas mammals (generally) have legs, fur, toes/hooves, and mouths. Studying how concepts relate to structure present in the world is a critically important topic. It would be a mistake, however, to equate concepts with experience. Instead, concepts are *interpretations* of experience. Piaget illustrated this vividly by showing us how different interpretations of even mundane experiences are possible: What we identify as the same object over time could instead be construed as a series of distinct objects; what we view as unthinking and inert (such as a stone) could instead be construed as living and feeling.

A related point is that concept learning includes a crucial inductive component. A concept extends beyond an instance presented at a given point in time and includes other instances (in the case of categories) or other manifestations over time (in the case of individuals). One of the inductive problems children face is how to extend a concept to novel instances (e.g., if I tell you that this is a hamster, how do you decide what other instances are also hamsters?). Another inductive problem that children face is figuring out when to use concepts. If a child sees her pet hamster eating a lettuce leaf, this observation becomes a conceptual problem: Is this an idiosyncratic event, or an event that can be applied to future instances? If the latter, has she learned something about her hamster, about hamsters in general, or about animals in general? Thus, another theme of the chapter will be that concepts entail active inductive processes and that human heuristics, predispositions, frameworks, and biases influence the form of concepts that children develop.

Why Conceptual Development Is Important

Concepts play an important role in children's cognition. Children's memory, reasoning, problem solving, and word-learning all powerfully reflect their concepts (Bruner, Olver, & Greenfield, 1966; Rakison & Oakes,

2003). As numerous scholars have noted, concepts serve at least two critical functions: They are an efficient means of representing and storing experience (obviating the need to track each and every individual interaction or encounter), and they encourage people to extend knowledge and learn about the world by means of inductive inferences (e.g., Smith, 1989). By studying concepts, we learn about the representation of experience and about reasoning by induction.

Studies of conceptual development are also important for providing a detailed portrait of children's knowledge and beliefs about the world. Certain concepts are themselves basic and far-reaching in their consequences. Consider the concept of animacy (Gelman & Opfer, 2002). The distinction between animate and inanimate arises early in infancy (Rakison & Poulin-Dubois, 2001), appears to have neurophysiological correlates (Caramazza & Shelton, 1998), is cross-culturally uniform (Atran, 1999), and is central to a broad array of more complex understandings, including causal interpretations of action (Spelke, Phillips, & Woodward, 1995), attributions of mental states (Baron-Cohen, 1995), and attributions of biological processes (Carey, 1985). Indeed, a creature that was incapable of distinguishing animate from inanimate would be severely impaired. Oliver Sacks (1985) describes a real-life example of a man who could not identify things as animate or inanimate on the basis of visual perception, thus, for example, mistaking his wife for a hat (and attempting to place her head on his own).

Equally important, the study of concepts allows one to examine issues at the heart of the study of cognitive development: Are there innate concepts? Are cognitive systems modular? Can complex concepts emerge out of perceptually based associative learning mechanisms? How domain-general versus domain-specific is human cognition? Does children's thinking undergo qualitative reorganizations with age? These questions are not unique to the study of conceptual development, but studying conceptual development can provide unique insights into these questions.

Finally, understanding children's concepts has implications for many other developmental issues, both basic and applied. Three examples provide a flavor. First, children's stereotyping of social categories (such as caste, gender, or race) is rooted in children's concepts, and undergoes predictable developmental patterns as a function of developmental changes in children's concepts (Hirschfeld, 1996; Maccoby, 1998; Martin & Ruble,

2004). A second example, in the area of motivation and school achievement, concerns children's concepts of intelligence. Children who view intelligence as fixed and unchanging treat corrective feedback as evidence of failure, and lose motivation in the face of it. In contrast, children who view intelligence as flexible and changing treat feedback as information about where they can direct their efforts, and work harder in the face of it (Dweck, 1999). There appear to be cultural differences in the models of intelligence that are most endorsed, with more fixed, essentialist views in the United States, and more flexible, effort-based views in China and Japan (Stevenson & Stigler, 1992). As a third example, in the field of education, it is now generally recognized that providing children with appropriate instruction requires first understanding their conceptual errors, in order to revise misconceptions rather than superimpose new ways of understanding on these misconceptions (Carey, 1986). The need to do so becomes evident when trying to teach children (and adults!) evolutionary theory. Children first need to *unlearn* that categories are stable, unchanging, and fixed, before they can fully grasp that species can evolve (Evans, 2000; Mayr, 1991; Slotta, Chi, & Joram, 1995).

Historical Background

As with so much of cognitive development, Piaget's work on concepts provides a useful initial framework (Inhelder & Piaget, 1964). In his view, concepts can be considered from two perspectives, either as logical structures or as components of a larger knowledge system. The first perspective focuses on form; the second focuses on content. In considering *logical structures*, Piaget assumed a strict and idealized characterization of what constitutes a true concept. In his view, defining features determine membership in a category. Thus, the intension of a concept (the rules or definition for inclusion) determines the extension of a concept (which things are classified into the category). When sorting geometric shapes, an adult may decide to put all the round shapes in one set, all the square shapes in another set, and so on. These "definitions" (round, square, etc.) determine the groupings. In contrast, a 3-year-old may switch rules repeatedly over time, first noting shape similarity, then noting color, then the holistic pattern obtained by spatial alignment of two shapes, and so on. Because young children do not successfully coordinate intension and extension, they are

said not to form true concepts. Piaget (1970) instead proposed a series of qualitative reorganizations that constituted progressive developmental stages. This characterization has been challenged (see, e.g., R. Gelman & Baillargeon, 1983), although the question of what form concepts take (their logical structure) is an enduring and fundamental one.

As part of larger knowledge systems, concepts reflect children's knowledge and understanding of the world (Piaget, 1929). Piaget's work in this area embodies a tension between focusing on general principles that govern the nature of children's concepts, and in-depth studies of children's knowledge and belief systems. For years, researchers avoided studying conceptual systems in detail; these were viewed as contingent, accumulations of facts, not revealing of deeper developmental principles. Why bother to learn what children know about any particular topic, if that knowledge is one tiny portion of the encyclopedic knowledge they are eventually to gain, and if gaining that knowledge is contingent on particular, idiosyncratic experiences? The answer, as we will see, is that knowledge about particular domains may turn out to be foundational, both in the sense of forming a basis for further knowledge, and in the sense of being robust across varying cultural contexts.

A tension between a focus on form versus content continues to the present day. The adult concept acquisition literature has long been an important source of theory and motivation for work with children, and has often focused on conceptual form. For example, prototypes, scripts, hierarchical classification, and exemplar models are all fruitful examples of how research with adults inspired and informed work with children (Eimas & Quinn, 1994; Johnson, Scott, & Mervis, 1997; Mandler & McDonough, 2000; Markman, 1989). Notably, this work tends to focus on form to the exclusion of content.

In the past, research on adult concepts often served as a contrast to developmental studies: Whatever it was that adults have, children were thought not to have. Thus, a whole host of developmental dichotomies were proposed: Children are perceptual, adults are conceptual; children are thematic, adults are taxonomic; children are concrete, adults are abstract (see Bruner et al., 1966; Inhelder & Piaget, 1964; Vygotsky, 1934/1962; Werner & Kaplan, 1963). These concepts acknowledged content in broad strokes only. As reviewed in detail later in this chapter, these contrasts are too simple, at least by the time children reach preschool age (i.e., by

2.5 years), if not earlier (Mandler, 2004). Preschool children consider an impressive range of cues, features, and conceptual structures. To characterize young children as perceptual would ignore their capacity to reason about intentions, number, and causation (R. Gelman & Williams, 1998). To characterize them as thematic would disregard the ease with which children extend novel words on the basis of shared features (Balaban & Waxman, 1997; Blanchet, Dunham, & Dunham, 2001; Waxman & Namy, 1997)—as well as the frequency with which adults rely on thematic relations (Lin & Murphy, 2001). To characterize children as concrete would overlook their capacity to talk and reason about abstract kinds of things (S. A. Gelman, 2003; Prasada, 2000; see also Uttal, Liu, & DeLoache, 1999, for evidence that concrete representations can at times limit—rather than scaffold—children's understanding of abstract concepts).

More recently, there has been a renewed focus on conceptual content in children and adults, with more reciprocal links between adult and child studies. There is much evidence that for both adults and children, concepts are influenced by knowledge-rich naive theories and explanatory models and cannot be characterized by form or structure alone (Keil, 1989; see Murphy, 2002, for review; Murphy & Medin, 1985; Rips & Collins, 1993). The past 30 years of research in developmental psychology have revealed surprisingly sophisticated domain-specific competencies in infancy and early childhood, in reasoning about physical objects, mental states, and biological processes (Wellman & S. A. Gelman, 1998). Young infants seem to have well-formed and fairly elaborate conceptual systems. In contrast to the blooming, buzzing confusion William James hypothesized in infancy, the world of the infant seems remarkably similar to that of adults.

Likewise, preschool children learn words with impressive speed. The oft-cited statistic, initially noted by Carey (1978), is that children between 18 months and 6 years of age learn on average one new word every waking hour. This accomplishment is particularly impressive given the well-known inductive problem children face: meanings are not simply sitting out there but rather need to be inferred from a complex set of cues (Quine, 1960; Waxman & Lidz, Chapter 7, this *Handbook*, this volume; Woodward & Markman, 1998). Bloom (2000) notes that this rate of word learning is not special to the preschool period, but is ever increasing (up to about

40,000 words by age 10), until at some point in adolescence, it reaches a plateau. This stunning achievement alone implies a wealth of corresponding concepts.

Conceptual development during childhood is profound. The course of concept acquisition is not random or piecemeal; the premise of conceptual development is that there are important regularities. Historically, researchers have focused on *formal* changes over development, such that children's concepts may differ from adults' in structural ways (e.g., from global to analytic, from thematic to taxonomic). Although this perspective continues to guide research, a considerable body of work now focuses on the *content* of children's concepts. One reason is that formal models of adult concepts have not fared as well as initially hoped (Carey, 1982; Murphy, 2002; Rosch, 1978). A second reason is that conceptual content appears to affect the acquisition of new concepts, so that what people know affects what they can learn. This perspective is most clearly articulated in theory-based accounts of concepts (Carey, 1985; Keil, 1989; Murphy & Medin, 1985). Much of conceptual development may be due not to structural changes in the nature of concepts but to the network of existing beliefs within which new concepts must fit (Carey, 1985).

Current Approaches to Children's Concepts

There are three broad theoretical approaches to understanding concept acquisition, dating back to long-standing philosophical debates: nativist, empiricist, and naive theory approaches.

Nativist Approaches

Nativist approaches come in all shapes and sizes. Indeed, there are as many nativist approaches as there are developmental approaches, for the simple reason that any theory of development assumes *some* innate capacities (Wanner & Gleitman, 1983). Even under the most domain-general and empiricist of approaches, children must have innate capacities (e.g., representational abilities, associational capacities). The questions that are under debate are how richly specified and detailed these innate capacities are, the variability of the resulting concepts across backgrounds and contexts, and the degree to which these capacities are open to modification from the environment. Accounts range from innate attentional biases due to perceptual limits in the infant (Mandler, 2004), to the possibility of innate concepts of

cause, animate, and so on. (Spelke, 1994), to the extreme claim that all lexicalized concepts are innate (including *dog, cup, car*; Fodor, 1981). As Bates (1999) put it, with a focus on language development:

The debate today . . . is not about nature versus nurture, but about the “nature of nature,” that is, whether language is something that we do with an inborn language device, or whether it is the product of (innate) abilities that are not specific to language.

The same could be said of conceptual development: Are there innate concepts of a particular content or type (e.g., innate concepts of “animacy”), or rather more general innate capacities that can give rise to concepts?

Modular theories posit strong, innately specified, domain-specific constraints on conceptual acquisition and change. One of the most well-worked-out arguments for modularity comes from the domain of language, specifically, syntax:

Evidence for the status of syntax as a module was its innate, biologically driven character—evident in all and only humans; its neurological localization and breakdown—the selective impairment of syntactic competence in some forms of brain damage; its rapid acquisition in the face of meager developmental data—syntactic categories of great abstraction, such as verb or subject, are easily acquired by small children faced with impoverished input; and the presence of critical periods and maturational timetables. (Pinker, 1994; Wellman & Gelman, 1998, p. 527)

Although it is widely accepted that human vision is modular (Marr, 1982), and often accepted that modularity aptly characterizes language (but see Tomasello, Chapter 6, this *Handbook*, this volume, for a critique of this view), more debatable is the suggestion that higher-level cognitive processes can be captured in this way (e.g., Elman et al., 1996). Evolutionary psychologists propose that an array of cognitive capacities is modularized, including reasoning about biological taxonomies, mate selection, and social exchange (Cosmides & Tooby, 2002; Pinker, 1994). They characterize cognitive modules as innately specified, and as impervious to revision. Thus, modules (in this view) are mandatory in their processing of environmental inputs: Experience provides inputs, and these inputs are represented in a mandatory, nonrevisable manner.

However, modularity is only one extreme in a continuum of innate structures. Innate conceptual structure may also be characterized as a set of skeletal principles (R. Gelman & Williams, 1998) or biases that provide initial conditions for conceptual development but may be modified, and even superseded, during development (Gopnik, Meltzoff, & Kuhl, 1999). Skeletal principles would be compatible with both associationist and theory-based accounts of conceptual development. R. Gelman (2002) proposes a “rationalist-constructivist” approach, in which innate skeletal principles get elaborated with experience and development.

Empiricist Approaches

According to empiricism, knowledge derives from our senses. Concepts are therefore either direct representations of perceptual/sensory experience, or combinations of such experiences. The two-pronged argument against nativism is that conceptual structure may be derived from input via basic learning mechanisms and that experiential variation produces substantive conceptual variability. Theories of similarity provide formal accounts of concept representation and acquisition (see Hahn & Ramscar, 2001; Rakison & Oakes, 2003). The central focus of this work is on processes of comparison, association, and composition. How does the learner combine diverse experiences to arrive at a summary representation of a concept? The processes involved tend to be general ones; it is the structural relations that matter, not the content, domain, or specific features. Several researchers have argued that children’s conceptual development is largely based on processes of similarity (Jones & L. B. Smith, 2002; Sloutsky, 2003). The challenge for empiricist accounts of development is to explain how the rich and complex set of adult concepts is produced by the operation of basic learning mechanisms over a reduced set of initial representations.

How might this work in development? L. B. Smith, Jones, and Landau (1996) suggest that a child could learn the distinction between count and mass nouns by noting that count nouns are uttered in the presence of consistent shapes (e.g., “This is *a book*” in the presence of rectangular solids; “This is *a banana*” in the presence of crescents), whereas mass nouns are uttered in the presence of consistent colors and textures (e.g., “This is *some rice*” in the presence of white, sticky stuff; “This is *some sand*” in the presence of tan, granular stuff). By tracking the empirical regularities of linguistic form

and perceptual cues, children learn familiar words and build up expectations about novel words.

Empiricist approaches have had a resurgence in recent years, in part because it has been demonstrated that infants can track low-level statistical cues with much greater accuracy than had been thought (Baldwin, Baird, & Saylor, 2001; Saffran, Aslin, & Newport, 1996), and in part because new empiricist models provide a more detailed and realistic appreciation of children's concepts (Sloutsky & Fisher, 2004; Yoshida & Smith, 2003). Empiricism faces the following major issues: How much can it account for, and (relatedly) how great a challenge or contrast does it provide to other approaches, such as the naive theory approach? We return to empiricism later in the chapter, when we consider mechanisms of conceptual acquisition and change.

Naive Theory Approaches

Naive theory approaches come in a wide variety, but all assume that children construct something like naive or commonsense theories in which concepts are embedded. The shared commitment is to some inferential processes of conceptual development. Roughly, concepts are acquired based on their meaningful relations with existing concepts and beliefs. In most cases, these inferential processes are seen as supplements to either nativist or associationist mechanisms, or both. Theory-based views are compatible with some amount of innate structure. The claim, however, is that innate structure is supplemented and revised in the face of evidence and attempts to explain and make predictions. Nature may provide initial conditions or general constraints, but there is room for substantial conceptual development and change (R. Gelman, 2002). Theory-based views also admit processes of association-based learning (S. A. Gelman & Medin, 1993; Keil, Smith, Simons, & Levin, 1998). Intuitive theories connect with data. People experience surprising outcomes, notice new connections, and realize failures of predictions. Associations are therefore important data for building theories.

Theory-based views are often taken as committed to the position that children are little scientists (or scientists are big children, Gopnik et al., 1999). Different strands of theory-based approaches take this connection more or less literally, though all acknowledge important differences between scientists and children in the *process* of constructing theories (see Gopnik & Wellman,

1994). The basic point may be that just as scientists have means of forming new concepts that go beyond maturation and association learning, so, too, do laypeople—including children. A way of posing the central research question for theory-based approaches is to ask whether the kinds of thinking demonstrated by scientists and other experts are unprecedented in everyday experience, or whether such "advanced" forms of thinking are somewhat continuous with basic processes of conceptual development. Research in the field often takes the form of demonstrating that associationist or maturational processes are not sufficient to account for some aspect of cognitive development, and thus theory-building must be admitted.

One way to characterize theory approaches is to review briefly relevant findings in the adult concept literature. How adults incorporate different features into their category judgments varies, depending on their theories about the domain (Wisniewski, 1995; Wisniewski & Medin, 1994). The probability of accepting novel instances as category members is also dependent on theoretical beliefs rather than statistical correlations alone (Medin & Shoben, 1988). Thus, in some cases a property equally true of two different concepts is more central to one than the other (e.g., the property *curved* is more central to boomerangs than to bananas, even though in all our prior experience, curved applies equally often to both concepts). There is also evidence that adults' ability to categorize successfully is intimately tied to the kinds of explanations they can generate. Murphy and his colleagues have designed experiments in which subjects form their own concepts of unfamiliar items (such as underwater dwelling or floating house) and have varied only whether the features of the items could be potentially linked by an explanatory scheme. In their results, categories that included features that were related and linked to a theme were learned much faster than those with unrelated features (Murphy & Allopenna, 1994). In general, people appear to benefit by their ability to form concepts in which features are linked in sensible causal frameworks.

A further crucial aspect of the theory approach is the assumption that conceptual change entails more-or-less radical reorganizations. The model for conceptual change is theory change in science (Smith, Carey, & Wiser, 1985). Just as science undergoes revolutions that introduce new concepts and mental organizations, so too, do children during normal development. The claim

is that initial structures can be modified; they provide a starting point for conceptual development but not absolute limits.

The theory view does not *replace* approaches that argue people attend to online, at-hand statistical information: collation of features, salience, similarity, prototypes, exemplars, and the like; instead, it argues for their insufficiency. Prototypes are accurate descriptions of the information people use to identify category instances on many tasks (E. Smith & Medin, 1981). A wealth of evidence demonstrates that people classify robins (prototypical bird) more rapidly than penguins (atypical bird), which typicality influences the kinds of sentences people generate, and so on (Rosch, 1978). Importantly, however, prototype accounts do not provide the full story. Is a penguin any less a bird than a robin? Some researchers have argued it is not—that typicality and category membership are independent judgments that can be dissociated (Diesendruck & S. A. Gelman, 1999; Kalish, 1995; Rips & Collins, 1993). Later in this chapter, we will return to the theme that concepts are hybrids, incorporating both theory and similarity (Keil et al., 1998; Murphy, 2002).

Approach in This Chapter

In this chapter, we assume a naive theory approach, as we find that it best accounts for the widest range of evidence. However, ideas from both nativist and empiricist traditions continue to have important influences. The mapping between approaches and mechanisms is neither simple nor clear-cut. The theory approach assumes some innate starting-points (Carey & Spelke, 1994) as well as the importance of associative mechanisms. Likewise, some (though not all) who espouse an empiricist or associationist approach recognize the need for innate constraints to get the system off the ground (Rakison, 2003a). And anyone who posits innate mechanisms also acknowledges the need for appropriate environmental input and support, as well as the mechanisms to enable environmental learning (Chomsky, 1975). We find most merit in a framework that assumes some role for each of these approaches. Specifically, the theory approach, which we endorse, assumes (a) some important innate frameworks to give children a conceptual grounding, (b) sophisticated associationist and statistical learning procedures to acquire new information and detect regularities in the environment, and (c) theory-building impulses and ca-

pacities, to enable fundamental reorganizations of the input over developmental time.

Organization of This Chapter

The remainder of this chapter is organized around three central themes: *conceptual diversity*, *concepts embedded in theories*, and *mechanisms of conceptual acquisition and change*. First, we discuss the case for conceptual diversity, and its importance to understanding the vast literature on children's concepts. Concepts are not all alike, and concept learning is not a single, unitary process. Serious attention to conceptual variation promises to shed light on developmental regularities. Conversely, focusing on only one sort of concept can lead to a skewed portrait of what concept learning entails and what children bring to the task. Second, we make the case that at least by the time children are able to speak, a good portion of their concepts are embedded in theories. Third, we consider possible mechanisms of conceptual acquisition and change. Following consideration of these three major themes, we raise questions that to date have received rather less attention, though the questions are important and deserving of more focused research. In a section titled "Experience and Individual Variation," we consider variation due to individual differences and expertise, as well as the nature of the input children receive.

Any treatment of concepts must be selective. This chapter includes relatively little about concepts of mind, space, or number. These concepts are of fundamental importance in any consideration of children's thought, but they receive fuller treatment elsewhere in this *Handbook*. We also do not attempt to review the vast literature on concepts in infancy (see Cohen & Cashon, Chapter 5, this *Handbook*, this volume), although selected examples from the infancy literature are included, as relevant.

CONCEPTUAL DIVERSITY

What is involved in learning a concept? This question is difficult to answer in part because not all concepts are alike. How college students acquire a concept of "red triangles" in a classic verbal learning experiment of the 1950s would appear to differ in important ways from how infants acquire a concept of animacy. Although

there are innumerable ways to divide up concepts, many of them are doubtless irrelevant to processes of acquisition (e.g., the concepts “cat” and “dog” differ from each other but are learned in much the same way). In this section, we lay out some of the distinctions that are likely to have broad theoretical significance.

At minimum, the concepts children learn in the first few years of life include (but are not limited to):

- Concepts corresponding to words, including not just concrete nouns (dog, cookie, girl) but also mass nouns (water, sand), abstract nouns (furniture, toys), collective nouns (family, army), verbs (jump, think), adjectives (purple, good, little, happy, unfair, alive), and a range of other word types (three, in, because, all, mine)
- Concepts reflected in grammatical usage (e.g., singular versus plural; gender); “covert categories” (Whorf, 1956)
- Ontological distinctions that may or may not be encoded in language but lead to important predictions (e.g., animate versus inanimate entities)
- Concepts for individuals (including significant people or animals, as well as individual objects such as a favorite blanket or even a particular piece of candy)
- Systems for organizing concepts with respect to one another (e.g., hierarchies; scripts)

Concepts vary from one another in content (e.g., natural kinds versus artifacts; individuals versus kind), process (e.g., learned explicitly in school versus implicitly in ordinary interactions versus learned by overhearing), structure (e.g., basic versus superordinate level), and function (e.g., used for quick identification versus used for making inductive inferences). Strikingly, there are studies of each of these kinds of concepts in the cognitive development literature, often reaching different conclusions about children’s skills and abilities.

We review this conceptual variety by considering several key contrasts among concepts. Our criteria for including a contrast are that it has far-reaching implications for how children reason and that there are relevant developmental data. Specifically, we consider concepts encoded in language versus those that are not encoded in language; object concepts versus relational concepts; concepts at different levels of abstraction; and natural kinds versus arbitrary groupings. In no case are we proposing developmental dichotomies (e.g., children can’t do X but they can do Y). Rather, children have access to

multiple sorts of concepts, but the nature of the concept influences processing. There are many other important distinctions in the literature that we do not cover because of space limitations (e.g., scientific versus spontaneous concepts, Vygotsky, 1934/1962; object versus relational concepts, Bornstein et al., 2004, Gentner, 1982; Tardif, 1996; classes versus collections, Markman, 1989).

Concepts Encoded in Language versus Those That Are Not

Many concepts correspond to a word in a language (e.g., *shoes*), whereas others do not (e.g., objects that begin with the letter *s*). The former are also called “lexicalized” concepts. Generally, we can assume that lexicalized concepts have some importance to speakers of the language: They are shared by a community, remembered over time, and passed down from one generation to the next. They are not simply a passing fancy in the mind of a specific individual. However, the converse is not true; important concepts are not necessarily lexicalized. For example, the concept *living thing* is rarely lexicalized across the world’s languages (Waxman, in press).

There has been an upswing in research on the role of language in conceptual development (e.g., Bowerman & Levinson, 2001; Gentner & Goldin-Meadow, 2003). A classic question is how language changes or influences the nature of a concept. Piaget’s proposal that language is simply a vehicle for thought is no longer tenable. Nor do concepts require a conventional language system: Witness the impressive conceptual abilities of preverbal infants, nonhuman primates, and deaf children with no language input (Cohen & Cashon, Chapter 5, this *Handbook*, this volume; Goldin-Meadow, 2003; Tomasello, 1999).

Rather, we must ask, What is the nature of the relation between words and concepts, and how are they coordinated in development? The question is particularly important from a developmental perspective, as language is an important means of expressing concepts.

The finding that speakers of different languages possess different concepts, particularly early in development, provides important evidence on this question. One example comes from the spatial domain. Whereas English distinguishes containment (*in*) versus support (*on*) relations, Korean distinguishes loose-fitting containment (*nehta*) versus tight-fitting containment (*kkita*). The relevant developmental evidence is that children, from their

earliest word productions, use spatial language in a manner that conforms to the system presented by their language (Bowerman & Choi, 2003). Thus, English-speaking children and Korean-speaking children use spatial terms in cross-cutting ways, thereby apparently demonstrating contrasting conceptual frameworks.

A question raised by this work is whether the speakers of the two languages have acquired only the language-relevant system (i.e., support for language influencing initial concepts), or instead whether they have access to a wider range of spatial relations, including those of the other language, but choose to use only the conventional ones when talking because language is a conventional system. The latter is a weaker claim, according to which language influences "thinking for speaking" (Slobin, 1996). Recent work with adults provides more support for the first interpretation. When English-speaking adults are given a task that requires them to group spatial relations in the Korean way (i.e., loose- versus tight-fitting), they have great difficulty (McDonough, Choi, & Mandler, 2003). Interestingly, 5-month-old infants exposed to English were able to categorize both contrasts (Hespos & Spelke, 2004). It appears that children are initially open to a wider range of conceptual possibilities that become narrowed as a function of language experience (see Werker & Desjardins, 1995, for an analogous finding in speech perception).

In any case, these data suggest that concepts that were once thought to be innate (e.g., in, on) turn out to be language-specific, thereby arguing against there being a small set of universal primitives—at least in this domain. And children from their earliest word-learning acquire the spatial concepts provided by their language, not the spatial concepts provided by some universal conceptual set.

Relatedly, speakers of different languages seem to notice different aspects of experience, and to draw conceptual boundaries differently from one another. Lucy (1996; Lucy & Gaskins, 2003) studied speakers of Yucatec Mayan, who use a classifier system such that different-shaped things can receive the same name but with a different classifier attached. In Yucatec, the word for banana, banana leaf, and banana tree are all the same root word, varying only in the classifier. This pattern contrasts with the English system of naming, for which shape is a fairly good predictor of how a count noun is used (e.g., bananas are all crescent-shaped; trees are all roughly a certain shape). Correspondingly, when asked

to group objects on the basis of either shape or substance in a nonlinguistic sorting task, English speakers are more likely to use shape, whereas Yucatec Mayan speakers are more likely to use substance. Surprisingly, however, this differentiation does not appear until somewhere between 7 and 9 years of age, suggesting that perhaps metalinguistic awareness of the language pattern is required for the effect.

Other examples of language influences on children's concepts can be found in the work of Imai and Gentner (1997) and Yoshida and Smith (2003), both of whom find that Japanese-speaking children draw the boundary between objects and substances differently than do English-speaking children. Whereas both English and Japanese speaking children agree that a complex object (such as a clock) is an individual and a continuous boundless mass (such as milk) is a substance, they differ when it comes to simple objects. A molded piece of plastic, for example, would be an object for the English speaker but a substance for the Japanese speaker. These findings do not suggest radically different ontologies for speakers of English and Japanese, but rather subtle effects at the margins.

A difficult question remains: Can language effect change or just direct attention? For example, can language create concepts that weren't there to begin with? Or does language serve to draw attention and highlight available concepts? Boroditsky (2001) shows that, for adults, time concepts in Chinese are conceptualized differently than time concepts in English, in ways that can be traced to differences in how English and Chinese speakers *talk* about time (either horizontally or vertically, respectively). However, she also finds that these differences can be readily reversed with a simple priming task, thus suggesting that the language effects are not deeply entrenched.

The difficulty in determining the effects of language can be seen by considering the effects of labeling on inductive inferences. Some have proposed that hearing the word *bird* for a wide variety of dissimilar birds (hummingbirds, eagles, ostriches) signals to the child that something other than surface similarity must bind these instances together (Hallett, 1991; Mayr, 1991). In this view, labels have a powerful causal force in directing children to look for underlying similarities that category members share. Consistent with this view, experimental work with children demonstrates that they draw more inferences to items that share a label than to instances that do not (S. A. Gelman & Markman, 1986; Welder &

Graham, 2001) and more generally respond differently to items that are labeled than to items that are not (Markman & Hutchinson, 1984; Waxman & Markow, 1995; Xu, 1999). Moreover, hearing a label for a concept provokes a more stable, immutable construal (e.g., a person who is “a carrot-eater” is assumed to eat carrots more consistently and persistently than someone who “eats carrots whenever she can”; S. A. Gelman & Heyman, 1999).

However, these findings do not unambiguously locate the source of the labeling effect. Is the relevant factor the label *per se*, or does the label work as a cue because it activates other assumptions, such as essentialism? We would argue the latter (see S. A. Gelman, 2003, for more extended discussion). A problem with assigning too central a role to language is that not all names promote inductive inferences. Children learn homonyms (Lily as a name versus lily as a flower), adjectives (sleepy), and nonkind nouns (passenger; pet), and these words do not seem to work in the same way as category labels such as bird or carrot-eater. When learning novel words, children do not automatically assume that the words promote inferences, if perceptual cues compete (Davidson & Gelman, 1990). A striking example of children’s willingness to interpret a word for two dissimilar things as homonyms came from a 3-year-old who remarked: “Isn’t it funny—‘chicken’ sounds just like ‘chicken’”—not realizing that the bird and the food were indeed manifestations of the same kind. The point here is that sameness of label did not by itself command the inference that the instances shared deeper commonalities.

These examples suggest that language may provide important cues to children regarding their concepts, without necessarily being the mechanism by which concepts first emerge. If sameness of label is to convey underlying sameness, children must first have the capacity to understand that appearances can be deceiving. Armed with such an understanding, naming practices could provide important information to children about the structure of concepts. However, that initial understanding must already be in place for children to benefit from labeling.

Despite this caveat, there is reason to suspect that language may play a broader role in conceptual change. Spelke (2003) argues that language may provide a mechanism for acquiring concepts that go beyond those innately specified. She notes that innate concepts in humans are highly similar to and overlap with innate concepts in other species: object constancy, number

tracking, and so on. What seems to distinguish humans from nonhuman species is the ease with which we combine concepts across domains. In navigating space, we can combine geometric concepts (e.g., “to the left”) with nongeometric concepts (e.g., “blue”) to arrive at novel combinations (“to the left of the blue wall”). Strikingly, preverbal infants and nonhuman animals seem to lack the ability to construct such cross-domain concepts. When faced with a task that requires this sort of conceptual combination, only language-using humans can solve it. In further studies, Spelke has found that manipulating the use of language (either training children on a new linguistic expression or preventing internal or external use of language in adults) directly affects a person’s capacity to use these combinations. She uses this same model to explain conceptual change in the realm of number. Language provides only a limited degree of flexibility, however, as the constituent concepts of a linguistically mediated combination must be initially established within an innate module.

Levels of Categorization

Object concepts are universally organized into hierarchical systems of classification possessing 3 to 5 levels, in which an intermediate, “basic” level of abstraction is most commonly used by adults (Rosch, 1978). One of the most robust and well-studied findings regarding concepts in the 1970s and 1980s concerned the differences in processing and development of different levels of abstraction for concepts in a hierarchy. Concepts at a basic level of generality are learned first (Mervis & Crisafi, 1982). Children acquire the label *dog* before *collie* or *animal*. It is probably not coincidental that parents tend to label objects at the basic level (Shipley, Kuhn, & Madden, 1983). It is at the basic-level that children prefer to categorize and extend novel labels (Golinkoff, Shuff-Bailey, Olguin, & Ruan, 1995; Waxman, Lynch, Carsey, & Baer, 1997). Shown a picture of a collie and told it is a *dax*, children assume other dogs are daxes, rather than extending the label to all animals, or restricting it to only collies.

Children do acquire concepts at superordinate and subordinate levels, but such concepts may require special learning conditions (but see Callanan, 1989; Tenenbaum & Xu, 2000). Exposure to multiple distinct instances supports acquisition of superordinates (hearing a dog and a cat both called *dax*, Liu, Golinkoff, & Sak, 2001). Providing a novel label also encourages su-

perordinate classification (Waxman & Gelman, 1986). Contrasts can support subordinate classification (Waxman & Namy, 1997). Domain knowledge also affects levels of categorization. Individuals with greater expertise are more likely to focus on subordinate level categories (Tanaka & Taylor, 1991); this includes child experts (Johnson & Eilers, 1998). When a single feature is recognized or important, young children will use that feature to make a subordinate level distinction (Waxman, Shipley, & Shepperson, 1991).

The finding of a basic-level advantage suggests a convergence among several distinct sources of evidence, including universal patterns of naming in language, processing patterns in adults, and developmental patterns of acquisition—implying the existence of common principles at work underlying all these diverse findings. The result is of interest because it demonstrates that children are not resolutely concrete in their first concepts. If they were, then children would start out with the most specific level of categorization (e.g., collie); instead, they seem to prefer categories at a moderately abstract level (e.g., dog).

However, despite the primacy of a basic level in language, there is controversy regarding whether children's first (nonlinguistic) concepts are also at this level. Mandler and McDonough (2000) find evidence that a global level of categorization emerges first. The global level is broader than the basic level. It might be something along the lines of *land animal*, including cats, dogs, horses, and pigs. The researchers use a generalized imitation technique, in which a researcher models a particular action with a given object (e.g., giving a toy dog a drink from a cup), then gives the child an opportunity to model that action on either or both of a pair of additional objects (e.g., a different dog and a cat, or a bird and an airplane). In an important series of studies with 14-month-olds, Mandler and McDonough found that infants treated members of different basic-level categories as equivalent, as long as they were within the same global category (either animals or vehicles). So, for example, 14-month-olds generalized drinking from a dog to a cat, a bird, and even an anteater (which was unfamiliar). They did not generalize across domains: They did not generalize drinking from a dog to a vehicle, either familiar, such as a car, or unfamiliar, such as a forklift. Mandler and McDonough (1998) obtained similar results with 9- and 11-month-olds. They concluded that 14-month-olds generally do not yet subdivide the domains of animals and vehicles into finer-grained categories (Mandler & McDonough, 1996, p. 331).

A potential problem for the global level argument is that much younger infants appear to have something like basic level concepts available to them. Quinn and his colleagues find that infants about 3 to 4 months of age demonstrate great facility in distinguishing different basic level categories, such as dogs versus cats (Eimas & Quinn, 1994). Babies make use of perceptual cues in the form of featural similarities to identify same-category instances (Quinn, Bhatt, Brush, Grimes, & Sharpnack, 2002). By 4 months of age, infants can form categorical representations of images of cats and dogs (Quinn, Eimas, & Tarr, 2001). However, Mandler (2004) argues that an important difference is that the basic-level categories shown by infants are represented at a perceptual level only, and not a conceptual level. These representations are based on perceptions of general contour information. For infants, head shape seems particularly salient. Infants are also highly sensitive to perceptual features and correlations among them (Bhatt, Wilk, & Hill, 2004; Younger, 1990). In contrast, Mandler and McDonough argue that the global-level advantage emerges on tasks that require children to process instances in a more active (arguably more conceptual) way: either sequential touching of objects, or induction of a novel property. Mandler and McDonough's results demonstrate several important findings: Even infants are not limited to basic-level categories but instead have access to broader categories; infants' inductive inferences need not conform to perceptual groupings; and inductive inferences yield different results from other classification tasks.

Where the jury is still out, however, is whether global categories are somehow privileged for young children, and conversely, whether basic-level categories are inaccessible to young children for induction. Several additional results would suggest that basic-level categories are also accessible even in infancy. By 9 to 12 months of age, infants draw novel inferences from one object to another of the same kind, when the property is distinctive to that sort of thing (e.g., turning a special kind of can upside-down to make a funny sound) (Baldwin, Markman, & Melartin, 1993). Twelve-month-olds also treat different basic-level categories (e.g., cup, duck, car, bottle) as distinct (Xu & Carey, 1996). Waxman and Markow (1995) found basic-level categorization in 12-month-olds, using the same task Mandler and McDonough (1993) had used. Finally, children's first words appear by about 13 months of age, and typically include names for basic-level categories (such as *dog*, *cracker*, or *ball*; K. Nelson, 1973). Also, children between 13 and 18

months are generally quite good at making at least one sort of category-based inference: reporting the distinctive sounds made by different animal kinds (e.g., cow says “moo”; dog says “woof-woof”). Perhaps the use of language on some of these tasks scaffolds children and permits use of a basic-level category earlier than on a nonlinguistic task.

A further possibility is that the global categories studied by Mandler et al. may in part reflect children’s use of broader ontological categories (e.g., animate versus inanimate). Consider that one of the major pieces of evidence for global categories is that toddlers generalize from one animal to another, but not from an animal to a vehicle. If we focus on within-category similarity, this looks like a global category (the infant has formed a category that includes both dogs and cats). Yet if we focus on the between-category contrast, this looks like an ontological category (the infant has formed a contrast between animate and inanimate things). As noted years ago by Rosch (1978), both within-category similarity and between-category differences are relevant in considering the nature of a classification. As can be seen in Figure 16.1, depending on the contrast category selected, the same classification (e.g., Cats + Dogs) could

be evidence for either a global, superordinate, or ontological distinction. When Cats + Dogs is contrasted with Birds + Butterflies, a global-level category is revealed (land animals versus air animals). However, when Cats + Dogs is contrasted with Trees + Flowers, a superordinate-level category is revealed (animals versus plants). Moreover, when Cats + Dogs is contrasted with Cars + Airplanes, an ontological-level category is revealed (animate versus inanimate). Studies of categorization in young children must keep in mind both within- and between-category similarity.

Natural Kinds versus Arbitrary Groupings

The designation *natural* has a long history in concept research. Kalish (2002) describes several senses in which concepts may be natural: They may refer to objects that are naturally occurring (versus construed by humans); they may possess clusters of co-occurring features (rather than single, arbitrary features); or they may have scientific content (rather than informal knowledge). One foundational sense of “natural” is the realist assumption that certain categories truly exist in the world—they are discovered (not invented); they carve up nature at its joints. Just as an individual tiger has a reality beyond our perception of it, so too does the *category* of tigers. Natural kinds contrast with artificial or nominal kinds. Nominal kinds are arbitrary collections having no basis outside the mind. The natural/nominal distinction is often traced back to Locke (Locke, 1671/1959) and is at the center of contemporary philosophy of language, particularly causal theories of reference (Kripke, 1972; Putnam, 1975).

John Stuart Mill (1843) similarly noted a distinction between natural and arbitrary concepts. The concept *green things* (green hat, green plant, green car, green frog) captures little beyond the property of being green. All other properties that green things share are linked to the fact that they are green. In contrast, other concepts seem to carve nature at its joints (pigs, maple trees, mammals). Mill refers to these “nature-carving” concepts as Kinds; other philosophers refer to them as “natural kinds” (e.g., Schwartz, 1977). In Mill’s words:

Our knowledge of the properties of a Kind is never complete. We are always discovering, and expecting to discover, new ones. (1843, p. 438)

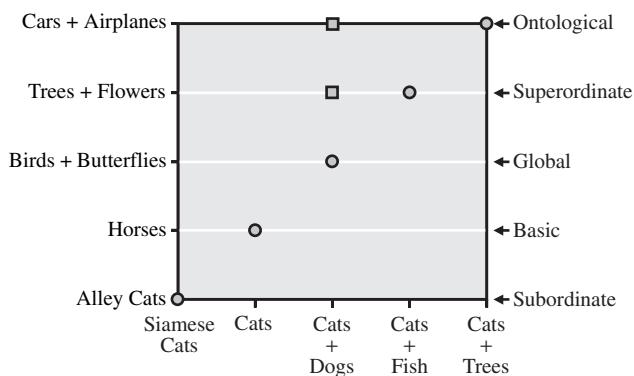

Figure 16.1 Levels of contrast as a function of within-category similarity and between-category difference. Note: Circles indicate contrasts in which within-category similarity occurs at the same level of abstraction as between-category similarity (e.g., cats and horses are basic-level categories, and the contrast between them represents a basic-level contrast). Squares indicate contrasts in which there is a mismatch between within-category similarity (for at least one category) and between-category similarity (e.g., cats + dogs and cars + airplanes are global categories, but the distinction between cats + dogs and cars + airplanes is an ontological distinction).

Much of the older developmental work seemed to assume something more like the green-things model of concepts than a natural kind model of concepts. Inhelder and Piaget (1964) thought about categories as starting with a rule, and extending through logical application of that rule. A category might be something like “green triangles,” and the challenge for children was to hold onto that rule and apply it with logical precision (a challenge that young children find difficult). In contrast, natural kinds do not seem to fit that model. Rather than starting with a defining rule, a natural kind category is a placeholder for properties that have not yet been learned.

A goal of more recent research is to explore when in development children begin to form natural kind concepts. One theory is that children’s early concepts are simple tabulations of feature co-occurrences, and that only with the development of content knowledge and causal intuitions do children seek the explanations behind the experiential groupings (e.g., Quine, 1977). Keil (1989) describes this as the doctrine of “original sim” (where “sim” is short for “similarity”). He notes that although there is evidence for developmental shifts in conceptual representation (e.g., characteristic to defining; Keil, 1989), young children also have fundamental intuitions about conceptual kinds (Keil et al., 1998).

An alternative perspective is that children start out assuming that concepts represent natural kinds, and only over time come to appreciate the arbitrary or conventional nature of some categories. S. A. Gelman and Kalish (1993) describe this position as “categorical realism”: labels and kinds pick out real objectively significant groups. Millikan (1998) proposes a similar developmental progression. In her terms, substance concepts are basic. Substances are entities that exist in the world and persist across experience. Individuals (*Mama*), masses (*milk*), and kinds (*mouse*) are all substances. The mental representation of a concept is not a definition, or even a probabilistic description, but is instead a set of heuristics for keeping track of a substance. A good way to tell if you are encountering a mouse is to check its insides, its parentage, and so on, but those properties do not define or characterize “mouseness.”

Millikan’s account is similar to other treatments of concepts current in the philosophical literature (Margolis, 1998). Millikan acknowledges that concepts can be used in a purely descriptive way. Thus “A home run is a fair ball hit out of the park” is not a heuristic for identi-

fying some preexisting category of things in the world—it is conventionally specified. Millikan suggests this perspective on concepts is a developmental achievement. Some evidence for this position comes from Kalish’s (1998) finding that young children are more likely to treat category membership as an objective matter of fact. Whereas adults treat the distinction between a pot and a can as an arbitrary convention, children seem to feel there is a real difference that must be identified. Adults accept that the distinction is a matter of convention, so that people in other cultures could legitimately form different concepts. Young children seem to feel there is a fact to the matter; different categorization practices are errors.

Research on word learning (Markman, 1989), theory-based concepts (Keil, 1989; Murphy & Medin, 1985), and essentialism (S. A. Gelman, 2003) also involve the notion of conceptual naturalness. Natural kind concepts have several distinctive characteristics (Markman, 1989): they are inferentially rich, have a nonobvious basis, and have explanatory power.

Even quite young children treat concepts as natural. S. A. Gelman (2003) describes the inordinate power names have for children; to label something is to say something very deep about its nature (also Markman, 1989). Thus if one member of a natural kind is found to have a novel property, children assume that other members of the kind will share the property. This kind of category-based induction is characteristic even of toddlers (S. A. Gelman & Coley, 1990; Jaswal & Markman, 2002; Welder & Graham, 2001), and extends to reasoning about categories in the social domain (Heyman & Gelman, 1999, 2000b) and to children in varying cultural contexts (Diesendruck, 2001). An empirical orientation to concepts makes sense given children’s positions as novice conceptualizers (see Kalish, 2002 for discussion). From a child’s perspective, if adults in the community have identified a kind, it is *prima facie* evidence that the kind is important and meaningful.

Also central to the representation of a concept as natural is the idea that it characterizes things as they are, not just as they appear. Natural kinds may have a nonobvious basis; they reflect deep, not surface similarities (S. A. Gelman, 2003; Markman, 1989). Implicit here, too, is the importance of domain. Categories like *penguin*, *apple tree*, and *male* (all living things) imply inherent nonobvious properties and inductive potential in ways not found with categories like

window, crayon, and sidewalk (all artifacts). Although artifacts, too, may have nonobvious properties (contrast an original Picasso painting with a reproduction; Bloom, 1996), for the most part simple artifacts cannot be natural in this sense.

Categories versus Individuals

The study of concepts typically focuses on categories (e.g., dogs, chairs), but children also develop rich concepts of individuals. Among the most studied are the object concept (e.g., whether an infant realizes that an object continues to exist when out of sight) and the self-concept. Children are sensitive to linguistic differences that indicate whether an act of naming refers to a kind (e.g., dogs) or an individual (e.g., Fido) (Hall, Waxman, & Bredart, 2003; Macnamara, 1982). For example, “This is a fep” implies a kind, whereas “This is Fep” implies an individual—especially if the entity is animate. One of the central intuitions underlying concepts of individuals is persistence across time and transformations. Individual identity may persist despite changes in characteristic properties (Gutheil & Rosengren, 1996) and even material composition (Hall, 1998). For example, if a doll wearing a distinctive green cloth cape is named Daxy, and the doll is then moved to a new location and the distinctive cape is removed while a new doll is placed in the old location with the distinctive cape added, 3-year-olds report that the original doll—not the new doll—is Daxy (Sorrentino, 2001). Moreover, individual identity may persist across changes in category identity and labeling. Gutheil and Rosengren (1996) found that young children realized that a change in name did not necessarily signal a change in individual identity. Similarly, the same individual may change from a caterpillar to a butterfly (Rosengren, Gelman, Kalish, & McCormick, 1991). What is crucial to determining individual identity is historical path, not the location, appearance, or even name that was present at the original naming.

Anecdotal evidence suggests that, by about 2 years of age, children may be particularly sensitive to tracking identity of an individual through time and space—as seen by their fanatical attachments to transitional objects (Winnicott, 1969) and precocious sensitivity to ownership and possession. *My* and *mine* are among children’s earliest words (Fenson, Dale, Reznick, & Bates, 1994).

Critically, individual identity is not independent of categories; for an individual to persist over time, it would typically retain at least some kinds of category identity

(fictional frogs turning into princes notwithstanding). Thus a table ground to dust and reconstituted at some later time in a similar form is a new table. One individual has been destroyed and another created. A table painted blue at one time and red at another persists as the same individual (Hirsch, 1982). Categories that function as conditions for individual persistence are called *sortals* and are typically encoded in common nouns such as dog or table (Hirsch, 1982). Macnamara (1986) notes that sortals are required for individuating entities. The question “How many?” makes no sense without supplying the sortal—how many *what* (e.g., dogs? legs? molecules?). Likewise, sortals are required for making judgments of identity. “Are these two things the same?” makes no sense without supplying the sortal—the same *what* (see also Carey & Xu, 1999, for discussion).

Sortal concepts have become significant in the developmental literature because of suggestions that the set of sortals may undergo fundamental developmental change; specifically, infants may appreciate only very global sortal concepts. Xu and Carey (1996) note that infants are often insensitive to radical changes in the appearance of individuals. If a cup moves behind a screen and a ball emerges from the other side, 10-month-old infants appear to construe this event as involving a single individual, whereas adults (and 12-month-olds) construe the event as involving two distinct individuals (but see Wilcox & Baillargeon, 1998, for an alternative interpretation of these data). Carey and Xu argue that the concept “object” functions as a sortal for young children (allows tracking of individuals), but more specific kinds do not.

There is a further way in which the distinction between categories and individuals is of great interest, and this concerns the uses to which concepts are put. Although most developmental studies of concepts focus on categories, they do not examine children’s concepts of categories *per se*, but rather of individuals as instances of these categories. Consider the category *dog*. Most typically, a word-learning researcher might ask which things get called dog (“Is this a dog?” or “What is this?”). A categorization researcher might ask a child to sort instances (“Put the dogs in this box”), or make inferences (“Does this dog have an omentum inside?”). In all these cases, the category is considered with respect to the classification of individual instances (this dog, the dogs, a dog). However, a different type of use entails thinking about the category as a whole—so-called generic uses of the category. “Is this a dog?” or “Put the

dogs in this box" are expressions that refer to individuals; "Dogs have four legs" or "I like dogs" refer to the larger category.

Traditional approaches to concepts often treated categories as reducible to individuals. The concept of bird was treated as a summary of individual birds. Yet this approach is flawed. Although the concept of bird is obviously related to its instances, a category is not just the sum of these instances. The issue here is the sense in which it is true to say "Birds fly" even though not every bird flies. This knowledge is represented in concepts of generics (S. A. Gelman, 2003; Prasada, 2000).

Generic knowledge is vital to human reasoning. Thinking about generic categories leads children to make rich inferences about the world (Shipley, 1993). As noted earlier, once a child learns that something is a member of a kind (e.g., that a dodo is a bird), he or she tends to infer that the entity shares properties with others of the same kind (S. A. Gelman & Markman, 1986). "Category-based" reasoning is predicated of kinds (Heit & Hahn, 2001; Lo, Sides, Rozelle, & Osherson, 2002; Osherson, Smith, Wilkie, Lopez, & Shafir, 1990). More generally, "semantic" (versus episodic) memory (e.g., Collins & Quillian, 1969) tends to be generic.

Despite the centrality of this form of reasoning, it poses a challenging learning problem for children (see Gelman, 2003). Generics are never directly instantiated in the world, but can only be theorized. One cannot show a child the generic class of dogs. One can never demonstrate, with actual exemplars, photos, or drawings, the distinction between a generic kind (dogs) versus a plurality of instances (some dogs). Furthermore, as noted, generic knowledge is not disconfirmed by counterexamples (e.g., birds lay eggs, even though a majority of birds—male birds and infant birds—do not; McCawley, 1981). Thus the puzzle, concisely framed by Prasada, is an extension of the classic riddle of induction: "How do we acquire knowledge about kinds of things if we have experience with only a limited number of examples of the kinds in question?" (2000, p. 66).

Sensitivity to generics in language seems to develop by about 2.5 to 3 years of age (S. A. Gelman & Raman, 2003; S. A. Gelman, Star, & Flukes, 2002). Young preschoolers interpret a generic noun phrase as referring to an abstract kind—even when it conflicts with the instances present during testing (e.g., when presented with a picture of two penguins, they report that "birds fly," but "the birds don't fly"). However, it is not until about 4 years of age that children show sensitivity to a

distinction between generics ("birds") and quantified predication ("all birds," "some birds") (Hollander, Gelman, & Star, 2002). Although more research is needed in this area, it may be during the preschool years that children come to represent fully the notion of a kind as distinct from its instances.

Implications for Children's Concepts

What are the implications of these distinctions for understanding children's concepts? The most direct implication to emerge from this review is that we cannot rely on a monolithic model of children's concepts (see also Siegler, 1996). Historically, it has often been assumed that there is a single, unitary process of categorization (Bruner, Goodnow, & Austin, 1956; Hull, 1920; see Smith, Patalano, & Jonides, 1998, for review). The work we have reviewed, however, makes clear that categorization cannot be said to be a single thing. The importance of naive theories can be overestimated when focusing exclusively on natural kind concepts and providing a task that requires children to make biological inferences. Likewise, children's reliance on outward appearances can be overrated when focused on nonlexicalized categories for which theories are barely possible—such as a U-shaped piece of plywood, for which children have little prior knowledge (Landau, Smith, & Jones, 1988). Some of the differences in theoretical positions may emerge in part from focusing on different parts of the elephant, so to speak (borrowing from the story of the blind men and the elephant). The information a child uses will be limited by the information supplied. If the only information children receive concerns shape, texture, and size, then frequent use of shape is unsurprising. In contrast, when children are reasoning about real-world living kinds, then dimensions related to biological classification (including parentage, ontology, essence, and kind) become important.

More controversially, Keil et al. (1998) proposes that *even when considering a single concept*, children consider multiple kinds of information: On the one hand, they focus on associations and feature tabulations; on the other hand, they consider propositions that interpret features and relations. Perceptual and conceptual are tightly linked—the salient perceptual features are those that give us conceptual purchase. Different conceptual structures also reflect task variability and conceptual variability. Rather than possessing a global or stable conceptual preference at any age,

children and adults apparently have multiple kinds of categorization available to them (Lin & Murphy, 2001; Waxman & Namy, 1997).

A second implication to follow from considering conceptual diversity is the speculation that what is “concept-learning” for an adult is not what it is for a child. An adult who learns a concept in the laboratory already has a fully formed conceptual system in place. This adult already has a large stock of concepts to consult. He or she already has figured out which dimensions are relevant to a wide range of other concepts. “Concept-learning” for an adult is simply adding to a rich system of already available concepts. We cannot assume that children’s concept learning is of the same sort (see also Jaswal & Markman, 2002; Rakison, 2003b for discussion of the distinction). This critical point needs to be kept in mind in any comparison of concept learning in children and adults.

In addition to conceptual differences, different tasks tap into different ways of thinking. We have already seen some of this when discussing the debate concerning whether the basic or global level develops first in children (see earlier subsection, “Levels of Categorization”). Categorization serves many different functions, and children recruit different sorts of information depending on the task at hand. Rapid identification calls for one kind of process; reasoning about genealogy calls for another. (However, as Keil et al., 1998 point out, even rapid processing could recruit theory-relevant information. One might identify a stick-insect as an animal after only a quick glance, if one happens to focus on its head and eyes, or if one happens to see it moving on its own.) Rips and Collins (1993) provides an elegant demonstration that task differences yield different categorization processes. For example, when adults are told to think about an object three inches in diameter (with no additional information), they judge it to be *more similar to a quarter than a pizza, but more likely to be a pizza than a quarter*.

Even when the task is restricted to object identification, people make use of different sorts of information depending on the task instructions (Yamauchi & Markman, 1998)—at times even in parallel on the same trial (Allen & Brooks, 1991). Smith, Patalano, and Jonides (1998) show that two separate categorization procedures—rule application and judging similarity to an exemplar—can readily apply to the same categories. These procedures seem qualitatively distinct, in that they activate different neural regions in the adult brain.

We suspect that some of the disagreements between theories of conceptual development stem from taking different kinds of concepts as paradigmatic. Children acquire a wealth of different kinds of concepts, and these likely develop in different ways. Certain concepts may have an innate basis; others may be readily acquired on the basis of perceptual learning; still others require causal reasoning and integration of facts within a growing commonsense theory. Furthermore, certain concepts are important in organizing others, and can be called *foundational concepts*. A concept such as *alive* is an example: Once one possesses the concept of *alive*, it has implications for how one thinks about a range of other concepts, such as plants (and how they are similar to animals) and clouds (and how they differ from animals, despite being apparently self-moving). In contrast, other concepts (e.g., *stapler, green triangles*) are unlikely to have implications for much other knowledge. Foundational concepts cannot be understood as distinct from a child’s larger set of beliefs or theories. We turn to this issue next.

CONCEPTS EMBEDDED IN THEORIES

There are two competing metaphors for thinking about concepts: the dictionary and the encyclopedia. The dictionary metaphor frames each concept as a self-contained unit that can be accessed and understood separately from all the others. In contrast, the encyclopedia frames a concept as interconnected with larger bodies of knowledge. Each metaphor has strengths and weaknesses: The dictionary metaphor provides a manageable enterprise (concepts can be studied in their own right) but artificially, in a way that ignores the ways in which concepts depend on assumptions and information outside the concept itself. The encyclopedia metaphor is more complete and realistic, but explodes the problem of understanding concepts into one that is far more complex and daunting.

Relatedly, Lin and Murphy (2001) make a distinction between the *internal structure* of a concept and its *external relations*. They point out that much research has focused on questions of internal structure: Do concepts have definitions? Are they characterized by prototypes? Are they based on perceptual or conceptual features? In contrast, concepts also have relations to entities outside themselves: larger bodies of knowledge, theories, func-

tions, relations, goals, and so on. These external relations are, in a sense, the whole point of concepts: We construct them in order to use them in these larger knowledge systems. This section concerns these external relations—how concepts relate to larger bodies of knowledge.

We believe that the encyclopedia metaphor is more fruitful, and the external relations of concepts must be considered. An example from the history of science illustrates why. The concept *planet* has a long history in scientific thinking, stretching back in Western tradition to antiquity. We recognize the continuity of the concepts; in English the planets are still identified by their Roman names (derived from the Greek). Yet at the same time, the twenty-first century understanding of planets is radically different from that of ancient celestial observers. How has the concept changed? One could point to definitional changes: Modern planets must orbit stars, whereas ancient planets could include stars and moons (and exclude earth). Yet any such definitional differences would understate the conceptual differences. Modern and ancient concepts were located in radically incommensurate theories (T. Kuhn, 1962). The interrelated assumptions and beliefs that motivated the ancient concept of planet do not apply to the modern concept. It is only given the larger background of ancient belief systems that we can make sense of the old concepts. Similarly new astronomical facts change the larger context within which the concept *planet* is embedded. Given that concepts are enmeshed in larger knowledge structures, it becomes problematic to identify when two concepts are really the same, or when a concept has changed. The general point, however, is that internal (definitional) properties are not sufficient to characterize concepts.

As this example illustrates, concepts are domain-specific, embedded in larger explanatory structures, often described as theories (Wellman & Gelman, 1998). Thus a full account of foundational concepts such as *force*, *living thing*, and *belief*—or even a full account of more mundane concepts such as *drop*, *hamster*, or *afraid*—would require a discussion of the nature and development of children's thinking about physics, biology, and psychology (respectively). It is beyond the scope of this chapter to consider the domain-specific factors underlying development of the full range of children's concepts. To do so would be to provide an overview of cognitive development more generally (see other chapters in this volume). Rather, in this section we present evidence for the link between concepts and theories, drawing many of the examples from the specific domain of intuitive bi-

ology. We first review research evidence that children's categories are imbued with theories, by providing examples of how children attend to ontology, causation, function, and other nonobvious properties. For ease of exposition, we have organized the literature review into distinct sections that address each of these kinds of evidence separately; in reality, however, the different sections address overlapping issues.

Ontology

Keil (1979, p. 1) defines ontological knowledge as “one's conception of the basic categories of existence, of what sorts of things there are.” Ontologies form the foundation of intuitive framework theories. Physics deals with masses, velocities, and energy. Psychology deals with thoughts, desires, and beliefs. Biology deals with species, genes, and reproduction. The same entity can be construed in different theories: Thus, a person is at once a *physical* mass, possessing *psychological* states, and undergoing *biological* processes. The difference between an ontological distinction and other categorical distinctions is that, with ontologies, predicates assigned to the wrong ontological category are not false—they are nonsensical. For example, “The cow is green” is false but sensible; in contrast, “the cow is one hour long” is an ontological category error.

When do children begin to honor ontological distinctions, in their categories and in their language? There is a rich literature demonstrating that children honor at least two ontological distinctions quite early in life, that of mental versus physical (Wellman, 1990), and that of animate versus inanimate (Rakison & Poulin-Dubois, 2001). We focus primarily on the latter, as its relevance for categorization is especially clear.

Animacy is a central concern by the time children can talk. Cross-linguistically, animacy is marked through pronouns (as in English: *he* or *she* versus *it*), classifiers, selectional restrictions on which verbs can appear with which nouns (e.g., Silverstein, 1986), and so on. Although there is no single respect in which animacy influences syntactic development across the world's languages, animacy is a pervasive theme that informs and structures the way speakers communicate. For children learning English, subject nouns are typically animate, object nouns tend to be inanimate (Slobin, 1985), and children are aware of these regularities by preschool age if not earlier (Golinkoff, Harding, Carlson, & Sexton, 1984). For children learning English, animacy is an

important factor in learning the passive construction (Lempert, 1989), in the types of implicit causal attributions children make when interpreting verbs (Corrigan & Stevenson, 1994), and in interpreting nouns such as “move” (S. A. Gelman & Koenig, 2001).

Thus, many studies show that even infants distinguish animate from inanimate on a variety of measures. An immediate question is whether this is correctly construed as a conceptual distinction, or instead can be reduced to other features that correlate with the ontological distinction. A child may distinguish mammals and vehicles in a manner that appears to reflect an ontological distinction between animate and inanimate. However, it is possible that lower-level perceptual analyses yield the categorical distinction. Cues such as spatial distribution of facial features (two eyes centered above a mouth, or, more schematically, three dots in an inverted triangle), irregular contour, dynamic patterns of movement (autonomous motion, contingent motion), and so forth, are all low-level correlates of animacy to which infants are sensitive (Bertenthal, Proffitt, Spelke, & Thomas, 1985; Bornstein & Arterberry, 2003; C. Nelson, 2001; Rakison, 2003b). An infant who distinguishes horses from airplanes (Mandler & McDonough, 1998) may not have an abstract concept of animacy, but instead a sensitivity to critical perceptual features.

One way to examine whether animacy is wholly a perceptually based distinction or one with ontological significance is to determine what meaning it has for the child (Legerstee, 1992). Some of the earliest evidence that infants distinguish people from inanimate objects comes from infants’ socioemotional reactions including gazing, smiling, and cooing (Legerstee, Pomerleau, & Malcuit, 1987) as well as infants’ novel inferences (Mandler & McDonough, 1998). Furthermore, several researchers have proposed that infants imbue animates (particularly people) with important psychological characteristics and distinguish surface behaviors from deeper psychological interpretations of those behaviors (Baron-Cohen, 1995; Legerstee, Barna, & DiAdamo, 2000; Meltzoff, 1995; Premack & Premack, 1997; Woodward, 1998).

A further piece of evidence is that, in children’s classifications, ontology can trump other salient information, such as object shape. By 9 months of age, infants group together different basic-level animal categories (e.g., dogs and fish) and separate birds-with-outspread-wings from airplanes (Mandler & McDonough, 1993).

Ten-month-olds classify together containers differing in shape and distinguish between same-shaped objects that differ in their capacity to contain (Kolstad & Baillargeon, 1996). By age 2 years, children weight substance more heavily than shape on a match-to-sample task on which the items are nonsolid masses (Soja, Carey, & Spelke, 1991). Even children’s overextension errors (e.g., referring to a cow as a “dog”) are not based primarily on shape alone, but typically require similarity on both shape and taxonomic relatedness (S. A. Gelman, Croft, Fu, Clausner, & Gottfried, 1998).

By 3 and 4 years of age, children treat plants and animals as belonging to a single category (things that grow and self-heal), despite the extreme differences in shape between, say, a cow and a tree (Inagaki & Hatano, 2002). Conversely, children treat humans and apes as belonging to distinctly different categories, despite their greater similarity. Thus, when given triads consisting of a human, a nonhuman primate, and a nonprimate animal, elementary-school children are more likely than adults to group together the primate and the animal, isolating the human (Johnson, Mervis, & Boster, 1992). This pattern is also found among preschoolers, even when the primate and animal differ radically in shape (e.g., chimpanzee and centipede) (Coley, 1993).

A further argument is that the perceptual cues that correlate with animacy are insufficient. Prasada (2003) suggests that so-called animate motion, in fact, is not perceptually given, nor can it be represented as a correlation between properties, but rather requires “an appropriate relational structure” (p. 18) (see also R. Gelman & Williams, 1998). Self-motion (in the sense of self-generated movement) is not simply a matter of detecting whether an object moves without a visible causal agent because wind and magnets can be (and indeed sometimes are) imputed as causal agents in such cases (e.g., R. Gelman, Durgin, & Kaufman, 1995; S. A. Gelman & Gottfried, 1996; Subrahmanyam, R. Gelman, & Lafosse, in press). How to represent such relational structures on a perceptual-learning account is not clear (but see Yoshida & Smith, 2003, for suggestions).

Ontological concepts are significant because they provide a foundational structure for other concepts. Thus, learning that a sugar-glider is a kind of animal suggests one might be able to learn about the ways sugar-gliders reproduce and take in energy, but not about their truth-value or original inventor. There is no sharp dividing line between concepts that provide an or-

ganizing structure and those that do not. For example the distinction between plants and animals is conceptually important, but it is less clear whether plants and animals are different ontological kinds (Carey, 1985). Ontological status may best be understood as a kind of relative centrality. To the extent that a concept has vast implications for other concepts and knowledge, it can be considered ontological. Ontological status, then, is a consequence of laws and causal relations recognized within intuitive theories. This perspective highlights the role of causal relations in conceptual organization, to which we turn next.

Causation

Some years ago, we proposed that, if children's categories are theory-based, then causes should be crucial to their category representations (S. A. Gelman & Kalish, 1993). Similarly, Ahn (1998) formulated the "causal status hypothesis," in which causal features are more central than effect features (see also Rehder, 2003). Thus, even given equal frequency, cause and effect features will be weighted differently. When the causal status of features is manipulated experimentally, adults weight the identical feature more heavily when it serves as a cause than when it serves as an effect (Ahn, 1998). Of particular interest to the present context, Ahn, Gelman, Amsterlaw, Hohenstein, and Kalish (2000) found evidence for the causal status effect in children 7 to 9 years of age. Children learned descriptions of novel animals, in which one feature caused two other features. When asked to determine which test item was more likely to be an example of the animal they had learned, children preferred an animal with a cause feature and an effect feature rather than an animal with two effect features.

Other studies add to the support for the importance of cause in children's concepts. Barrett, Abdi, Murphy, and Gallagher (1993) find that, when asked to categorize novel birds into one of two categories, children of elementary-school age noticed correlations that were supported by causal links, and used such correlations to categorize new members (e.g., correlation between brain size and memory). The children did not make use of features that correlated equally well but were unsupported by a theory (e.g., the correlation between structure of heart and shape of beak). Krascum and Andrew (1998) likewise found beneficial effects of causal infor-

mation on category learning in children as young as 4 and 5 years of age. As the authors note, "[T]he meaningfulness of individual features is not a significant factor in children's category learning, and instead, what is important is that attributes within a category can be linked in a theory-coherent manner" (p. 343).

Causal relations are central to concepts in theories because they involve explanatory as well as associative relations. Features in causal relations are linked by some sort of mechanism. Mechanisms provide a deeper explanatory structure to concepts and knit superficially disparate phenomena into a coherent theory. Preschool children recognize that baby animals tend to resemble their parents (Springer, 1996; Gelman & Wellman, 1991). They also recognize that there is a highly regular and constrained pattern of development across the lifetime of an individual animal (Rosengren et al., 1991). The two facts can be explained and integrated through the idea of some sort of intrinsic species essence. Similarly, young children recognize that many behaviors can lead to illness, including getting sneezed on, sharing a toothbrush, or eating a dirty piece of food. What links these apparently dissimilar events is a common underlying mechanism, transmission of germs (Kalish, 1996).

The detail with which children represent mechanisms remains an open question (Au & Romo, 1999; R. Gelman & Williams, 1998; Keil et al., 1998). For example, children might initially represent causal relations with an abstract mechanism placeholder. At the same time, the nature of the mechanism is where the critical theoretical connections lie. Consider the concept of "inheritance." Some researchers have argued that young children recognize a physical or biological mechanism mediating parent-offspring resemblance (Hirschfeld, 1996; Springer & Keil, 1991). This sort of representation links inheritance to a set of other beliefs and concepts, an intuitive theory of biology. Alternatively, if children assume that intentional or social mechanisms underlie inheritance (Solomon, Johnson, Zaitchik, & Carey, 1996; Weissman & Kalish, 1999), then the conceptually central links would be quite different. Use of a concept (e.g., "mother," "sick") involves, in part, coming to appreciate which mechanism is operative. The organization of concepts within intuitive theories entails imputing underlying, nonobvious properties and causal relations. Just which nonobvious properties children represent, and how that set changes, are the major questions driving research on the development of

theory-based concepts. We turn next to consideration of some of these nonobvious properties.

Nonobvious Properties

The importance of nonobvious properties can be seen in several respects. It is implicit in children's understanding of causation and ontology. It can also be seen more directly in children's formulation of domain-specific theories that posit nonvisible constructs: mental states in a naive theory of mind (Wellman, 2002), physical force and gravity in a naive theory of physics (Wellman & Inagaki, 1997), and a wealth of constructs in children's formulation of biological theories, including germs (Kalish, 1996; Siegal, 1988), vital powers (Gottfried & Gelman, in press; Inagaki & Hatano, 2002; Morris, Taplin, & Gelman, 2000), elements of reproduction (Springer, 1996), and cooties (Hirschfeld, 2002). That children appear to learn and accept such constructs readily would argue against the notion that their concepts depend on concrete, perceptually apparent properties.

Furthermore, studies that focus specifically on nonobvious properties, such as internal parts or substance, find that children rely on such properties for categorizing (see also R. Gelman & Williams, 1998). (Precisely when in development children do so is a matter of some dispute, however.) In a by-now classic series of studies, Keil (1989) asked children to consider animals and objects that had undergone transformations leading them to appear to be something else—for example, a raccoon that underwent an operation so that it looked and acted like a skunk. Second graders realized that animal identity was unaffected by superficial transformations (e.g., the animal was judged to be a raccoon despite its skunk-like properties).

Even younger children demonstrated a similar understanding when considering items that were transformed to resemble something from a different ontological category (e.g., preschoolers reported that a porcupine that was transformed to look like a cactus was still a porcupine), or that were transformed by means of a costume. Gelman and Wellman (1991) similarly found that preschool children appreciated that for some objects, insides are more important than outsides for judgments of identity and functioning (e.g., a dog without its insides cannot bark and is not a dog, whereas a dog without its outsides can bark and is a dog). Moreover, when asked what differentiates pairs of identical-looking animals that differ

in kind (e.g., real dog versus toy dog; dog versus wolf), both 5-year-olds and adults are more likely to invoke internal parts/substance than the irrelevant property of age (S. A. Gelman, 2003; Lizotte & Gelman, 1999).

Interestingly, children appreciate that insides are important at an age when they do not yet know much about *what* insides objects have. For example, although 4-year-olds recognize that insides are crucial to object identity and expect that animal insides differ in consistent ways from machine insides, they cannot accurately identify which photo corresponds to the insides of an animal, or which photo corresponds to the insides of a machine (Simons & Keil, 1995). This result led Simons and Keil to suggest that children's grasp of insides is an abstract appreciation that precedes a concrete, detailed understanding. This is a surprising reversal of the usual developmental story (that concrete understandings precede abstractions), and implies that children may be predisposed to consider nonobvious properties important, even in the absence of direct evidence.

In the remainder of this section we briefly review two particular kinds of nonobvious properties: function and essence.

Function

Kemler Nelson, Russell, Duke, and Jones (2000) explain the importance of function to a theory-based approach as follows:

Attention to functional information can be understood as evidence for conceptual categories when it supplements or overrides the pull of superficial, functionally irrelevant aspects of appearance as the basis for using artifact names. The use of functional information implicates interpretive mechanisms beyond those of immediate perception and indicates a mode of categorization that is at least partly knowledge based, rather than strictly perceptually driven. (p. 1271)

However, the extent to which children are capable of using function for their classifications, particularly in word learning, is highly controversial. Smith, Jones, and Landau (1996) argued that 3-year-old children selectively ignore functional information when extending new labels. The basis of their argument is that word learning is guided by "dumb" (nonreflective, involuntary, automatic) attentional mechanisms. They conclude, on the basis of a series of experiments, that "children's naming was im-

mune to influence from information about function" (p. 143). Their evidence included a series of four experiments in which 3-year-olds—unlike adults—failed to use function when extending novel labels to novel objects.

Landau, Smith, and Jones (1998) extended this line of work using a greater range of both novel and familiar objects. Across three studies of similar design, 2-, 3-, and 5-year-olds and adults were asked to extend labels (Naming task) or to infer novel functions (Function task; e.g., "Could you carry water with this one?"). In general, children selected based on function on the Function task, and selected based on shape on the Naming task, regardless of whether they were presented with explicit demonstrations of function. These results demonstrate the children are capable of reasoning about functional concepts. However, Landau et al. argue that when extending words, children are "pulled" by nonreflective attentional mechanisms that serve to spotlight the most salient (and unreflective) aspects of the situation.

If these provocative results are interpreted as the authors suggest, this would be damaging to the "concepts in theories" position. Nonetheless, the theory position could be saved in either of two ways: One possibility is that function is indeed used by children to categorize, but at a later point in development compared to the subjects in the Landau et al. experiments (Smith et al., 1996). This possibility, if true, would weaken the theory position, particularly the suggestion that theories contribute to concept development, rather than being the outcome of concept development (Murphy, 1993). It would argue for a developmental shift, from perceptually based to theory based categorization. A second possibility, and the argument we favor, is that children can and do use functional information while naming, but that certain items and tasks have limited children's capacity in prior studies. When care is taken to design tasks and items that reflect functions that are salient, sensible, and nonarbitrary, then young children incorporate function into their naming as early as 2 years of age. This latter argument has been pursued vigorously in the past few years, and we now turn to the evidence that supports it.

Kemler Nelson et al. (2000) point out that children cannot be expected to appreciate just any type of function they encounter, any more than would an adult. They suggest that, for a fair test, it is critical to examine function/structure relations that are "compelling and nonarbitrary in a way that young children can make sense of

(and may expect)" (p. 1272). Specifically, they posit that the functionally relevant aspects of an object's design should be easily perceptible, that structure/function relations should be based on principles of causality that are familiar to young children, and that function/structure relations should be "convincing." They introduced 3-, 4-, and 5-year-old children to a novel artifact that could function in two distinct and novel ways: to paint parallel lines (with brushes) and to make music (with wires that could be plucked). Thus, certain features were contingent on one function, whereas other features were contingent on the other function. Each child encountered only one of these functions, in either a Painter or Instrument condition, when the target artifact was named a *stennet*. When asked to extend the novel name to test objects that varied from the target in similarity and function, children tended to extend the name in accord with the function that they saw demonstrated (though similarity relations were also taken into account).

Similarly, Diesendruck and Markson (1999) argue that young children can appreciate function when it is a permanent, exclusive property of an object that is demonstrated and explained (e.g., "this was made for X"). In one study, 3-year-olds participated in a sorting task with triads of novel objects. Each target object was paired with an object similar in shape but which could not perform the function, and an object different in shape but that could perform the same function. When the function was explicitly stated, demonstrated, and shown to be exclusive to one of the test choices, children typically sorted based on function.

What is it that makes a function more compelling to children? Kemler Nelson, Frankenfield, Morris, and Blair (2000) found that 4-year-old children were more likely to generalize novel names for artifacts when functions "made sense" and were more reasonably related to structure and the designer's intent. A sensible (plausible) function for an object with a horizontal and vertical tube might be "when you put balls in here, it drops them one at a time," whereas an implausible function for the same object might be "a toy snake can wriggle in it." That is, although the object could readily carry out either of these functions, only the first is likely to be a function designed by the creator of the object.

Similarly, Bloom (2000) proposed that function is used to the extent that it is perceived as intended by the designer of the object under consideration. Children relied on function when it was highly specific and

unlikely to be accidental (e.g., an object with a hinged part shaped to fit into its base like a puzzle-piece; Kemler Nelson, Frankenfield, et al., 2000) but did not rely on function when it was simple, general, and probably accidental (e.g., a square, U-shaped object that “a toy dog sits in”; Smith, Jones, & Landau, 1996). Indeed, when children view two objects of *identical* shape that have different intended functions (e.g., an object and its same-shaped container), they do not sort them together (Diesendruck, Markson, & Bloom, 2003; but see German & Johnson, 2002, for evidence that 5-year-olds attend to any intended goals for which an object is used, not just original intent).

Essence

Another example of a nonobvious construct is that of an “essence” (S. A. Gelman, 2003). Essentialism is the view that categories have an underlying reality or true nature that one cannot observe directly but that gives an object its identity (S. A. Gelman, 2003; Locke, 1671/1959; Schwartz, 1977). According to essentialism, categories are real, in several senses: They are discovered (versus invented), they are natural (versus artificial), they predict other properties, and they point to natural discontinuities in the world. Essentialism requires no specialized knowledge, and people may possess an *essence placeholder* without knowing what the essence is (Medin, 1989). For example, a child might believe that girls have some inner, nonobvious quality that distinguishes them from boys and that is responsible for the many observable differences in appearance and behavior between boys and girls, before ever learning about chromosomes or human physiology.

Evidence for essentialism is indirect but extensive. It includes several expectations children hold about certain categories: that they permit rich underlying structure, have innate potential, and have sharp and immutable boundaries (S. A. Gelman, 2003). Essentialism is a powerful, fairly general structure for concepts. It specifies that underlying features are causally responsible for observable qualities but does not necessarily imply anything about the nature of the features or causal processes. Thus, essentialism may guide children’s construction of social categories (Giles, 2003; Heyman & Gelman, 2000a; Hirschfeld, 1996; Rothbart & Taylor, 1990), of artifacts (Bloom, 2000), and of food (Hejmadi, Rozin, & Siegal, 2004). When children begin to acquire a novel concept, they assume that causal features will be the most central (Ahn et al., 2000; Gopnik & Sobel,

2000). Essentialist intuitions also lead to incorporation of new properties into the concept. The assumption of shared essence warrants the inference that properties possessed by one (or a few) instances will be true of the general kind. How children decide which categories to essentialize remains an unsolved puzzle.

Essentialism is a hypothesized construct based on indirect evidence, and so cannot be demonstrated definitively. Not surprisingly, then, there are debates as to whether this is the most apt characterization. One set of questions concerns whether there is a single essentialist stance (Keil, 1994), or instead an amalgamation of tendencies (S. A. Gelman, 2003). If the latter, then how coherent are essentialist beliefs? Do different strands (e.g., nativism, inductive potential, boundary intensification) all hang together, or do they develop piecemeal? Another set of issues was raised by Strevens (2000), who suggests that the data taken as evidence for psychological essentialism could instead be accounted for if people simply assume that there are causal laws connecting kind membership with observable properties. He terms such causal laws *K-laws* (kind laws), and his alternative formulation the Minimal Hypothesis. Strevens’s account, though eschewing essentialism, overlaps with the current model in emphasizing that people treat surface features as caused and constrained by deeper features of concepts.

Other scholars have argued that the essentialist model cannot account for certain experimental findings with adults (Braisby, Franks, & Hampton, 1996; Malt, 1994; Sloman & Malt, 2003). For example, the extent to which different liquids are judged to be water is independent of the extent to which they share the purported essence of water, H_2O . At issue are questions such as, What is meant by *essentialism* (see S. A. Gelman & Hirschfeld, 1999, for several distinct senses that have been conflated in the literature)? Which concepts are essentialized? Can there be a mismatch between language and concepts (e.g., an essentialized concept of “pure water” that does not map neatly onto uses of the word “water”)? Whether these findings undermine (or even conflict with) psychological essentialism is a matter of current debate (S. A. Gelman, 2003; Rips, 2001).

Summary

Any developmental theory needs to account not only for the acquisition of simple concepts (both familiar, such

as *cup*, and novel, such as *rif*) but also complex knowledge. By the time children are 2.5 to 3 years of age, many of their concepts incorporate properties that cannot be readily captured by perceptual description. We have reviewed several types of evidence to support this claim: the centrality of ontology, of causal features, and of nonobvious constructs (including function, intentionality, and internal parts). Children are not simply stringing together observed properties, but rather are searching for underlying causes and explanations. The resulting concepts are often called *theory-based*. In some cases, concepts are embedded in an identifiable, articulated theory (e.g., beliefs and desires in a theory of mind). In other cases, such a theory has not yet been identified, but the components of a theory (ontology, causation, nonobvious features) are present from an early age.

Theories are argued to contribute to concept development rather than to result from concept development (see Wellman & Gelman, 1998). Murphy (1993) argues that, without theoretical commitments of some sort, it may be difficult for children to acquire concepts at all. He posits that theories help concept learners in three respects:

1. Theories help identify those features that are relevant to a concept.
2. Theories constrain how (e.g., along which dimensions) similarity should be computed.
3. Theories can influence how concepts are stored in memory. The implication here is that concept acquisition may proceed more smoothly with the help of theories, even though the theories themselves are changing developmentally.

These data and arguments do not imply that perceptual features are unimportant to early concepts. Even within a “concepts-in-theories” framework, appearances provide crucial cues regarding category membership (Gelman & Medin, 1993). Similarity plays an important role in fostering comparisons of representations and hence discovery of new abstractions and regularities (Gentner & Medina, 1998). Rather than suggesting that perceptual cues are irrelevant, we suggest that many concepts have two distinct though interrelated levels: the level of observable reality and the level of explanation and cause.

It is this two-tier structure that may in fact serve to motivate further development, leading children to de-

velop deeper, more thoughtful understandings (Wellman & Gelman, 1998). Most developmental accounts of cognitive change include something like this structure, such as equilibration (Inhelder & Piaget, 1958), competition (MacWhinney, 1987), theory change (Carey, 1985), analogy (Goswami, 1996), and cognitive variability (Siegler, 1996). In all these cases, children consider contrasting representations. Not surprisingly, children also look beyond observable features when forming concepts.

Theory-based approaches argue for the interdependence of categorization and other cognitive processes, such as causal reasoning or reading of intentionality. Certainly no one would argue that categorization is a wholly separate process unto itself (consider the well-appreciated links among categorization, perception, and memory). Theory-based approaches to concepts have powerfully made the point that categorization is intertwined with knowledge and belief systems (Murphy, 2002). However, the extent of this interdependence has not yet been sufficiently plumbed. It would be intriguing to know, for example, how categorization changes (if at all) for those people with impairments that affect other high-level reasoning processes. We need more fine-grained studies of categorization in autism (which devastates theory of mind) or Williams syndrome (which seems to undercut theory construction; see S. C. Johnson & Carey, 1998).

MECHANISMS OF CONCEPTUAL ACQUISITION AND CHANGE

There is no doubt that by preschool age, children’s concepts are rich, varied, context-sensitive, and not simply rooted in perceived similarities (“observables”). How to account for these early developments? Some similarity-based and associationist mechanisms have been proposed that suggest simple attentional mechanisms to account for concept learning—yet questions remain as to how well they capture the complexity of the phenomena. At the same time, more theory-based mechanisms for understanding conceptual change are beginning to receive attention—yet are currently less well understood. In this section, we briefly review some of the major arguments in favor of associative and similarity mechanisms, discuss some limitations that they face as a full account of concept learning, and consider other promising directions.

Associative Mechanisms

Challenges to the concepts-in-theories position center around the idea that low-level associative mechanisms can account for children's seemingly sophisticated concepts, so that there is no need to appeal to higher-order processing. In this section we first review some of the evidence for the power of children's associative mechanisms, then arguments for why these are insufficient to account for children's concepts in full.

Human infants possess powerful mechanisms for detecting regularities in the environment and learning associations; they can respond to complex patterns of covariation. One kind of information infants use is frequency distributions. A basic principle of classical conditioning is that a learner who experiences that property A frequently co-occurs with property B but rarely with property C will learn to associate A and B over A and C. Infants are sensitive to associations between properties such as shape, movement, and texture (Madole & Oakes, 1999; Quinn & Eimas, 2000; Rakison & Poulin-Dubois, 2001). Saffran et al. (1996) showed that 8-month-old infants are impressively sensitive to distributional properties of sound patterns in speech. Such sensitivity allows babies to segment continuous speech into units; sounds with low frequencies of co-occurrence may mark word boundaries.

Associationist accounts have proposed that the basic mechanisms for conceptual change is bootstrapping. Bootstrapping is a process of multiple rounds or levels of statistical learning (Goldstone & Johansen, 2003). The basic principle of bootstrapping is that learners are initially sensitive to relatively low-level features that correlate with more abstract conceptual distinctions. In the field of language development, various bootstrapping models have emerged: Form can be a cue to meaning (syntactic bootstrapping), meaning can be a cue to form (semantic bootstrapping), intonation can be a cue to meaning or form, and so on (see Waxman & Lidz, Chapter 7, this *Handbook*, this volume). In the area of conceptual development more broadly, bootstrapping approaches include perceptual learning accounts (e.g., Goldstone, 1998) and form-function relations.

Language is one of the central inputs for conceptual bootstrapping. Language use provides patterns of associations between labels and objects. Infants initially respond to patterns of sound elements. Sound elements

cluster into chunks (words). With these new clusters, infants can learn patterns of association between words or between words and other parts of experience (Werker, Cohen, Lloyd, Casasola, & Stager, 1998). Attention to the distributional properties of words gives the learner access to a greatly enriched set of distinctions and associations (Oakes & Madole, 2003; Samuelson, 2002). Smith and Yoshida (Smith, Colunga, & Yoshida, 2003; Yoshida & Smith, 2003) argue that foundational concepts (e.g., animacy) may be extracted from regularities in language. Syntactic structures are associated with conceptual distinctions between objects and substances (e.g., count nouns versus mass nouns in English) and between animates and inanimates (e.g., plural marking is more common for animates than inanimates, in Japanese). For the young child, animacy falls out of those perceptual and linguistic correlations that can be found in the input, thereby leading to different conceptualizations of animacy depending on the language being learned (English versus Japanese).

This is not to say that the higher-order concepts, computationally or phenomenologically, reduce to their constituent associations. As the conceptual system is built up, clusters of associations may be compiled into phenomenological primitives. Adults hear speech in their native language as a sequence of words (or even sequence of meanings). The patterns underlying those segments are not perceived and may not even be retrievable. Mill (1843) describes this process as mental chemistry. When various wavelengths of light are perceived together, the experience of the whole (white) is qualitatively different than the sum of the parts (colors). Critically, the whole may provide unique associations. The associations with white are not simply derivable from associations with constituent colors.

A case study examining the role of associative mechanisms comes from studies of children's reliance on shape to form concepts. Much research suggests that shape is a crucial component of children's semantic representations. Two-year-olds overextend familiar words to unrelated objects (e.g., calling the moon "a ball"; Clark, 1973), and preschoolers extend novel words on the basis of shape (see Woodward & Markman, 1998, for discussion).

On an associationist view, a shape bias builds up gradually over time, based on statistical regularities in the input (Smith, 2000). In favor of this view is evidence

that the bias is not innate, but emerges at about age 2 years, after a cluster of initial words have been learned, and increases till about 36 months of age (Smith, 2000). Thus, attention to shape appears to undergo a characteristic developmental time course in which it grows more powerful as children acquire more experience with their own language—therefore suggesting that it may be the outcome rather than the source of word learning. The input children hear also seems to provide a rich source of data regarding such linkages between object shape and count nouns. The first count nouns that children learn in English tend to refer to categories for which shape is a salient dimension, suggesting that children may be hearing many shape-based count nouns. Exposure to different language inputs results in somewhat different word-learning biases, also implicating experience as an important influence on children's early assumptions about word meaning. Relatedly, experimental manipulation of the input by teaching shape-based nouns results in stronger noun-learning in early childhood (Gershkoff-Stowe & Smith, 2004).

One position we and others have argued is that the salience of shape derives largely from its value as an index or predictor of other information (S. A. Gelman & Ebeling, 1998; Medin, 1989; Soja, Carey, & Spelke, 1992; Woodward & Markman, 1998). When ontological knowledge and theoretical beliefs are available, and when they conflict with shape, children can and do sort and name on the basis of these other factors (see S. A. Gelman & Diesendruck, 1999, for review). If this interpretation is correct, then when children receive information about theoretical kind directly, this should influence which features are deemed relevant and used in children's judgments. Indeed, Booth and Waxman (2002) have demonstrated that conceptual information (in the form of verbal descriptions) affects children word extensions. In two experiments, 3-year-old children received a word-extension task with simple abstract objects, in which the objects were described as having either animal-relevant properties (e.g., "This dax has a mommy and daddy who love it very much . . . when this dax goes to sleep at night, they give it lots of hugs and kisses") or artifact-relevant properties (e.g., "This dax was made by an astronaut to do a very special job on her spaceship"). Children sorted the objects differently, depending on the conceptual information provided in the story. The data argue against the idea that children automatically activate purely percep-

tually based associations between the presence of eyes and the dimension of shape.

Similarity

Many associationist theories present similarity as the strongest organizing principle for young children's concepts. Similarity is a summary of degree of overlap in features (Hahn & Ramscar, 2001). It is typically thought of as a relation between sets of perceptual properties, such as shape or visible parts, and thus particularly suited to associationist accounts of concepts. However, similarity is an abstract relation that may hold between any sets of features (including nonperceptual ones). Nonetheless, as a hypothesis about children's concepts, similarity typically implies that nonobservable, conceptual features are not represented (Mareschal, 2003; Sloutsky & Fisher, 2004).

Similarity is a global or holistic representation (as contrasted with a rule-based or analytic representation). There is a long tradition of describing children's thinking as moving from holistic to analytic (Kemler & Smith, 1978) or from a focus on sets of characteristic features to selective representations of defining features (Keil, 1989). Consider two people: your father's infant brother (A) and an adult friend of the family who always comes for holidays (B). Adult intuitions are that B is more similar to a typical uncle, but that only A actually is an uncle. A similarity-based account denies that children would make this differentiated judgment. The calculation of similarity is not context-dependent. It does not matter whether one is judging which person (A or B) is more likely to give you a present, or which person is more likely to share an inherited feature; rather, overall perceptual similarity drives predictions. In contrast, a more sophisticated sense of similarity would allow for differential judgments depending on context (Medin, Goldstone, & Gentner, 2000). For example, one would judge that the adult family friend would be more likely to give you a present, but that your father's brother would be more likely to share your father's blood type. Another capacity that extends beyond a similarity-based account involves weighting certain features absolutely, yielding rule-based categories. Thus for nominal kinds (such as "uncle"), kinship relations are necessary and sufficient (no other features matter). We can distinguish, then, the simple similarity model (global, noncontext-dependent) from

two other sorts of models: one in which similarity is context-dependent, and one in which certain features are given absolute weights. A common developmental hypothesis is that the simple similarity model precedes both of these models.

Sloutsky (2003; Sloutsky & Fisher, 2004) has revived claims that young children's concepts are based on a relatively undifferentiated sense of overall similarity. Sloutsky has studied children's representations of animal kinds. Theory-based views describe young children's concepts as organized around biological essences and causal relations, with perceptual features providing evidence for underlying properties (S. A. Gelman, 2003). When judging which of two animals shares a novel property with a third, theory-based accounts suggest that children will base their judgment on biological relatedness, even when it conflicts with perceptual similarity. In contrast, Sloutsky proposes that young children fail to distinguish between perceptual and underlying features. One series of studies presented participants with a task in which they were asked to judge which of two objects shares an underlying biological property with a third (e.g., which of two items have blood; Sloutsky, Lo, & Fisher, 2001). Adults and older children use shared labels to the exclusion of perceptual features; the two entities with the same name share properties. Young children perform differently. Labels are accorded no special status, but just enter the similarity calculation as a kind of auditory-perceptual feature (Sloutsky & Fisher, 2004). Children judge two entities as more similar if they receive the same label (Sloutsky & Lo, 1999). Thus, children's inductive inferences from one animal to another are highly predicted by their judgments of how similar one animal is to another—at least as similarity is measured on this task.

Limits of Similarity and Associations

To many, empiricism has the powerful allure of common sense (Keil et al., 1998; Pinker, 2002). It also seems to account for knowledge acquisition with a minimum of machinery. Processes of general induction, based on association learning and similarity assessment, are undoubtedly potent tools for acquiring categories. However, we suggest that such processes are insufficient to provide a complete account for concept acquisition and conceptual change.

Context-Sensitivity

A major limitation of similarity-based models is accounting for context-sensitivity. Selective similarity is characteristic of young children's concepts. Preschool children realize that a person and a toy monkey look alike but are unlikely to share internal properties, whereas a worm and a person look different but are more likely to share insides (Carey, 1985). Simple attention to correlated attributes is not sufficient to account for even young children's knowledge. For example, 3- and 4-year-olds predict that a wooden pillow will be hard rather than soft, even though all the pillows children have previously encountered have been soft (Kalish & Gelman, 1992). Likewise, 2- to 4-year-old children are more likely to use perceptual similarity cues when similarity corresponds to function (McCarrell & Callanan, 1995). For example, after looking at pictures of two creatures that differed only in eye size and leg length, children were invited to make an inference concerning sight ("Which one sees really well in the dark?") or movement ("Which one can jump really high?"). Children attended selectively to different perceptual features depending on the particular function (eyes, when the question concerned sight; legs, when the question concerned movement). Giles and Heyman (2004) found that preschool children judged the same behavior differently depending on the category of the individual involved. If a girl (versus boy versus dog) spills a child's milk, the implications differ accordingly in how this is explained. These examples of selectivity would seem more readily explained as an instance of causal reasoning than as a reflection of attentional weights.

Unlike similarity accounts, associationist accounts have no difficulty in principle with context-sensitivity; indeed, they predict it (L. B. Smith, 2000). However, such accounts would assume that children have a prior database of associations that drive their judgments. In contrast, a theory-based model enables children to make novel inferences that are supported by theoretical assumptions (as in the wooden pillows study, where preschoolers correctly inferred that wooden pillows would be hard).

Role of Labels

The similarity view is that words serve merely as an additional feature in an undifferentiated similarity judg-

ment (Sloutsky, 2003). In contrast, an alternative proposal is that children treat different words as referring to different kinds of concepts (e.g., count nouns label taxonomic kinds; proper nouns label individuals), and these concepts mediate children's judgments. The best way to test between these hypotheses is to examine different kinds of words. The literature on children's sensitivity to different word types would suggest that a pure similarity model would have difficulty accounting for extant findings. S. A. Gelman and Markman (1986) found that children extended novel properties from one animal to another if their labels were synonymous (e.g., "puppy" and "baby dog"; identical labels were not required), and S. A. Gelman and Coley (1990) found that children did *not* extend novel properties from one animal to another if they received identical *adjectives* (e.g., labeling two birds as "sleepy"). Labels *per se* did not determine performance; rather, the concepts conveyed by the labels did.

Sloutsky and Fisher's (2004) results demonstrate that categorical (labeling) information is taken as more important for inductive inference than for judgments of similarity. S. A. Gelman and Markman (1986) offer an explanation: Shared properties are characteristic of members of the same category. Thus, when asked about shared properties, children look for cues about category membership. Shared labels are one such cue. When the task is to judge perceptual similarity, or shared perceptual properties (e.g., weight; S. A. Gelman & Markman, 1986), appearances are the better cues. Sloutsky and Fisher take issue with this account. First, they argue that Gelman and Markman are committed not just to labels being important to property projection, but to labels being criterial (they should override all other information). Second, they argue that labels function simply as auditory features rather than as cues to category identity. We examine both claims.

Sloutsky, Lo, and Fisher (2001) asked people to predict which of two animals would share a novel property. They manipulated information about common features: which animals looked alike, which shared labels, and which were biologically related. The finding was that children did not treat any single feature as criterial. However, it is not clear why criterial responding might be expected: Each feature is a reasonably good cue in this instance. The claim that category membership determines property projection is distinct from the claim that shared labels are criterial. Labels are only good

warrants for predicting shared membership; there may be other (competing) warrants. That two animals look alike is also generally fairly good justification for assuming that they share category identity (S. A. Gelman & Medin, 1993).

The second component of Sloutsky's similarity-based account is to deny any special status to labels. Instead, on this view, labels affect children's judgments because they are salient perceptual (auditory) features, and auditory features override visual features in children's processing. (This is a slippery claim to substantiate, as it is not clear how one could adequately calibrate the two dimensions to enable a head-to-head comparison.) This claim would seem incompatible with much of what is known about children's word learning. Not just any auditory association affects inferences. As reviewed by Bloom (2000), children make different judgments, depending on whether a label is a count noun, proper noun, mass noun, adjective, preposition, or verb (see also Waxman & Lidz, Chapter 7, this *Handbook*, this volume). If labels were simply attentional cues that are given heavy weight because of their auditory modality, then why should children differentiate between these different kinds of words? Even young children recognize that labels are intentions to refer (Tomasello & Barton, 1994). Jaswal (2004) found that children vary their attention to labels depending on the intentions of speakers: When a label was intended, then children relied on the label for drawing inferences, but when a label was accidental or un-informed, then it was not (see also Koenig & Echols, 2003; Sabbagh & Baldwin, 2001, for related results). This result is again consistent with the interpretation that children make use of labels to the extent that they indicate category membership, and not as a salient auditory cue. Young children use speaker intent to gauge value of the label: "[P]reschoolers do not treat labels as atheoretical features of objects; rather, they interpret them in light of their understanding of the labeler's communicative intent" (Jaswal, in press).

A related point is that the word-learning process itself relies heavily on impressively subtle social information. The manner in which children learn words would seem to belie simple associative learning mechanisms (though perhaps not more complex versions). Tomasello and Akhtar (2000, p. 181) list several ways that children as young as 24 months of age override spatiotemporal contiguity and perceptual salience when learning words:

- They assume that words refer to intentional actions, even if the target novel word is immediately followed by an accidental action and only later followed by an intentional action.
- They learn a word for an aspect of the context that is novel for the (adult) speaker, even though it is not novel for the child.
- They learn new action words for actions that they anticipate an adult will do, even when the adult has not actually performed the action.
- They use adult gaze direction rather than perceptual salience to determine reference.

Tomasello and Akhtar (2000) go on to point out that children are using well-known developmental mechanisms to acquire words (including speech processing, imitation, concept formation, and theory of mind)—but these mechanisms cannot reduce to associationism. See also Baldwin, 1993; Bloom, 2000; Diesendruck, Markson, Akhtar, and Reudor, 2004; Golinkoff and Hirsh-Pasek, 2000; and Woodward, 2000, for further arguments that associationism cannot be the sole mechanism of word learning.

Constraints

The central challenge for associationist accounts is to describe constraints that are sufficient to produce just those concepts and developmental phenomena observed. How is it that children acquire the basic concepts in a fairly regular way, without gross deviations? The general answer, for an empiricist view, is that the structure of the input is responsible. A major focus of research has been to demonstrate that basic conceptual distinctions can be recovered from low-level features of input. This demonstration requires first showing that the relevant associations are present in children's experiences, and second, that children are sensitive to them. A challenge for this line of theorizing is to explain the associations that are *not* extracted (Keil, 1981). Of all the possible concepts that might be constructed given a child's experience, why is it that he or she comes up with just the standard set rather than some others?

Another way to put this is that developmental accounts also need to have something to say about when a concept *isn't* learned or *doesn't* change. All approaches try to characterize why children have the concepts they do. Yet why are children at times resistant to instruction or input? Innate constraints deal with this by saying that

the concepts aren't part of the innate tool kit children bring with them. The theory approach talks about a mismatch between competing conceptual systems—incommensurability between the child's preexisting concept and the instructional lesson. An empiricist approach would presumably say that past experience outweighs current input, but would also predict that eventually new input could override the old.

Associationist theories have begun to address this issue by looking at variations in experience to track just how alternative conceptions may be acquired. Cross-linguistic experience may be one of the key contexts. As mentioned, Japanese and English provide different cues regarding the animate-inanimate distinction, and young speakers of English versus Japanese seem to classify boundary cases differently (Imai & Gentner, 1997; Yoshida & Smith, 2003). These are important and provocative demonstrations. What is not yet known is how deep this mechanism is for development. Does this variation illustrate how infants *build* an ontology, or instead how children *tweak* an ontology? Strict associationist models may need to be supplemented with some innate dispositions, such as attentional biases (Rakison, 2003a).

Conceptual Variation

A challenge for associationist accounts comes from claims that associations can account for all concept learning. Children are sensitive to patterns of covariation and basic similarity relations; yet mature examples of concept acquisition seem to extend beyond associations. Students in an advanced physics class are learning radically new ways of conceptualizing. Although physical intuitions, supported by long experience, continue to organize some aspects of thinking (diSessa, 1996), people also acquire abstract theoretical concepts that have no simple basis in associations given in experience. Is association the best way to characterize the processes of verbally and socially mediated learning? Most of us know the sun is a star (concept) and causes radio interference (causal relation) not because we have done the covariation analyses, but because other people have told us.

It is not clear whether associationists maintain that all thinking and learning is governed by the same basic principles—that cognition is associations “all the way down” (and up?). Rakison (2003b) seems to hold that communication (e.g., “the sun is a star”) just provides associations, though perhaps between nonperceptual

elements. Yet he also identifies “formal learning” in which people develop and apply explicit theories (Rakison, 2003b, p. 175). If both associationist and nonassociationist mechanisms of concept acquisition are possible, then the complex question becomes when is each active? Just because it is possible to acquire some concept through analysis of associations, is that the way that people typically do it? Associationist arguments for parsimony and simplicity also lose some force. If adolescents in school use various means of acquiring concepts, this would at least raise the possibility that these mechanisms are also available earlier in development (Gopnik et al., 1999).

Conceptual Placeholders

There is a broad class of proposed mechanisms that we may call “placeholders.” Conceptual acquisition does not occur all at once. Instead, the initial representation of a concept is a partial structure containing information about what more can be learned about the concept. Such partial representations underlie the “fast mapping” abilities to acquire concepts from brief and fragmentary presentations that make children such prolific word and concept learners (Carey, 1978). One area of current debate around conceptual placeholders is whether general principles of associative learning can produce such intuitions or whether their origins must be traced to innate structures or other learning mechanisms (Diesendruck & Bloom, 2003; Samuelson, 2002).

Words as Pointers

Words seem to provide conceptual placeholders for children even at the dawn of word learning (Waxman & Markow, 1995). We have already seen that children assume that objects with the same label have common underlying properties (S. A. Gelman & Markman, 1986). Waxman and Markow (1995) refer to count nouns as “invitations” to form categories and look for relevant conceptual correlates: Common labels lead children to search for commonalities; distinct labels lead children to search for differences (see also Waxman & Lidz, Chapter 7, this *Handbook*, this volume). When hearing two items labeled with a word, even 9-month-olds are more likely to attend to relevant categorical similarities (Balaban & Waxman, 1997). Thus, children do not assume that labels are mere conveniences—ways of efficiently referring to perceptually encountered information in a shorthand way. Instead, children expect

certain labels—and the categories to which they refer—to capture properties well beyond those they have already encountered.

The naming effect is particularly relevant in borderline or atypical cases, in which a nonlinguistic analysis might diverge from labeling. Children show these effects as early as 12 months of age—the very initial stages of word learning (Graham, Kilbreath, & Welder, 2004). In related work, Xu (2002) finds that hearing two identical labels for two objects encourages infants to treat them as the same kind of thing, whereas hearing two different labels for two objects encourages children to treat them as two different kinds of things.

Words can also serve as placeholders merely by linking to other words. Shatz and Backscheider (2001) have found that preschool children learn “word-word mappings” (e.g., that blue, green, and red are all kinds of “colors”) before they have any conceptual content, that is, before they develop the appropriate “word-world mappings.” The sketchy placeholder notion is that these words go together and form some sort of semantic domain. Only later does this minimal placeholder get linked to real-world referents. Shatz and Backscheider demonstrated evidence for these mappings in the domains of color words and number words. The phenomenon may be broader still. Consider that many concepts are acquired through language (oral or written; see Sternberg, 1987), and thus the only content for many words may be the surrounding linguistic context. At times, such context will supply rich conceptual information (e.g., if we hear “The tapir chased its prey,” we will infer that a tapir is animate, from which a host of other inferences follow; Keil, 1979). But at other times, the context may supply only a word-word mapping of the sort that Shatz and Backscheider discuss.

The idea of words as conceptual placeholders leads to the question of whether concepts may be in part stored by others in the community rather than wholly stored in the individual child’s mind. Several researchers have proposed that children may be sensitive to a division of labor—both linguistic and cognitive—such that some concepts are mere pointers to bodies of knowledge that only experts can access (Lutz & Keil, 2002; Markman & Jaswal, 2003; see also Coley, Medin, Proffitt, Lynch, & Atran, 1999, for an important distinction between knowledge and expectations). This idea follows from Putnam’s famous example of elms and beeches: He knows they are different kinds of trees, but is unable to tell one type from the other.

After much more extensive argumentation, he concludes, “Concepts just ain’t in the head!”

Experimental evidence suggests that adults defer to experts in matters of naming natural kinds (Malt, 1990; but see Kalish, 1995), and children do so even more strongly (Kalish, 1998). Children readily accept experimenter-provided labels, even when such labels are surprising and counterintuitive (S. A. Gelman & Coley, 1990; S. A. Gelman & Markman, 1986; Graham et al., 2004; Jaswal & Markman, 2002). In a detailed case study, Mervis, Pani, and Pani (2003) provide the example of a child who deferred to adults in the matter of naming, a process they refer to as the “authority principle,” which seemed in place by about 20 months of age in the child under study (Ari). For example, when Ari’s father said, “That birdie’s a cardinal,” Ari accepted that it was a subtype of bird, not a synonym for bird (p. 265). A 2-year-old in one study we conducted even articulated the authority principle explicitly: “I thought it was a stick, but the man [that is, the experimenter] said it was a snake.”

It would be interesting to know the depths of children’s deference to experts. Does it extend across the board in all knowledge domains, perhaps as a result of children’s genuine ignorance about most things, or is it particularly strong in the case of naming? Do children defer to adult naming in all realms (including attribute terms and simple artifacts), or only for natural kinds? What is the developmental course of this willingness to incorporate others’ knowledge? Are young children *most* open to expert knowledge because they are least knowledgeable and most in need of adult input? Or does deference to expert knowledge grow as children become more metacognitively aware of their own limitations?

More specific structures for concepts may be encoded by overhypotheses (Goodman, 1955; Shipley, 1993). Overhypotheses specify the kinds of features or dimensions that will be represented in a concept. Four-year-old children have a general expectation that, for animals, members of a kind tend to be alike with respect to habitat, diet, and movement. More plainly put, this means that when children encounter a novel kind (e.g., wallabies), they assume that members of this kind will all tend to live in the same kind of habitat, eat the same kinds of food, and move in the same manner—even before they learn the habitat, diet, or movement of a single instance. In this respect, children’s category-based in-

ferences partly reflect a specifically *biological* theory of animal kinds.

Superordinate concepts within a domain may be structured as sets of overhypotheses. Such a structure seems to characterize species of living things (Shipley, 1993) and kinds of illnesses (chicken pox, measles, and so on, Kalish, 2000). There are no necessary and sufficient conditions for something being an illness (Kalish, 1994). Rather, the superordinate concept of illness involves a representation of the kinds of properties that will characterize each kind of illness. Kinds of illnesses each specify values on the same dimensions (cause, cure, symptoms, time course, Lau & Hartman, 1983). Knowing that a concept is a kind of illness provides information about what can be learned about the concept; for example, it will have a characteristic cause and set of symptoms. In contrast, attributes not covered by overhypotheses may be treated as accidental. Like essentialist intuitions, overhypotheses provide means for elaborating on initial representations of concepts.

Modes of Construal

How does domain-specific knowledge come about? Some suggest that many domain differences lie neither with the perceptual structure nor with the conceptual organization of the domain itself, but at the level of more abstract mechanisms or modes of understanding that come to be incorporated in different domains (Keil, 1994; Sperber, 1994). A relatively small number of modes of understanding (or modes of construal) have been proposed: an intentional mode, a mechanical mode, a teleological mode, an essentialist mode, perhaps a vitalistic mode (Inagaki & Hatano, 2002; Morris, Taplin, & Gelman, 2000), and a deontological mode (Atran, 1996).

Modes of construal involve recruiting fairly abstract representations of entities and interactions for explanatory purposes. Treating a phenomenon as involving goal-directed action provides a model or lens that directs explanations into certain forms. Positing an overarching goal suggests there might be subgoals, barriers to achieving goals, and adjustments to goal failures, and so on. Additional information about the system or phenomenon will serve to elaborate the general framework. What kinds of goals are pursued? What kinds of capacities for adjustment are present?

A good example of children’s use of modes of construal can be found in Kelemen’s work on teleology

(Kelemen, 1999, 2004). Young children seem prone to ascribe functions to objects in their experience. They adopt the functional stance of asking “What is this for?” From an adult perspective, young children apply this mode of construal too widely. They think of naturally occurring objects, such as rocks and rivers, as having functions (Kelemen, 1999). Young children do not at first make the distinctions that older children and adults do. For adults, artifacts have functions because people make them for specific reasons; living things have functional parts because of a history of selection; and non-living objects may be used for purposes, but are not generally thought of as having functions. Such distinctions may be absent from young children’s application of a teleological mode of construal.

Modes of construal are not uniquely assigned to particular domains. An essentialist mode would fit well with domains in which categories seem to capture clusters of information in the face of outward variation (such as living kinds), but would not be exclusively biological in any fixed sense. In several publications, Keil suggests that the linkage between mode of construal and domain occurs as children and adults search for resonances between modes of construal and the “real world structure” (1994, p. 252). Elsewhere he elaborates, proposing that “much of our adult intellectual adventures involve trying to see which mode of construal best fits a phenomenon, sometimes trying several different ones, such as thinking of a computer in anthropomorphic ‘folk-psychology’ terms, in fluid dynamic terms, or in physical-mechanical terms” (1995, p. 260).

The advantage of this approach is that it can accommodate phenomena such as essentialism that are broad in scope (e.g., applied to nonbiological categories, which is difficult for a biological modular position) but not promiscuous (e.g., not all categories are essentialized, thereby arguing against a wholly domain-general account).

Causal Learning

Causal learning represents something of a bridge between associationist mechanisms and theory-based mechanisms. The inputs to causal learning are patterns of covariation. The outputs are representations of causal relations that would form the basis for theory building. Most accounts of causal induction within psychology focus on the problem of learning whether a

causal connection exists between a set of given entities (Cheng & Novick, 1992; Shanks, Holyoak, & Medin, 1996). Such learning can be an important source for new concepts. Theory-based accounts hold that concepts form around networks of causal relations. As noted, features that are causally related are more central to a concept than those with merely spatial, temporal, or similarity associations.

Accounts of causal induction based on Bayesian networks have even more direct implications for conceptual change (Glymour, 2001; Pearl, 2000). Algorithms based on Bayesian networks also generate predictions about the existence of hidden variables. Given certain patterns of conditional dependence and independence between a set of entities, a learner might conclude that some additional, unknown entity is having a causal influence. Such a conclusion effectively provides the learner with a new (placeholder) concept: the kind of thing with such causal powers. The learner acquires not just new beliefs about relations between existing entities, but ideas about novel kinds of entities. These and other features of Bayesian networks seem to hold great promise as accounts of theory and conceptual development (Gopnik, Glymour, Sobel, et al., 2004).

Children as young as 2 years of age draw causal inferences from patterns of covariation (Gopnik, Sobel, Schulz, & Glymour, 2001). Gopnik and Sobel (2000) conducted studies in which 2-, 3-, and 4-year-olds learned that a novel object with a novel name (e.g., a “blicket”) had a certain causal power (placing the object on a machine would, apparently, cause the machine to light up and play music). Results indicate that even 2-year-olds use causal information to guide both naming and induction. For example, objects that had the same causal effects were more likely to receive the same label than objects sharing perceptual appearance (but differing in causal powers). Importantly, merely being associated with machine activation (the experimenter activates the machine while holding the object nearby) does not produce the same effects. Thus, correlational information alone did not determine children’s naming. Instead, even 2-year-olds used causal information to guide both naming and induction.

One of the critical elements of Bayesian causal inference is the idea of conditional independence (Gopnik et al., 2004). Suppose one notices a relation between a set of objects and some causal power: Whenever a blue object and a red object are placed on a machine, the machine

beeps. A way to identify which object is causing the beeps is to look for conditional independence. What happens given only the red or only the blue? If we observe an effect given only blue but none given only red, this pattern suggests that the blue object is the cause of beeping (beeping is independent of red given blue). Such patterns have the capacity to provide novel concepts. Critically, this kind of deconfounding seems distinct from mere inconsistent correlation. In this example, blue is associated with beeping 100% of the time, red only 50%. Producing the same rates of association without evidence of conditional independence (e.g., by showing two successful blue-only trials and one success and one failure with only red) does not produce the same effect. In cases of inconstant versus constant conjunction, children are at chance at selecting the causal object (Schulz & Gopnik, 2004). In contrast, the demonstration of conditional independence leads to reliable causal intuitions. Children even override existing domain-specific intuitions when patterns of conditional independence indicate novel causal relations (Schulz & Gopnik, 2004). As theories grow in complexity and scope, through causal learning and other mechanisms, so too will concepts.

Causal learning mechanisms raise a difficult question: If people seek causes, explanations, and nonobvious properties, then why is adults' knowledge in many domains so shallow, incomplete, and in error? If there is any doubt as to the truth of this last part of the paradox, we need look no further than the fundamental attribution error (Nisbett & Ross, 1980), error-laden reasoning heuristics (Kahneman, Slovic, & Tversky, 1982), and gaps and flaws in logical analyses (Johnson-Laird & Byrne, 1991). There are several relevant issues here. One issue is that gathering and evaluating evidence is difficult, even when children attempt to identify causes (D. Kuhn, 1989). The impulse to explain phenomena and discover causes is powerful even in childhood, but the scientific method poses difficulties throughout the life span. The question of when and how evaluation of evidence is relatively easier or more difficult is complicated and beyond the scope of this chapter. Kuhn and Franklin (Chapter 22, this *Handbook*, this volume) provide a more detailed discussion of the difficulties children face when attempting to coordinate prior expectations with new data (as contrasted with isolating causes in a multivariate context, which children do with greater ease). Another issue is that people tend to be satisfied with shallow explanations (Keil, 1998) and in fact have the illusion that their explanatory knowledge is deeper than it

actually is (Keil, 2003; Mills & Keil, 2004). When trying to figure out how a cell phone works, we do not seek, in an infinite regress, the electrical engineering principles that allow it to operate. Similarly, when reasoning about biological species (as well as social kinds), children appeal to underlying causes without constructing highly accurate biological models.

Summary

Associationist and similarity accounts are powerful mechanisms in concept development, but appear to be insufficient in and of themselves without positing further conceptual and theory-building capacities. Such capacities include the two mechanisms reviewed here (conceptual placeholders and causal learning accounts), as well as other means of extending knowledge, such as structure mapping (see Larkey & Love, 2003, and A. Markman & Gentner, 2000, for review). Evidence for similarity cannot be taken as evidence *against* theories (and vice versa: evidence for theories does not argue against similarity). Rather, the two classes of accounts are likely to be mutually beneficial.

A relatively unexplored question is how information-processing demands are related to the development of intuitive theories. Researchers have explored the link between inhibitory control (IC) and conceptual development in the domain of theory of mind (Perner, Lang, & Kloo, 2002). One hypothesis is that tasks used to assess theory of mind have strong IC demands and thus may mask early conceptual competence. An alternative is that IC is a precondition for conceptual development in the domain of psychology and perhaps for other conceptual domains as well (Carlson & Moses, 2001; Flynn, O'Malley, & Wood, 2004). A third possibility is that, at least in this domain, conceptual development may drive improved information processing. As children acquire new concepts of mental function, they are better able to direct their thinking. Whether information-processing abilities have such a strong relation to conceptual development in other domains is an intriguing area for future research.

EXPERIENCE AND INDIVIDUAL VARIATION

In the beginning of this chapter, we cautioned that concepts do not reduce to experience. Nonetheless, a full

understanding of conceptual mechanisms requires an examination not just of concepts in the abstract, but also of the relation between experiences and conceptual structure. We examine the issue in this section, with a focus on individual variation and input.

Individual Variation

One of the challenges for an account of concepts is addressing the tension between the shared and idiosyncratic natures of mental representations. On the one hand, shared concepts are a prerequisite for communication. On the other hand, each individual has some unique perspectives and associations. It is only because two people share the concept *dog* that they can talk about dogs, yet one representation of dog will differ somewhat from the next. Such conceptual variations are particularly salient when considering cultural differences. When do people have different concepts and when just different representations of the same concept? A similar question arises about conceptual development. In what sense do concepts change rather than undergo replacement? Is a 10-year-old's concept of dog a revised version of the concept she possessed at age 5, or a different concept altogether? In part, the issue of individual differences is the theoretical question of how concepts are identified and individuated. There are also important empirical questions about individual differences. Just how much variability is there across people in their concepts and what are the sources of these differences?

A central question for accounts of conceptual development is whether there is an in-principle distinction between different degrees of conceptual variation. Classical theories made a sharp distinction between differences in definition and differences in characteristic associations. Because *male* is one of the defining features of *bachelor*, people who disagree over whether there are female bachelors have different concepts. Because neatness is only a characteristic feature of bachelorhood, people may share the concept *bachelor* but disagree whether bachelors are slovenly. One of the consequences of a move from classical to similarity-based theories of concepts was abandonment of the distinction between characteristic and defining features. Similarity-based theories treat all conceptual distinctions as matters of degree. No two people ever have exactly the same concept, and no concepts remain the same across changes in experience.

Fodor (1998) sees this consequence of nonclassical theories as unacceptable and concludes that if mental representations provide no absolute basis for identity of concepts then concepts cannot be based on mental representations. Fodor argues, contra similarity theories, that virtually no differences in mental representation affect concept possession. One person's mental representation of *dog* may have nothing in common with another's, yet both have the same concept because both can think and talk about dogs. Such a view underlies the provocative claim cited earlier that meanings "just ain't in the head" (Putnam, 1975).

Foundational knowledge approaches attempt to reestablish the classical dichotomy between core and peripheral representations of concepts. Concepts are grounded within foundational theories. The core of the concept "heat," for example, is grounded in principles of physics. Smith, Carey, and Wiser (1985) describe different theories of physics that include different concepts of heat; a contemporary perspective that distinguishes heat from temperature and an older view that conflates the two senses. People holding different theories had incommensurable concepts; there was no direct way to represent one concept of heat within the conceptual framework of the other theory. Other conceptual differences are more like factual disagreements. Is light a particle or a wave? The concepts of light are different but the holder of one concept can represent the other. The disagreement is about which specific concept is represented. In the history of science, there are clear examples of incommensurable concepts. Carey (1985) argues there are examples across development. To what extent are individual and cultural differences characterized by incommensurability?

With these distinctions in mind, we now turn to variation due to expertise and variation due to cognitive style.

Expertise

One of the most striking findings in the study of concepts is that young children can become highly expert in a domain, and that expertise has consequences for how concepts are organized (see Wellman & Gelman, 1998, for review). In a set of classic demonstrations, Chi and her colleagues found that young dinosaur experts not only had a larger set of facts at their disposal, but also organized this knowledge into a more cohesive hierarchical network of knowledge that permitted inductive inferences (Chi, Hutchinson, & Robin, 1989; Chi &

Koeske, 1983; Gobbo & Chi, 1986; see also Lavin, R. Gelman, & Galotti, 2001, for related findings with child Pokémon experts).

A particularly impressive example of the benefits of expertise can be found in Mervis, Pani, and Pani (2003), who report a detailed case study of a child bird expert between 10 to 23 months of age. This child had acquired 38 labels for types of birds, organized them into an appropriate hierarchical organization, and recognized the principle that baby animals must be the same species as their parents, even if they look like something else. Child experts also experience many other cognitive advantages in memory organization and problem solving (Chi et al., 1989; Gobbo & Chi, 1986). In the domain of theory of mind, children who have greater opportunity to engage in thinking about mental states develop more rapidly (Perner, Ruffman, & Leekam, 1994; Peterson & Slaughter, 2003).

Expertise affects conceptual organization even for adults (Medin, Lynch, Coley, & Atran, 1997; Shafto & Coley, 2003; Tanaka & Taylor, 1991). Medin and colleagues have found that expertise can lead to qualitatively distinct reasoning strategies. Whereas college undergraduates use diversity among premise exemplars as a basis for generalizing new facts about trees, tree experts do not. Further, experts develop unique conceptual schemes, such as quantum physics, population genetics, or dynamic systems models of psychology. It remains something of an open question whether such expert concepts actually replace foundational knowledge structures or whether expert knowledge remains a supplement alongside foundational knowledge (Carey & Spelke, 1994). Do physicists really experience objects as clouds of wavicles? Can mathematicians conceive of an N-dimensional object? Can biologists give up the decidedly nonbiological concept of tree?

Expertise is a phenomenon that leads to several key observations. First, it argues against qualitatively distinct, domain-general constraints on children's conceptual structures. At least some 2-year-olds *can* form taxonomic hierarchies and classify counter to outward similarity. Second, expertise demonstrates the importance of detailed experience. Third, expertise seems to increase conceptual interrelatedness (see also R. Gelman, 2002).

To some extent, the implications of expertise have not yet been fully tapped. Well-documented case studies of "naturally occurring" expertise tell us a great deal—but how far can expertise take the child? Can children acquire truly novel conceptual structures, with sufficient

expertise (and, importantly, sufficient motivation)? The broader, more difficult question that these findings raise is the following: Can different experiences result in different foundational concepts (see Slobin, 2001, for the suggestion that they can)?

Cognitive Style

Cognitive style is a venerable idea that seems to be coming back in new form. Whereas prior work on cognitive style tended to focus on broad personality differences along dimensions such as creativity, field-dependence, and reflectivity-impulsivity (e.g., Kogan, 1983), current research suggests more local individual differences in conceptualization. At present, several unrelated findings are provocative for reminding us that conceptual development is not all of one piece. Here we discuss style differences in flexibility, essentializing, intense interests, and attention to thematic relations.

Deák (2003) has been pursuing the issue of conceptual flexibility. To measure conceptual flexibility, he constructed a word-meaning induction task, where children are given a linguistic cue to help them figure out the meaning of a new word. For example, a child might see a novel alien, hear a novel word in one of three predicate forms (e.g., "looks like a plexar," "is made of plexar," or "has a plexar"), and be asked to select another instance with the wording that was used during instructions (e.g., "Find another one that is made of plexar"). This task reveals marked developmental change between 3 and 6 years of age in children's ability to infer meaning *flexibly* (e.g., to switch from "looks like" to "has"). Deák notes that preschool children also vary considerably from one another in performance. Correlations between different versions of the task were fairly high, suggesting consistent individual differences among 3- and 4-year-olds.

Another kind of broad individual difference concerns children's preference for thematic versus taxonomic relations. Taxonomic relatedness is based on shared similarity—cows and horses are alike in that both are alive, have four legs, eyes, and so on. Thematic relatedness is based on interrelatedness in the world—cows and milk go together because cows give milk. The two kinds of relations are at times overlapping (cows and horses also share thematic relatedness, in that they both are found on farms). Although prior theorists had suggested a "thematic-to-taxonomic shift" (e.g., Smiley & Brown, 1979), more recent studies with young children have found no clear thematic preference even in young chil-

dren (Blanchet, Dunham, & Dunham, 2001; Dunham & Dunham, 1995; Gelman, Coley, et al., 1998; Waxman & Namy, 1997). Some find a thematic bias across ages (Greenfield & Scott, 1986), some find a taxonomic bias overall (Dunham & Dunham, 1995), and others find highly mixed responses (Waxman & Namy, 1997). Moreover, adults are not averse to thematic relations, leading Murphy (2002, p. 838) to bluntly conclude: "[T]he idea of a thematic-to-taxonomic shift is wrong."

What is interesting in the present context is that individual differences in thematic versus taxonomic preferences at age 3 can be traced back to individual differences in behavior at 13 and 24 months of age (Dunham & Dunham, 1995). The authors propose that individual differences in perceptual-cognitive styles may be responsible. Likewise, Lin and Murphy (2001) find large individual differences in adult responses—some opting for thematic responses, others for taxonomic responses. Whether these adult patterns reflect anything stable, or instead momentary response strategies, cannot be known without further tracking the stability of these individual differences over time and contexts.

Individual differences in conceptual flexibility and thematic relatedness are (presumably) domain-general. In contrast, other kinds of individual differences in children's concepts seem to function at a more domain-specific level. An intriguing (though little-understood) example is that of intense interests (Simcock, Macari, & DeLoache, 2002). Certain children from a very young age become deeply fascinated with particular content areas, and develop highly specialized vocabularies and knowledge bases concerning those areas. This can be seen in cases of atypical development (e.g., Asperger syndrome), but also in normal development. These examples deserve further study. One question is whether there are stable differences in the intensity of specialized interests. Another concerns whether the concepts that develop in such cases are qualitatively distinct from those in nonintense domains. A further question is one of motivation: These children have highly developed motivation that leads them to attend to relevant inputs in a much more focused way; what are the effects of this motivational stance? If an "intensely interested" child and a "nonintensely interested" child were to get equal exposure to a novel concept in the relevant domain, would their representations vary significantly? In a sense, these children provide a special look at the expertise questions raised earlier.

A further content-specific example of individual differences concerns essentialism. Adults differ from one another in the degree to which they endorse essentialist views (Haslam, Rothschild, & Ernst, 2000). What about children? An example of individual variation in essentialist reasoning comes from children's beliefs about intelligence (Dweck, 1999). Dweck finds stable individual differences in this regard, with some children consistently endorsing an "entity" theory (that intelligence is fixed and immutable; in other words, an essentialist theory) and other children consistently endorsing an "incremental" theory (that intelligence is flexible and can be improved with practice and experience; in other words, a nonessentialist theory). These differences can be seen in children as young as first grade, and have powerful implications for children's persistence in the face of failure by fifth grade (Cain & Dweck, 1995). When entity theorists fail on a task, they more or less tell themselves, "I'm no good, so there's no point in my trying any more." When incremental theorists fail they tell themselves, in effect, "I need to improve, so I'd better try harder next time."

Even below first grade, children show individual differences in their beliefs about the stability of antisocial behavior (Giles & Heyman, 2003; Heyman, Dweck, & Cain, 1992). Among kindergartners, the belief that someone who misbehaves at the present time will always misbehave, is associated with "motivational vulnerability" (feeling as if one mistake means you are not smart, and difficulty generating strategies to solve academic difficulties; Heyman et al., 1992). And among 3- to 5-year-olds, the belief that antisocial behavior is stable is associated with the tendency to agree that hitting someone is an appropriate means to solve problems and with lower teacher ratings of children's social competence (Giles & Heyman, 2003). Although judgments of stability are not equivalent to essentialism, they are an important component.

The research literature on individual differences in conceptual development, though relatively sparse and scattered, is suggestive. Both domain-general and domain-specific differences have been suggested. Future research would do well to explore these in greater detail.

Input

People learn from each other as well as by direct experience. Tomasello (1999) argues that such cultural learning is in fact an important contributor to what makes

human conceptual systems human. This can be illustrated with examples both lofty (conceptual systems that are embedded in language and passed from one generation to the next, such as biological taxonomies) and mundane (individual facts, such as how to use a particular tool). Most of us did not acquire the belief that cigarette smoking causes cancer from direct experience of patterns of covariation; rather, this information was communicated to us from others (Ahn & Kalish, 2000).

Language can be an important source of information about novel causal and conceptual relations. Sperber (1996) provides the hypothetical example of the young child learning about plant reproduction who encounters the claim that there are male and female plants. The connection between the concepts of gender, plants, and reproduction may be largely incomprehensible at first. Such connections, though, provide a spur to theory development that ultimately generates enriched concepts. Similarly, children who are unable to receive detailed parental input perform much more poorly on false belief tasks, apparently reflecting their lack of opportunity for the conceptual enrichment provided by fully complex conversations (Peterson & Siegal, 2000).

We emphasize that more detailed characterizations of the input are needed. For many years, researchers have rightly focused on characterizing children's conceptual systems, with relatively little attention paid to the kinds of information children receive. Yet for a full understanding of what children bring to the task of conceptual learning, we also need to know much more about what they hear. Both matches and mismatches are informative. For some useful examples, see Jipson and Callanan (2003), Crowley, Callanan, Jipson, et al. (2001), S. A. Gelman, Coley, et al. (1998), and Sandhofer, Smith, and Luo (2000). Even in accounts that depend heavily (theoretically) on knowing what the input is, better characterizations are needed. For example, Smith (2000) makes assumptions about what children are exposed to based on what the *children* produce; it will be important to discover how tightly children's productions follow the input. Microgenetic methods also offer great potential for examining conceptual change as it occurs, with specific focus on the role of input (Opfer & Siegler, 2004; Siegler, Chapter 11, this *Handbook*, this volume; Siegler & Crowley, 1991).

Another point that arises from this work is the subtlety of the input that children are getting. In the case of psychological essentialism, parents provide no direct es-

sentialist talk to their young children, but they do provide a wealth of *implicit* essentialism talk (e.g., talking about categories with generic noun phrases, "Bats live in caves," thereby implying that bats as a group are alike). See also S. A. Gelman, Taylor, and Nguyen (2004) for a detailed examination of the implicit ways that mothers emphasize gender categories to their preschool children, including referring to gender categories, providing gender labels, contrasting males and females, and giving approval to their children's stereotyped statements. Another example of implicit input comes from a study of parental talk to children during a visit to a science museum: Parents are more likely to explain science concepts to boys than to girls, despite talking equally often about the exhibits to girls and boys (Crowley, Callanan, Tenenbaum, & Allen, 2001). Subtlety in input can also extend to fine-grained conceptual distinctions. Sandhofer (2002) found that subtle aspects of parental input (e.g., either emphasizing the categorization of single objects, or emphasizing the comparison of multiple objects) seems to have implications for how children learn dimensional adjectives. Findings of subtle input cues and rich child concepts provide a pattern that is most consistent with interaction between the child's expectations and parental cues.

Considerations of input lead us to an important puzzle that is only now beginning to receive serious attention. Namely, what counts as knowledge or facts to a child's developing theories? Most strikingly, how do children screen off fiction, pretense, and metaphor from their factual knowledge base? How can a cartoon inform children that sponges are found in the sea without also convincing them that sponges walk, talk, and wear square pants? Or consider that an episode of *Sesame Street* might use singing Muppets to explain that animals but not rocks are alive. There are potentially numerous generalizations a child could form, including the biologically correct one (which things are alive) as well as biologically incorrect ones (that puppets talk and sing). Interestingly, 2-year-old children treat information differently depending on whether they believe it is coming from a TV screen versus being watched through a window directly (Troseth & DeLoache, 1998), suggesting that they may have some mechanisms for tagging certain kinds of input as not-real. Furthermore, 3- and 4-year-olds are skeptical of statements made by a speaker who previously said untrue things (Koenig, Clément, & Harris, in press). Presumably these assessments operate at a

level other than the usual process of source-monitoring, which children (and adults) find difficult to track (Lindsay, Johnson, & Kwon, 1991).

Pretense is another interesting case. Does a child who sees her mother talking on a banana get confused about bananas and telephones? Lillard and Witherington (2004) make the interesting proposal that in the case of pretense, implicit cues in the input guide children to a nonliteral interpretation. When mothers pretend to have a snack with their 18-month-olds (versus really have a snack), they differ in behavioral variables, including talking about their behaviors, sound effects, increased smiling, and increased looking at the child. Importantly, children are sensitive to several of these behaviors.

Natural language, too, can be highly misleading regarding domain distinctions. Metaphors—including unintended metaphors—are rampant in everyday talk (Lakoff, 1987). We say that cars, batteries, and (alas) computers “die”; that deficits, crystals, and feelings “grow”; and the like. Are children ever misled by these cases? Are metaphorical uses somehow marked (by context or inflection) as nonliteral? Or do these observations imply that linguistic predicates have rather minimal consequences for children’s developing theories?

The complexity of these issues suggests that existing concepts place constraints on new concepts. The nature of these constraints is currently largely unknown and will be fruitful to address in future research.

CONCLUSION

The competing theoretical positions outlined in this chapter reflect a tension between two realities: children master so much so quickly, yet at the same time a young child still has so far to go before achieving adult competence. This tension can be seen in the competing metaphors of children (e.g., children as novices, as aliens, and as little adults; Wellman & Gelman, 1998).

Interleaving Mechanisms

As we suggested earlier, there is no principled reason why different theoretical approaches could not be combined to account for conceptual learning even within a particular domain. R. Gelman (2002) reminds us that *innate* and *learning* can go hand-in-hand. This point is unquestionable in other species. For example, white-

crowned sparrows typically produce a characteristic song that has an innate template (acquired only by birds of this species) yet requires appropriate input between 10 and 50 days of age (Marler, 1991). In short, the song is both innate and learned.

An example that is closer to the current case can be seen in the domain of word learning, which overlaps considerably with concept learning (Waxman & Lidz, Chapter 7, this *Handbook*, this volume; but see Clark, 1983, for an important distinction between concepts and word meanings). Woodward (2000) proposes that different levels of explanation work together when children acquire word meanings, arguing strongly against monolithic accounts that try to explain word-learning wholly (or even primarily) in terms of just one kind of factor. Although theorists often argue for a particular position (e.g., social-constructivist, constraints-based, or associationist), she notes that each position explains different developmental phenomena. As she puts it, “There is no silver bullet for word learning” (p. 174).

We also have a sketch of how such coordination among levels might look, when considering the acquisition of intentions (the purposes that underlie actions). “Intention” is a concept informed by theory of mind. There are certainly many examples of intentions that are hidden, nonobvious, in conflict with surface cues, and that require understanding a web of motives, goals, and desires. Much of legal reasoning entails attempting to discern intentional from accidental action, on the basis of ambiguous behaviors for which multiple stories can be told. Nonetheless, despite the theoretical richness of the concept, Baldwin (2003) outlines how low-level patterns in the available percepts could form a basis for children’s initial ability to detect intentions. She proposes that domain-general skills for covariation detection, sequence learning, and structure mapping may give rise to the detection of intentions (judging whether or not something was purposeful). For example, subtle cues regarding the acceleration of limbs toward goal objects might provide characteristic information about the beginning and end points of intentional sequences:

predictable patterns emerge again and again in the sequencing and temporal dynamics of bodily motion that are probably unique to intentional action, and that correlate with the initiation and completion of intentional acts. For example, to act intentionally on an inanimate object, we first must locate that object with our sensors. . . . We then typically launch our bodies in the direction specified by

our sensors, extend our arms, shape our hands to grasp the relevant object, manipulate and ultimately release it. . . . All of this typically coincides with a characteristic kind of ballistic trajectory that provides a temporal contour or “envelope” demarcating one intentional act from the next. . . . This is all to say that on a purely structural level—the level of statistical regularities—there is considerable information correlated with intentions that is inherent in the flow of goal-directed action. Differing statistical patterns may even arise for intentional as opposed to unintentional action; for example, in intentional action we first locate with our sensors, and then display directed bodily motion. In unintentional actions, such as stubbing one’s toe or slipping on a banana peel, motion comes first and location with sensors after the fact. (Baldwin & Baird, 2001, p. 174)

Initial evidence suggests that infants are sensitive to some of these low-level cues (Baldwin, Baird, & Saylor, 2001; Behne, Carpenter, Call, & Tomasello, in press). Importantly, the proposal is not that intention-detection reduces to low-level pattern detection, but rather that pattern detection jump-starts and facilitates intention detection. This integration of approaches seems to hold great promise for a full understanding of conceptual development.

Beyond Initial Understandings

Much of the research on children’s concepts that we have reviewed focuses on initial states and early frameworks—concepts in the first few years of life—in infants, toddlers, and preschool children. This is so for very good reason. Some researchers focus on this period to uncover developmental primitives; others do so to reveal developmental change. These initial states and early frameworks are critical to any understanding of concept acquisition. If nothing else, research on cognitive development over the past 30 years convinces us of the sophistication of conceptual processes in the ages 0 to 5 years. The process of acquiring concepts in young children cannot simply reduce to the models for adding on new concepts in adults (Markman & Jaswal, 2003; Rakison, 2003b). This central early period of concept development remains a highly fertile ground for future research.

Later developments are also critical—and perhaps even less well understood. Conceptual development is open-ended: We do not acquire all our concepts by age 5, or 10, or even 45. Issues of conceptual change can continue throughout a person’s life. We have seen

glimpses of the complexities children face in trying to integrate bits of conceptual knowledge, adjudicate domain boundaries, and wrestle with incommensurate conceptual systems. Children also must consider larger cultural messages (Astuti, Solomon, & Carey, 2004; Coley, 2000; Lillard, 1999). Furthermore, later childhood raises important practical issues of the implications of basic research on conceptual development to issues of education and instruction (e.g., Au & Romo, 1999; Evans, 2000; Vosniadou, Skopeliti, & Ikospentaki, 2004). Schooling is only the most formal context in which conceptual change takes place. Any sort of communication (e.g., hearing a story, reading a newspaper) or informal learning (visiting a museum or zoo, tending a garden) depends on, and potentially modifies, existing concepts. To return to the metaphor that opened the chapter, if concepts are the building blocks of thought, manipulating these blocks is not mere child’s play. The complexities of concepts and conceptual change are fundamental issues, and many puzzles remain.

CHAPTER 17

Development of Spatial Cognition

NORA S. NEWCOMBE and JANELLEN HUTTENLOCHER

DEVELOPING TOWARD MATURE SPATIAL COMPETENCE	736
Do We Need Cognitive Constructs?	736
What Is the Nature of Mature Competence?	737
What Is the Nature of the Referent System?	740
What Does Symbolic Spatial Representation Add?	741
Summary	741
THE SPATIAL CAPABILITIES OF INFANTS	742
The A-not-B Error	742
Egocentric to Allocentric Shift	743
What Is an Object?	744
Summary	745
MODULARITY OR ADAPTIVE COMBINATION?	746
Modular Spatial Processing	746
The Development of Spatial Processing from an Adaptive Combination Point of View	749

For animate creatures, directed movements in space are critical for survival. Turtle hatchlings make their way to the sea, seed-caching birds hide and retrieve myriad tiny pieces of food, and human beings move around their houses, go to work or school, complete a variety of errands, and occasionally travel to distant and novel locations. Although these activities differ in many ways, they all involve using spatial information about the world to determine the direction of movement that permits obtaining a desired goal. Thus, the ability to deal with the spatial environment is a problem that evolutionary forces can be expected to have acted on in an important way. For developmental psychologists, this fact frames three vital issues about spatial knowledge and its development.

First, because spatial abilities are essential for survival and are found even in very humble organisms, spatial development provides an interesting arena in which to consider the question of the origins of human knowledge. Answers to this question in philosophy and in psychology have varied from extreme nativism to radical

REPRESENTING SPATIAL RELATIONS BETWEEN VIEWER AND ENVIRONMENT	755
Mental Rotation and Perspective Taking	755
Navigation	756
USING SYMBOLIC SPATIAL REPRESENTATIONS	758
Maps and Models	759

empiricism. On the face of it, spatial development is an excellent candidate for a domain with strong innate underpinnings, due to its adaptive significance for all mobile organisms. Piaget, however, offered a developmental theory in which innate underpinnings of spatial understanding were rather humble, hypothesizing that simple sensorimotor experiences such as reaching are the departure point for a gradually increasing spatial competence that emerges from the interaction of children with the world. His approach dominated developmental thinking about space for several decades, and inspired a great deal of research, some lines of which are still active. Recently, however, there has been a return of interest in a more strongly nativist theory in which infants come equipped with specific knowledge of the spatial world, along with similar specific understandings of domains such as language, physical causality, and number (e.g., Spelke & Newport, 1998).

The question of what capabilities are available at the start of life is obviously of central importance to understanding the origins of knowledge. However, debate

about infant capabilities is only one aspect of research on this issue. Understanding the mature cognitive architecture to which the developing child is headed also has crucial implications for the origins debate. An important specific issue concerns the extent to which adults combine various kinds of spatial information. In a modular view, various sources of spatial information are processed independently in separable cognitive processing units (e.g., Wang & Spelke, 2002). In alternative models, information sources are combined, using mechanisms that weight sources based on their potential usefulness (e.g., Ernst & Banks, 2002; Huttenlocher, Hedges, & Duncan, 1991). Modularity is typically associated with nativist views, although this relation is by no means forced by logic (Fodor, 2001). Similarly, the adaptive combination view is often associated with empiricism because it seems natural to suppose that the weightings in an integrative process are affected by experience. However, it would also be possible to suggest that they are innately specified.

A second question that emerges from an evolutionary perspective regarding human spatial knowledge concerns development over evolutionary time. Understanding the ability of our species in full requires comparing our spatial capacities with the spatial capacities of other species. To what extent do humans share basic aspects of spatial adaptation with other species and in what ways might we be unique? Work on nonhuman animals has revealed many cross-species similarities, but also shows striking differences across species, with some distinctive characteristics of human spatial orientation (for reviews of the literature on spatial behavior in other species, see Jacobs, 2003; Jacobs & Schenk, 2003; Shettleworth, 1998). On the one hand, humans lack certain sensory mechanisms that other species rely on, such as a magnetic sense that would orient us directly to true north, or olfactory, tactile, and sonar sensitivities that could be used for spatial localization. On the other hand, humans also show certain spatial capabilities that other species do not possess. Most notably, our capability for complex internal processes allows us to represent entire spatial scenes from various perspectives and to visualize objects undergoing rotational transformation. Humans can utilize these symbolic abilities to communicate about the spatial environment in a flexible and powerful fashion and to carry out imagined activities in thought, as when reasoning about the behavior of gears or pulleys (Hegarty, 2004). In addition, these symbolic spatial mechanisms can be used to structure thought in

nonspatial domains. For example, people can imagine a set of items that vary along some dimension, such as intelligence or beauty, in terms of a spatial ordering that preserves information about order in that domain. The use of such orderings can support transitive reasoning (Huttenlocher, 1968) and has been shown to engage areas of the brain used for spatial processing (Goel & Dolan, 2001; Knauff, Mulack, Kassubek, Salih, & Greenlee, 2002). Further, communicative devices such as graphs or flowcharts can be valuable in discovering relations among nonspatial entities (e.g., the relation of poverty with premature birth) (Gattis, 2001; Gattis & Holyoak, 1996). The use of spatial reasoning and spatial symbolism in many kinds of human cognition that are not intrinsically spatial underlines the centrality of spatial processes to wider aspects of human cognitive adaptation.

A third important aspect of spatial development concerns individual differences in spatial skills, and here again, placing our thinking in an evolutionary context raises interesting questions. Since the ability to store and retrieve information about location is critically important, spatial competence might be expected to be a capability that would be under strong selective pressure and thus "canalized," showing a high degree of uniformity in development and eventual outcome. This appears to be true in some but not all cases. On the one hand, for example, although babies differ slightly in the age at which they exhibit certain spatial achievements (e.g., being able to find a hidden object), this variation is relatively small and generally assumed to be unimportant, in part because all normally developing children eventually acquire such understanding. On the other hand, certain lines of spatial development that seem adaptively important show considerable divergence across individuals. For example, the speed and efficiency of mental rotation show large individual differences. Yet mental rotation underlies adaptive functions such as finding desired objects from new vantage points or making tools.

Why do some adaptive spatial abilities show marked individual differences? The answer to this question is not yet clear. Some individual variation may be due to biological mechanisms, variation in which is perpetuated for adaptive reasons we do not yet appreciate, or merely because evolution does not ensure perfect adaptation. Alternatively, variation may reflect differences in the importance of certain spatial activities in the lives of different people, so that common biological potential is realized to variable extents. A challenge for

researchers in cognitive development is to integrate understanding of normative development with understanding of the development of individual differences. Defining the sources of individual differences is basic both to comprehensive theoretical understanding and to the applied goal of maximizing performance in many spatial skills, ranging from basic tasks such as finding one's way to a store or office, to more complex ones such as assembling an electronic device, to even higher-level challenges such as reasoning in mathematics and the physical sciences.

In short, there are many reasons why the development of spatial skill is a central problem in cognitive and developmental science. A goal in the study of spatial development is to answer, with regard to this domain, some of the classic questions in the history of psychology, biology, and philosophy: the extent to which adaptation rests on innately available representations or represents emergent knowledge based on interaction with the world, the uniqueness of our species and the course of comparative evolution, the interplay of symbolic and more basic spatial processes, and the nature of individual differences. In addition, spatial development is an important research area because understanding how it occurs is likely to have considerable practical relevance for devising educational curricula that support optimal acquisition of skills that underlie many essential real-world activities.

This chapter is divided into eight major sections. We begin by describing current views of the nature of mature spatial competence, as well as issues concerning how to assess children's progress toward this adult state. The next two sections concern the two issues we have identified as relevant to the debate concerning the origins of knowledge: what we know about the spatial capabilities that exist in infancy and whether early spatial skills are modular. The fourth and fifth sections deal with capabilities that seem to be distinctively human aspects of spatial adaptation, namely, the capacity for mental transformation of spatial information and the capacity for symbolic representation of spatial information. In the sixth and seventh sections, we examine the development and causes of individual differences, including gender differences, and also consider what we can learn about the nature and mechanisms of spatial development from cases in which children have abnormal bases for learning based on genetic differences (Williams syndrome) or abnormal environmental contexts based on sensory limitations (impaired vision). Fi-

nally, we try to delineate the challenges to be addressed in the next years of research.

DEVELOPING TOWARD MATURE SPATIAL COMPETENCE

Any consideration of how human beings come to develop adult levels of cognitive functioning would seem to begin most naturally with a consideration of the nature of mature competence, which would establish the standard against which to assess the developing capabilities of children. Such a goal is not easily attained, however, because investigation of adult functioning is an ongoing enterprise with its own uncertainties and controversies. (For overviews of research on adult spatial functioning, see Landau, 2003; Newcombe, 2002b; B. Tversky, 2000.) In this section, we concentrate on several key issues in characterizing how human adults process information about their spatial environment. However, we begin with a prior overarching issue involving the conceptual tools we should use, not only in describing mature competence but also in evaluating development.

Do We Need Cognitive Constructs?

In general, cognitive theories posit internal states in explaining intelligent behavior, but questions have been raised about the scientific necessity of doing so (e.g., Brooks, 1991). Those who take a Gibsonian perspective emphasize the role of environmental "affordances" (e.g., Warren, 2005). Investigators working within the dynamic-systems perspective have also argued that we should avoid notions of representation (e.g., Thelen & Smith, 1994). The qualms expressed by these theorists involve the homunculus issue (nothing is explained if a mysterious entity must interpret representations) and the problem of falsifiability (unobservable entities can proliferate in some representational theories). However, representations seem to be needed as principles to explain behavior in various cognitive tasks (Huttenlocher, 2005). While some users of the term *representation* may be guilty of using a plethora of unobservable entities in complex theories that are not easily testable, such problems are not inevitable outcomes of using the construct. Careful work can tie explanations involving the idea of representation to multiple converging operations that can test implications derived from them.

In developmental work, the notion of mental representation can seem especially ill founded because very different results are obtained when small changes are made in test situations, especially with young children. For example, some developmental milestones in infancy seem to be achieved at earlier ages when assessed with regard to looking rather than reaching (e.g., Ahmed & Ruffman, 1998; Hofstadter & Reznick, 1996; Kaufman & Needham, 1999). Similarly, young infants seem to grasp that solid objects cannot pass through other solid objects when studied using habituation-of-looking or violation-of-expectancy techniques (e.g., Spelke, Breinlinger, Macomber, & Jacobson, 1992), but even 2-year-olds have difficulty in using solidity principles in the context of a seemingly simple task involving judging where to search for a rolling ball (Berthier et al., 2001; Hood, Cole-Davies & Dias, 2003; Keen, 2003; Mash, Keen, & Berthier, 2003). Yet another striking example of variations in children's apparent competence, in this case within a single action sequence, occurs when toddlers interact with small objects as if they were much larger (e.g., attempting to enter a toy car), yet as they do so, adjust their actions to the size of the object by, for example, using a precise grip to open the small door of the miniature vehicle (DeLoache, Uttal, & Rosengren, 2004).

Such facts lead certain investigators to reject the notions of representation and of competence as misleading reifications (Thelen & Smith, 1994). However, there are other ways to approach development that recognize the existence of task-specific variability but retain notions of representation and competence. First, in some cases, we can regard the age at first emergence of the simplest version of a competence in the most supportive circumstance as one bracketing date for a developmental process, and the age at which a competence is robustly evident in the most challenging circumstance as a second bracketing date. Along similar lines, we can define competence relative to an ecological standard of what is normally required in everyday life or what is typically possible for normally functioning adults (Newcombe & Huttenlocher, 2000). For example, we regard a digit span of approximately seven numbers as representing mature competence, despite the fact that fewer numbers can be retained when attention is divided or the fact that more numbers can be retained when special strategies are utilized. We do so because we view both distraction and the application of focused chunking strategies as exceptional circumstances.

Second, findings of this kind can be construed as invitations to explore the processes and mechanisms that underlie them, rather than as indicating that cognitive constructs have no utility at all. An example of such an approach comes from research on adults' susceptibility to the horizontal-vertical illusion, in which a horizontal line and a vertical line of equal length are in contact so as to make a capital T or an inverted capital T. Adults judge the horizontal line to be shorter than the vertical line in this display, even though the lines are equal. However, when they are asked to grasp the lines, their hand configurations suggest that they regard the lines as equal (Vishton, Rea, Cutting, & Nunez, 1999). Patterns such as these are often interpreted as indicating the existence of separable systems of thought and of action, or else as suggesting a need to analyze particular situations without positing any abstract competencies. However, exploring further, Vishton et al. (1999) showed that the different behavior patterns depended, not on the contrast between conscious judgment and physical action, but on the fact that the judgment task required a comparison between lines (a relative judgment) while the grasping task focused on a single line at a time (an absolute judgment). Absolute judgments do not show the illusion. Thus, a puzzling dissociation gave way, when probed analytically, to an interesting rule-governed generalization about cognitive functioning, namely that tasks requiring quantitative comparisons can lead to illusions not seen when we deal with quantities one at a time.

Overall then, judicious and careful use of cognitive constructs such as representation and competence are important in both cognitive and developmental psychology. Given this prologue, we proceed to a discussion of the nature of mature spatial competence that revolves around three issues: To what extent are spatial representations accurate and integrated? What spatial referent systems are used in constructing such representations? And, what do external symbolic representations such as maps and spatial language add as compared with internal spatial representations taken alone?

What Is the Nature of Mature Competence?

Piaget and Inhelder (1948/1967) suggested that mature spatial competence is accurate, metric, and well-structured, involving a Euclidean system of spatial representation. They portrayed adults as easily able to remember and reconstruct spatial layouts, to take the perspective

of others, and to perform a variety of other spatial tasks that children find difficult, using spatial representations that code location with respect to X and Y coordinates. This characterization of human capability has long been questioned, however, by researchers focused on spatial cognition in adults. Several alternative models currently claim to capture the nature of human spatial knowledge.

Some cognitive psychologists have asserted that adults' spatial representations are inevitably erroneous, biased, and fragmentary (e.g., Byrne, 1979; Kuipers, 1982; McNamara, 1991; B. Tversky, 1981). Such conclusions are based on well-known studies indicating that adults estimate spatial location in ways that create surprising errors, such as the judgment that Reno is east of San Diego (Stevens & Coupe, 1978) or the judgment that the distance from location A to location B is different from the distance from location B to location A (McNamara & Diwadkar, 1997; A. Tversky, 1977). Errors of this kind have been taken to indicate that adults do not encode metric information about precise spatial location. Rather, these judgments have seemed most compatible with models in which people remember location imprecisely or in terms of larger categories. For example, one can explain Stevens and Coupe's findings as arising from a spatial memory that encodes only qualitative categorical information regarding the location of cities in states (such as that Reno is located in Nevada) together with rough pointers about the relative arrangement of the states (that Nevada is east of California).

Other investigators of spatial functioning have focused less on the content and accuracy of spatial representations and more on the cognitive architecture that supports acquisition of spatial knowledge. Specifically, Gallistel (1990) and Spelke and her associates (Hermer & Spelke, 1996; Wang & Spelke, 2002) proposed that various features of space may form distinct modules, with one important example being a *geometric module* that encodes information about the relative length of environmental surfaces and the relation of these surfaces to each other (e.g., that a longer surface is to the left of a shorter surface). These authors argued that geometric sensitivity is modular in nature because there is evidence that featural information, such as knowledge of the color of surrounding surfaces, is not used to disambiguate two geometrically congruent locations. These capabilities are said to form separate and noninteracting cognitive units, that is, to be mutually impenetrable. Since these different aspects of spatial information have no direct contact with one another in a modular architec-

ture, extra principles are needed to explain how the information might become combined. One hypothesis is that language allows for communication among these modules (Spelke & Hermer, 1996).

An alternative to modularity proposals for conceptualizing how various sources of spatial information are used is a family of models that can be termed *adaptive combination models* (which are modular only in the relatively modest sense that initial perceptual processing of the various kinds of information relevant to spatial location may occur using physiologically distinct pathways or specific cortical regions). These approaches share a focus on combination of various sources of spatial information in a weighted fashion. One such model was proposed by Huttenlocher and Hedges and their associates (Crawford, Huttenlocher, & Engebretson, 2000; Huttenlocher, Hedges, & Duncan, 1991; Huttenlocher, Hedges, Corrigan, & Crawford, 2004). They have hypothesized that adult spatial coding involves such adaptive combination. Their work stems from the observation that spaces are typically encoded into units of different sizes that are hierarchically organized. Larger units (such as states or nations) encompass smaller ones (such as cities or states). Huttenlocher and Hedges suggest that coding of spatial location occurs at both a fine-grained and a categorical level, and is unbiased at both levels. However, combination of fine-grained coding with information from a categorical level typically leads to the appearance of bias in estimation. These biases are adaptive; they capitalize on use of category information in a Bayesian fashion to reduce variability in estimating location. This *hierarchical combination model* can explain a variety of estimation patterns that otherwise seem to be evidence for nonmetric spatial processing. For example, asymmetries in judging the distance between location A and location B, as found by A. Tversky (1977) and McNamara and Diwadkar (1997), can be explained (and are in fact predicted) by the hierarchical coding model (Newcombe, Huttenlocher, Sandberg, Lie, & Johnson, 1999).

There are other adaptive combination models in the literature on spatial functioning (as well as in the wider perceptual literature; see Ernst & Banks, 2002). For example, in Cheng's (1989) *vector-sum model* of the use of landmark cues by pigeons, vectors based on near landmarks are weighted more heavily than vectors based on far landmarks, presumably because they are encoded with less variability. Similarly, Hartley, Trinkler, and Burgess (2004) have developed a *boundary proximity*

model of human memory for location within enclosed spaces that uses a mixture of absolute and relative distance information. Encoding of absolute distance from a wall is more accurate and less variable when the distance is short, while encoding of relative distances (ratios of distances from various walls) is less dependent on how close a location is to a wall. Hence, absolute information is weighted more heavily when encoding locations close to walls, while relative information is weighted more heavily when walls are distant (when a location is in the middle of the enclosure). The vector-sum model and the boundary-proximity model share a fundamental insight with the hierarchical combination model, namely, that it is adaptive to weight uncertain and variable information less heavily than more certain and less variable information. Such an approach may also serve to understand the conditions under which featural and geometric information are both used to determine location and the circumstances when one is used alone (Newcombe, 2005). In short, in all of the adaptive combination models, various sources of information about the spatial environment are combined in a way that weights an information source that is exact more heavily than one that is variable, and that therefore leads to maximal accuracy.¹

The developmental origins of adaptive combination are not known. It might be that the system derives from prior experience; it is also possible that at least certain aspects of these coding mechanisms are innately specified. Cross-species convergence in mechanisms of spatial memory may suggest the possibility of hardwired adaptive mechanisms, and it is, therefore, interesting that adaptive combination models are useful in considering the behavior of a variety of nonhuman species. For instance, the Hartley et al. model captures the behavior of place cells in the hippocampus of rats as well as human behavior, and the Huttenlocher-Hedges model has recently been shown to characterize location coding in the rhesus monkey as well as in humans (Merchant, Fortes, & Georgopoulos, 2004). A great deal of further research will be needed, however, to specify exactly what aspects of spatial coding mechanisms are hardwired, because some part of cross-species convergence

may arise from similar tuning of starting-point mechanisms by common environmental demands. For example, absolute distance from a landmark will inevitably be more precisely estimated when the distance is shorter than when it is longer, for psychophysical reasons, and hence weightings of information that depend on distance would be expected to arise naturally through expectable interactions with the environment. On this view, what is innate, hardwired, and shared across species is the capacity for learning that reflects these statistical principles. However, in all instantiations of this family of models, development consists in the acquisition of maximally informative and useful combinatorial rules.

There are some similarities between adaptive combination models and other recent ways of thinking about cognitive development. In particular, dynamic systems theory (Thelen & Smith, 1994) and overlapping waves theory (Siegler, 1996) also emphasize the interacting impact of a variety of data on behavior. However, there are also differences in emphasis and focus between the approaches. To take dynamic systems thinking first, theorizing in this tradition has been less specific than an adaptive combination approach about what determines the weighting of the various influences. Additionally, dynamic systems theorists eschew the use of terms such as representation and competence even though these constructs can support productive theorizing when used carefully.

An overlapping waves approach focuses on the co-occurrence in developmental time of different strategies for approaching problems, and the waxing and waning of these strategies as a function of factors such as how a situation is encoded and feedback about success. The similarity to adaptive combination approaches is in the recognition that behavior emerges from the interaction of different bases for action, and an interest in variability as grist for the mill of development. However, overlapping waves theory has focused on variability in strategies or procedures rather than on the variability with which different kinds of stimulus information are encoded, and tends to think of competing influences as racing to determine action rather than as being combined. These contrasts are at least partially due to the different kinds of cognitive development under consideration. Adaptive combination theory analyzes representations in memory and their use for behavior, while the overlapping waves metaphor has mainly been applied to the acquisition of cognitive skills (such as addition) or

¹Similar models have recently been proposed for other problems in adaptive combination, such as combining data derived from vision and from touch (Backus, Banks, van Ee, & Crowell, 1999; Ernst & Banks, 2002; Gepshtein & Banks, 2003).

rule-based judgments about dynamic problems (such as the balance beam problem).

What Is the Nature of the Referent System?

Spatial coding requires a set of referents, or frameworks, to specify location. In recent years, investigators have arrived at a rough consensus about the nature of such frameworks (Gallistel, 1990; Newcombe & Huttenlocher, 2000; Sholl, 1995). There is agreement that spatial location can be coded with respect to either external frameworks or with respect to viewers. The first way of coding location can sometimes entail the simple and direct use of external landmarks as markers, especially when such landmarks are contiguous with a desired location (e.g., when a flag marks the place to aim for on a putting green). Such landmarks have been called *beacons*, and such spatial learning has been called *cue learning*. But such beacons are not always available. Thus, a more important function of external features of the environment (such as the shapes of enclosing spaces, or sets of separated landmarks) is to provide a set of fixed reference points for noting distance and direction, and mapping desired locations. This kind of spatial learning has been called *place learning*. It is limited by the availability of fixed features, so that it does not work well on the open sea or in the dark.

The second way to code location is with respect to the viewer. One simple way of doing so is to remember actions required to get to a desired location, such as how to move one's hand to reach the alarm clock from bed, or how to walk to get to school in the morning. Such coding can be called *response learning*; Piaget termed it *egocentric*. It works only when the initial starting point is maintained, but fails when movement must be taken into account, for example, when one reaches for the alarm clock after having rolled to the other side of the bed than the one usually slept on. Another kind of viewer-centered coding results from adjusting an initial location memory by taking the direction and distance of one's own movement into account. Location coding of this kind has been termed either *dead reckoning* or *inertial navigation*. The viewer's position is continually tracked in this kind of spatial memory, which is invaluable in situations where external frameworks are unavailable. However, ultimately, dead reckoning must be referenced to external frameworks, both because otherwise drift in memory for direction and distance causes accumulating

error, and also because it is the external environment that is ultimately of interest.²

To what extent is the viewer's position bound up in all spatial representations that utilize the external environment? The issue of orientation-free versus orientation-specific representation is central to understanding of the processes of mental rotation, perspective taking, and navigation. It has sometimes been proposed that extensive experience in a particular environment could lead to the formation of orientation-free survey knowledge of the area (Presson, 1987; Presson & Hazelrigg, 1984; Siegel & White, 1975); it would incorporate the viewer as needed in a flexible manner without the viewer being an integral part of the representation. There has been long-standing debate about this claim, however. Many studies have found evidence that representations are primarily orientation-specific (for recent examples, see McNamara, Rump, & Werner, 2003; Mou, McNamara, Valiquette, & Rump, 2004; Shelton & McNamara, 2004; Sholl & Bartels, 2002). In addition, recent work on children's use of geometric information suggests that the viewer is represented in relation to the space rather than the space being represented in isolation (Huttenlocher & Vasilyeva, 2003; Lourenco, Huttenlocher, & Vasilyeva, 2005).

It is possible, however, that, in some circumstances or for some people, orientation-free representations may be possible attainments, even though orientation-specific representations are more common. For example, Sholl and Nolin (1997) found that people could point with equal facility to various locations in a space, independent of original viewing position and current location, when asked using certain specific spaces and acquisition and testing conditions. In addition, there may be individual differences, such that viewers with certain profiles of cognitive skill might be more likely than others to be able to form orientation-free representations. In terms of a different debate concerning the formation of situation models while reading text, inclusion of spa-

²One kind of spatial coding that may be considered viewer-centered is to retain the look of a particular area surrounding the target location, which makes it possible to locate the target again by matching the remembered and the current views (Wang & Spelke, 2002). This system is basically similar to cue learning, with the only difference, aside from terminological variations, being that the cues are multiple ones whose relations are taken into account, rather than simply being single beacons.

tial information has turned out to vary with spatial ability (Emerson, Miyake, & Rettinger, 1999; Friedman & Miyake, 2000). Perhaps the most interesting possibility is that the two kinds of representations coexist making it hard to find evidence of orientation-free representations because the coexisting orientation-specific representations will always exert some effect. Burgund and Marsolek (2000), for example, found viewpoint-independent processing in the left hemisphere and viewpoint-dependent processing in the right hemisphere. This effect may be dependent on the left hemisphere's ability to encode semantic information about objects (Curby, Hayward, & Gauthier, 2004).

Another fact worth keeping in mind is that, even if computing interpolated views that lie between actually experienced ones is difficult and time-consuming, humans appear to be able to perform the task, whereas other species, such as pigeons, do not (Sptch & Friedman, 2003). In fact, we are able to mix perspectives in describing environments (Taylor & Tversky, 1992a), to form similar spatial representations from descriptions of environments from different vantage points (Taylor & Tversky, 1992b) and, once representations are formed, to switch perspectives with rapidly diminishing costs (Tversky, Lee, & Mainwaring, 1999). Thus, while humans may show orientation specificity, we also appear to have considerable resources for coping with it.

What Does Symbolic Spatial Representation Add?

One of the distinctive characteristics of our species is the capacity for symbolic spatial representation. Language is the leading example of a powerful human symbolic system, but in the spatial domain, models, maps, diagrams, and graphs are also of focal interest. Symbolic devices greatly enhance the scope of spatial competence in several ways. They allow individuals to communicate information, so that we can gain spatial knowledge of areas we have never personally visited, and they allow us to store information so that it can be reliably retrieved later. In addition, constructing and viewing linguistic or nonlinguistic spatial representations is a powerful support for reflection, integration, and inference (Liben, Kastens, & Stevenson, 2002; Uttal, 2000). For example, drawing a sketch map of a city may lead to the discovery of a useful shortcut; giving someone directions to one's home may reveal a lack of knowledge concerning certain crucial distances; and

viewing an aerial photograph of a polluted marsh may reveal a pattern to the distribution of pollutants that tells us its cause.

There are interesting and important differences between nonlinguistic and linguistic communication about space. In many ways, language is not well suited for communicating spatial knowledge. Spatial relations can only be described in a linear and serial fashion using language, rather than apprehended in a simultaneous and integrated fashion. Spatial relations in language also need to be expressed with reference to a spatial framework agreed on by speaker and listener, and the framework can end up being ambiguous (Levinson, 2003). For example, if the ball is said to be "in front of the car," it could be at the car's intrinsic front, that is by the headlights. But it could also be located in front of a speaker looking at a side door of the car or even in front of a listener looking at the side of the car. Metric aspects of space are generally reduced to categorical descriptions; communicating them exactly requires the use of technical measurement language. On the other hand, spatial language has advantages. For example, it is always available, because it does not require access to drawing or modeling materials. In addition, it is easily used to highlight a crucial aspect of a spatial scene, directing attention to a particular relation and making it memorable (Gentner & Loewenstein, 2002).

Summary

This initial section has been devoted to an overview of some complex issues that are difficult to treat fully here, and yet which frame our approach to the development of spatial cognition. In brief, we believe that the concept of representation is essential in investigating the spatial capabilities of both adults and children; we think that mature spatial representation is neither fragmented and incomplete nor modularly separable, but rather consists of the adaptive combination of a number of different sources of spatial information; we adopt what is now close to a consensus view that both external frames of reference and viewer-centered ones are central components of an exploration of spatial cognition; and, we subscribe with many others to the view that symbolic spatial representations, both visual and verbal, are strikingly powerful augmentations of nonsymbolic spatial capabilities, whose adoption is one of our species' most distinctive spatial adaptations. These choices structure

the treatment of spatial development that follows. In addition, some of the matters discussed in this section, notably the value of an adaptive combination approach, receive fuller consideration in the following sections.

THE SPATIAL CAPABILITIES OF INFANTS

The classic approach to thinking about spatial development in infancy comes from Piaget, whose views structured much of the empirical work on the topic until relatively recently. Piaget suggested that infants initially interact with their world in a sensorimotor fashion, so that objects are located in terms of the physical actions required to make contact with them. Such egocentric coding was said to give way gradually over the 1st year of life to the notion of an object as having a permanent existence independent of action and to the associated ability to locate objects in relation to external landmarks. Piaget based these conclusions on his observations that, in the first 6 months or so, infants failed to search at all for completely occluded objects, and that, during the next 6 months or so, they searched in a fashion dominated by their memories of physical actions that had been successful in retrieving hidden objects in the past, ignoring more recent visual information about the objects' location.

Subsequent work has questioned this picture of the 1st year of life, but has not yet succeeded in replacing it with a coherent and consensually endorsed view. One possibility is that infants possess the idea of a permanent object early and even from birth, but lack specific abilities, such as perceptual sensitivities, inhibitory capabilities, or means-ends reasoning skills, to manifest this competence in every situation. An alternative account is that behaviors allowing for a mature conception of permanent objects and their location emerge gradually and as a result of interactions with the world. While basically constructivist, this account describes a sequence of developmental transitions different both in timing and in kind from the specific theory that Piaget offered. In this section, we examine these possibilities with regard to three phenomena: the A-not-B error, the egocentric-to-allocentric shift, and the infant's conception of an object.

The A-not-B Error

Hundreds and possibly thousand of studies have been done that are relevant to the A-not-B error, which Piaget

originally conceptualized as an interim step in the progression toward a concept of the permanent object, the hallmark of "Stage IV object permanence." Over the years, investigation of the error has taken on a life of its own. The error has been regarded as informative about a wide variety of constructs, including memory, inhibition, and means-ends reasoning. Currently, the main contenders for explanation of the error are dynamic systems theory (Smith, Thelen, Titzer, & McLin, 1999; Thelen, Schoener, Scheier, & Smith, 2001), connectionist approaches that emphasize strength of representations (Munakata, 2000, 2001; Munakata, McClelland, Johnson, & Siegler, 1997), and a memory-plus-inhibition model that emphasizes the brain bases of inhibition (Diamond, 1991). From the point of view of thinking about spatial development, however, these approaches share a common flaw, namely inadequate analysis of what kinds of spatial memory the task involves (Newcombe & Huttenlocher, 2000). Dynamic systems models describe competing action tendencies rather than discussing ways of coding location, although it may be possible to translate from one mode of description to the other (see Newcombe, 2001); Munakata's connectionist model uses the constructs of active and latent memory traces, and although they may also map onto an analysis in terms of modes of coding spatial location, "the network represents space in a very limited way" (Munakata, 2000, p. 181).

What are the possible kinds of spatial memory involved in the A-not-B task? One important kind of memory is response learning, or the tendency to regard an object as obtainable in a location defined by previous action. Although response learning figures in the A-not-B literature, discussed by Piaget as the sensorimotor definition of an object and by Diamond as a prepotent response, there has been relatively little discussion of just what response is involved or what aspect of the response history is given weight. Considering the A-not-B situation, we see that there are four such responses. First, because infants watch objects hidden and also reach for them, there are two response systems on which they could base their search: looking and reaching. Second, they could base searches on either of two kinds of information about prior looks or reaches: frequency or recency. Of course, only the most recent look actually provides relevant evidence about location. Search at the location that has been most frequently looked at, or most frequently reached for, will lead to A-not-B errors, as will search at the location most recently reached for.

In interacting with the environment, infants inevitably find that searches based on some kinds of information work, whereas others don't. Infants who experiment with a variety of bases for their decisions will eventually settle on the most useful option. This analysis suggests an explanation for recent findings that looking behavior is more advanced than reaching behavior in the A-not-B situation (Ahmed & Ruffman, 1998; Hofstadter & Reznick, 1996). Visual memory provides a correct answer to where the hidden object is located (i.e., where the infant most recently saw the object), whereas reaching correctly requires relying on a memory of a response in a different system.

Various forms of response learning are not the only possibilities for spatial coding in the A-not-B testing situation, and memory for where they most recently looked is not the only way to succeed. While cue learning is impossible because the search locations typically have identical covers, and dead reckoning is irrelevant because infants do not move, infants can potentially base a correct response on coding of the distance of the correct hiding location from an environmental referent such as the edges of the testing surface. Experiments using looking time to anomalous events indicate that they have the ability to remember such information by 5 months of age (Newcombe, Huttenlocher, & Learmonth, 1999; Newcombe, Sluzenski, & Huttenlocher, 2005). However, they may not base their searches in an A-not-B situation on this information until a few months later, for several reasons. First, the A-not-B testing situation pits competing response options against each other, so the sorting out of which evidential basis is most reliable may well take longer to emerge than simply the ability to use a certain kind of information when there is no conflict. Second, reacting with increased looking time to objects emerging from the wrong location involves recognizing an anomaly, not actively retrieving a location. Hence, it provides a much less stringent assessment of coding distance in continuous space than recall of a location of a hidden object.

In summary, to search successfully for hidden objects whose location is variable, infants have to learn to reach to the location at which they most recently saw the object, rather than to reach to the locations they have most frequently looked at, or the locations they have most recently or frequently reached to. (To the extent that these other tendencies are strong, they may need to be inhibited, so Diamond's analysis of the A-not-B error may be an important aspect of a complete explanation of

errors.) Because the infant does not move, reliance on a response memory of the most recent look can be successful. However, coding location in terms of an external framework provided by the surrounding environment provides a more widely useful form of spatial memory, and it may possibly come to be relied on to an increasing extent in the second half of the 1st year.

This analysis leaves open the question of whether, in coming to rely on the location of the most recent look, infants are guided simply by reinforcement contingencies or whether at some point, they realize that the object must necessarily, not merely contingently, be in this location. The latter kind of knowledge was what Piaget was interested in, but we have as yet no definitive means of assessing it. One speculative approach would be to suggest that response memories are more likely to be contingent, while reliance on location memory that uses external frameworks reflects a more deeply conceptual network of knowledge about how the world works.

Assessing whether there is a fundamental transition from success at searching for objects in B locations in a way guided by contingency to one guided by a feeling of necessity is an interesting agenda, we think, for future studies. At present, however, one contribution of thinking about the A-not B error as the product of shifting reliance on different spatial coding methods is that this framework serves also to integrate the numerous studies that have been done on another developmental transition in infancy—the egocentric-to-allocentric shift.

Egocentric to Allocentric Shift

Our account of the A-not-B error uses the idea that a variety of kinds of spatial coding compete for use during infancy, with development consisting in working out the best adaptive combination of these information sources. Such an account also provides a framework for thinking about a different line of research on infant spatial development, concerning a phenomenon that has been called the egocentric-to-allocentric shift. Acredolo (1978) and Bremner and Bryant (1977) showed infants objects or events located to their left or their right, and then moved them to the opposite side of the array or the room so that the positions were reversed. Through most of the 1st year, infants continued to search on the side on which they had originally seen the objects or events, without taking account of their movement. In the first half of the 2nd year, they began to take account of movement and to use external landmarks to track location.

Subsequent work suggested, however, that the transition to use of external landmarks does not occur as a single qualitative shift in infant functioning. Very salient external cues are useful as early as 6 months, especially in situations where they do not compete with other location cues (Acredolo & Evans, 1980; Bremner, 1978b; Lew, Foster, Crowther, & Green, 2004; McDonough, 1999; Rieser, 1979). Infants are fairly successful at looking in the right direction for objects when the motions that alter infants' relation to a location are familiar ones in their repertoires, such as twisting one's trunk when in a sitting position (Landau & Spelke, 1988; Lepécq & Lafaite, 1989; McKenzie, Day, & Ihnsen, 1984; Rieser, 1979). They succeed more often when initial searches are few or are not reinforced, so that memory for motor responses is less powerful (Acredolo, 1979, 1982; Bremner 1978a). They also do better when emotional stress is minimized (Acredolo, 1982). Finally, infants who can crawl show less egocentric responding than infants of the same age who cannot (Bai & Bertenthal, 1992; Bertenthal, Campos, & Barrett, 1984; see review by Campos, Anderson, Barbu-Roth, Hubbard, Hertenstein, & Witherington, 2000).

Overall, the data on the shift from egocentric to allocentric coding suggest that a variety of bases for spatial location coding are present early in life, including use of visual beacons and compensation for the infant's own physical movement, as well as simple memory for action. As suggested by an adaptive combination approach to development, reliance on each kind of information shifts as a function of factors such as salience and cue competition as well as, most importantly, accumulating evidence on the relative validity of different sources of information. That is, experience in interacting with the physical world provides feedback on the usefulness of the various methods of coding. The effect of crawling provides one notable class of experience, in which infants learn to appreciate that, after they change position, repeating an action (such as reaching with the left hand) is unlikely to produce the same result as it did before. However, crawling is probably not the only source of such instructive experiences. For example, sitting while twisting one's trunk will affect what the infant sees with a certain degree of head turn, or what a grasp in a certain direction will lead to touching, and these experiences may in turn affect weighting of various sources of information in an adaptive combination process. Further research may show that each new class of spatial

experience that infants become motorically capable of has its own specific effect on their spatial memory and spatial actions.

What Is an Object?

Research has modified other aspects of our understanding of the development of the object concept in addition to the particular issues associated with Piaget's Stage IV and the A-not-B error. A series of widely cited experiments have provided evidence that by the middle of the 1st year, babies look longer at events that suggest that an occluded object does not continue to exist than at events in which they do (e.g., Baillargeon, 1986; Luo, Baillargeon, Brueckner, & Munakata, 2003). Initially, such data were seen as indicating that babies have a mature concept of objects and their permanence from the start of life. However, in the past few years, evidence has emerged that infants' treatment of objects may be different in the first few months from that emerging toward the end of the 1st year of life. Specifically, young infants may regard objects as defined by spatiotemporal tracking of their movement and may have difficulty in coordinating such information with information about the objects' static perceptual attributes (Leslie, Xu, Tremoulet, & Scholl, 1998; Xu & Carey, 1996).

Researchers have found that young infants react to violations of where objects are expected to be or how many objects are expected to exist, in situations where they do *not* react to changes in attributes such as size, shape, and color (Kaldy & Leslie, 2003; Newcombe, Huttenlocher, & Learmonth, 1999; Xu & Carey, 1996). Infants' ability to bind auditory and visual stimuli together based on perceived location, and to track such information dynamically, supports the hypothesis that location could play a primary role in coordinating across modalities and hence structuring the infant's perceptual world (Fenwick & Morrongiello, 1998; Richardson & Kirkham, 2004). The hypothesis of spatiotemporal primacy initially appears contradictory to data indicating that infants can use perceptual characteristics such as size, shape, and color to identify objects in certain tasks (Needham, 2001; Wilcox, 1999; Wilcox & Baillargeon, 1998a, b). However, young infants may concentrate on static perceptual characteristics primarily when objects do not move, or when their trajectory is a simple one, or when displays are very simple (Mareschal & Johnson, 2003).

Is there then an innate ability to track location over occlusion, and hence to represent the existence of an object based on its spatiotemporal trajectory? Apparently not—this ability appears to undergo development in the first months of life. This conclusion is based on several lines of evidence. First, before 6 months of age, infants seem to represent location in retinocentric coordinates centered on the eye itself, rather than egocentrically in relation to the body as a whole (Gilmore & Johnson, 1997). The emergence of egocentric coding is an achievement that allows for coordinated spatiotemporal tracking. Second, a series of studies by von Hofsten and his associates have shown that infants' ability to represent the trajectories of moving objects develops considerably in the first 6 months and shows strong learning effects (e.g., Rosander & von Hofsten, 2004). The importance of learning is further supported by an intriguing study that demonstrated that infant reaching is less inhibited by blackout of the room lights than tracking is, whereas movement of an object behind an occluder affects reaching more than tracking (Jonsson & von Hofsten, 2003). In the real world, a person can of course reach to an object in the dark, but not to an object behind a solid screen, whereas one can track an object as it emerges from behind a solid object but cannot visually track in the dark. Thus, the Jonsson and Von Hofsten findings suggest the importance of interactive experience with the world to development. Along similar lines, Shinskey and Munakata (2003) have found that 6.5-month-old infants will search in the dark for hidden objects, that is, at an age at which they do not search, in an otherwise comparable task, for objects hidden under an occluder in a lighted environment. Third, work by Scott Johnson and his associates provides a different kind of evidence for the hypothesis that perceptual completion of simple object trajectories develops over the first 6 months (e.g., Johnson, 2004; Johnson, Bremner, et al., 2003). In particular, his group has recently shown that learning effects can be seen in the laboratory (Johnson, Amso, & Slemmer, 2003). Infants who were taught to anticipate the emergence of a horizontally moving ball from behind an occluder later showed the ability to anticipate the emergence of a ball moving vertically.

In sum, there is an emerging case that infants acquire various aspects of a mature approach to defining an object and tracking its existence, building on innate departure points but changing in important ways with accrued experience. A model of the development of object under-

standing along these lines has recently been proposed by Andrew Meltzoff and Keith Moore (Meltzoff & Moore, 1998; Moore & Meltzoff, 1999, 2004). In their account, the early basis of object understanding is termed object identity (i.e., "that's the same thing again"). Object identity is said to depend initially on spatial characteristics (e.g., "that's the same thing again because it's in the same place"). Object permanence is said to arise from object identity, as linkages are made among various appearances of the same object.

Summary

An adaptive-combination approach to spatial development is helpful in explaining the A-not-B error, the egocentric to allocentric shift, and developing abilities to track and define objects in terms of changes in the use of various information sources. Infants have early ability to code location in a variety of ways, and their task in the 1st year of life is to determine which methods are most likely to succeed in which situations. In the A-not-B task, they come to rely on most recent look or on a memory of distance from external landmarks, learning that frequency is completely the wrong principle to use and that most recent grasp is often misleading as well. Similarly, in the egocentric-allocentric paradigm, they come to rely on either memory in terms of distance from external landmarks or a dead reckoning that can correct for their rotational and translational movement, rather than using a simple response memory. In tracking objects, infants begin by relying heavily on spatiotemporal parameters in setting up and maintaining object files. While they separately code the static perceptual attributes of objects, they find it challenging to combine information about these attributes with spatiotemporal trajectory information, and sometimes they rely on the latter in tasks where an older child or adult would rely on the former.

Changes in the sorts of spatial activities that children can engage in are important in creating changed opportunities for feedback. The best-examined milestone is crawling, which allows infants for the first time to experience a continuous and actively produced change in their spatial location. Crawling is associated with a variety of cognitive and emotional changes, including the egocentric-to-allocentric shift and the A-not-B error (Campos et al., 2000). A reduced probability of making the A-not-B error is especially interesting because the

infant does not move during the search task. The improvement in search ability while remaining in the same position is plausibly related to increases in the reliance on most recent look or on distance from landmarks, created by the fact that these are useful information sources when one moves.

There may well be other spatial changes associated with locomotion. For instance, infants from 3 to 6 months show a very imprecise ability to determine their direction of motion from optic flow, and it is possible that improvement occurs only after the onset of crawling (Gilmore, Baker, & Grobman, 2004; Gilmore & Rettke, 2003). In addition, changes in motor abilities other than crawling may have important effects. The onset of walking may be associated with improvements in location coding (Clearfield, 2004); the onset of grasping is associated with improvements in object exploration and processing (Needham, Barrett, & Peterman, 2002).

In this section, we have briefly reviewed what is known about infant spatial ability, focusing on the A-not-B error, the egocentric-to-allocentric shift, and changing ways of treating objects. In each case, we analyzed existing findings as understandable on an adaptive combination view, in which a variety of possible bases for action and conceptualization compete, and in which the most useful ones eventually win. In the next section, we take a closer look at whether the adaptive combination approach can structure our knowledge about the spatial capabilities of somewhat older children. We begin with an examination of developmental findings that have been taken to support a competing modularity view, and go on to a review of work that examines development as viewed through the lens of the Huttenlocher-Hedges model of spatial coding.

MODULARITY OR ADAPTIVE COMBINATION?

Research over the past 2 decades has revealed a remarkable fact about spatial functioning in a wide variety of animal species, including fish, birds, nonhuman mammals, and humans: All these mobile organisms share a powerful sensitivity to geometric properties of enclosing spaces (e.g., the relative length of walls defining enclosures), using such information to reestablish spatial orientation after being disoriented (Cheng, 1986; Hermer & Spelke, 1996; for a review, see Cheng & Newcombe, 2005). Based on findings that both rats and

human children fail to use nongeometric (or featural) information (e.g., colors or markings on surfaces), even when use of featural information would be adaptive because it would disambiguate geometrically congruent locations, it has been suggested that such geometric processing constitutes a specialized cognitive module that is impenetrable to nongeometric information, even when that information has been processed (Gallistel, 1990; Hermer & Spelke, 1996). The fact that adults and children of 6 years and older *do* integrate featural and geometric information has led to the suggestion, working within the modularity framework, that language is necessary for combining the output of cognitive modules (Spelke & Hermer, 1996). These findings have been exciting both to researchers interested in spatial functioning and also to a wider audience focused on cognitive architecture, comparative cognition, cognitive development, and the role of language in behavior. However, there is debate about the data and how to interpret them. In addition, the adaptive combination approach to spatial processing and development provides an alternative framework to modular architecture for considering the phenomena in this domain of research. Specifically, three models of how spatial information from various sources is used are outlined schematically in Figure 17.1 (from Cheng and Newcombe, 2005). Model A postulates impenetrable modules, across which information combination relies on the use of complex spatial language available only to school-age children and adults. In the absence of a linguistic link, useful sources of information may be ignored, as special-purpose modules dominate behavior in particular situations. By contrast, both Models B and C utilize an adaptive combination approach where a continually changing mix of spatial information sources is utilized, with the exact mix responsive to factors such as the sources' reliability, variability and usefulness, and the certainty with which it has been encoded.

Modular Spatial Processing

Evaluating Model A requires a sharp differentiation between two aspects of the research on geometry. On the one hand, there is considerable evidence favoring early geometric sensitivity. These findings are, however, not directly germane to the modularity debate, although they are fascinating and important in their own right. After all, awareness of the relative length of extended surfaces and of the angles at which they connect is a sur-

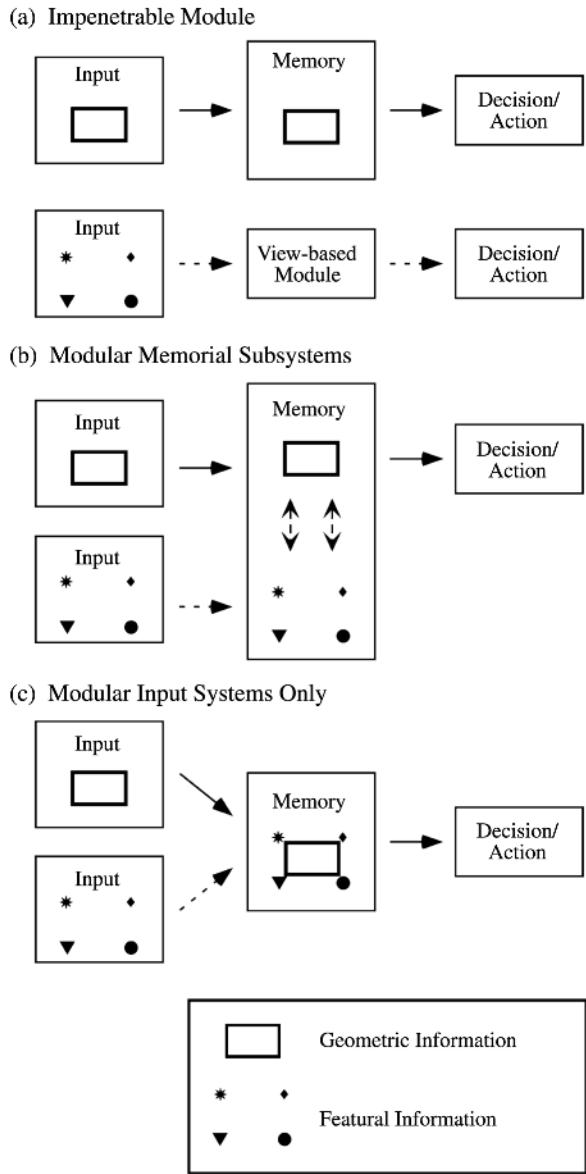

Figure 17.1 Views of modularity in reorientation. The input systems consist of perceptual and learning processes. Some modularity in processing geometric and featural information is assumed. (a) In the impenetrable module, featural information does not enter into the memorial system used for reorientation. If featural information is used at all, it goes through other central modules, one of which does view-based matching. (b) In a system with modular components, a metric frame (box inside of the memory box) contains only geometric information. Featural information may be pasted onto the frame in addition (represented by arrows inside the memory box). (c) An integrated system in which featural and geometric information are put together for reorientation. In both panels B and C, featural information may fail to be input into memory. This failure can cause systematic rotational errors. See the text for further details.

prising early competence that likely contributes in important ways to spatial behavior. On the other hand, whether this geometric sensitivity constitutes a cognitive module is controversial. We begin with the findings on geometric sensitivity, and only later proceed to discuss the question of whether such sensitivity constitutes a modular ability.

Geometric Sensitivity

A good place to begin reviewing this body of research is by describing the basic experimental paradigm that led to the detection of the sensitivity. Cheng (1986) placed rats in an unmarked rectangular enclosure, with food hidden in one corner. They were disoriented to eliminate their use of the dead reckoning system and necessitate their reliance only on environment-centered spatial systems; they were then replaced in the chamber. The rats went to both of the two geometrically identical corners to search for the food, but avoided the two corners in which the relation of the long wall and the short wall was different from that of the correct corner. This kind of search pattern shows coding of the geometric features of the environment: some aspect of the lengths of the walls (either relative length or absolute length) and the handedness, or *sense*, of the relation at the corners (e.g., the fact that the long wall is to the left or the right of the short wall). Very similar results have been reported for human children aged 18 to 24 months (Hermer & Spelke, 1994, 1996).

The hypothesis that children have an early sensitivity to the geometry of enclosing spaces has held up well in subsequent research. For example, Huttenlocher and Vasilyeva (2003) found that toddlers can locate a hidden object after disorientation in a triangular as well as in a rectangular space, thus demonstrating the generality of geometric sensitivity. Huttenlocher and Vasilyeva's studies also explored the nature of early geometric sensitivity. They found that children rarely surveyed the various locations before going to the corner where they believed the object was hidden. Thus, it seems likely that toddlers represent the entire space rather than the appearance of a particular corner where a toy is hidden. This overall representation allows them to know their relation to the hiding corner, no matter where they face after disorientation. In addition, children were not restricted to dealing only with spaces that surround them (as was suggested by Wang and Spelke, 2002), but rather could locate a hidden object when they were outside as well as when they were inside a space. Finally, although

children could use geometry when outside as well as when enclosed by a space, performance was better when children were inside the space. This finding suggests that the distinctiveness of the critical information about the enclosed space is important. For a viewer who faces the space from outside, all potential hiding corners lie in a frontal plane; these positions are similar and hence potentially confusable. In contrast, for a viewer who is inside, the potential hiding corners are not all in the frontal plane; these positions are more differentiated than in the outside condition (see Figure 17.2 for a visual illustration of how the corners are more distinct when a viewer is inside the space).

The data on better performance when inside the space argue for the hypothesis that the viewer is represented in relation to the entire space, rather than the space being represented in isolation. Further evidence for this hypothesis comes from work by Lourenco, Huttenlocher, and Vasilyeva (2005) examining situations in which children see a toy hidden while they are inside a space and are then translated outside it (or vice versa). Disorientation can occur either before or after the translation. If the translation occurs first, performance is not impaired, presumably because the tie between the viewer and the space can be maintained. However, when disorientation occurs first, children's performance falls to chance.

Existing data are conflicted on whether geometric processing occurs when separated objects are placed so as to define a rectangle or a triangle. Some studies have found that 3- and 4-year-old children could not use isolated elements to define geometric information (Gouteux & Spelke, 2001), to locate the middle of an array (MacDonald, Spetch, Kelly, & Cheng, 2004), or to locate one of the elements in terms of relations to the others (Uttal, Gregg, Tan, Chamberlin, & Sines, 2001). Other studies have shown that younger children do abstract geometry from separated objects (Garrad-Cole,

Lew, Bremner, & Whitaker, 2001) and also that rats and pigeons are able to do so (Benhamou & Poucet, 1998; Spetch, Cheng, & MacDonald, 1996). This contradiction is important to resolve in future research because the natural environment does not contain many continuously enclosed spaces. The usefulness of the geometric module in the natural environment (which was, after all, the environment of adaptation within which the module is supposed to have evolved) depends on showing its activation in such situations.

Modularity

Sensitivity to geometry is a remarkable finding. Having established the existence of this capability and elucidated some aspects of its nature, we can now evaluate whether such sensitivity necessarily depends on modular processing. Postulating modularity is based on a very surprising finding in the rectangular room experiments, seen when features of various kinds, such as a colored wall, were added to the unmarked rectangular enclosure. Rats and human children continued to divide their searches evenly between the two geometrically correct corners, as they had in unfeatured rooms, ignoring the additional data that would have allowed them to search successfully on all trials. Children do this even though it is easy to show that they can notice and remember information about the colored wall. Evidence of this kind points to encapsulation or impenetrability, a crucial attribute of modularity in Fodor's (1983, 2001) treatment (although note that Fodor doubted the existence of central modules, which a geometric module would arguably be).

Although the findings of geometric sensitivity have held up well, there has been a good deal of controversy about the claim that such sensitivity forms a module. One challenge to the modular hypothesis, especially to a version where language plays an important role in using information from different modules, is that nonhuman animals (other than rats) have been found to integrate featural and geometric information. Vallortigara, Zanforlin, and Pasti (1990) have found such evidence in experiments with chickens, Kelly, Spetch, and Heth (1998) have found such evidence in pigeons and perhaps most dramatically, Sovrano, Bisazza, and Vallortigara (2002) found such evidence in fish, specifically *Xenotoca eiseni*. Similarly, Gouteux, Thinus-Blanc, and Vauclair (2001) found that monkeys did not show encapsulation of geometric knowledge; they used a colored wall to reorient and find a reward after disorientation in a rectan-

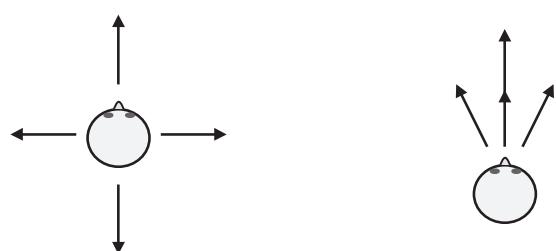

Figure 17.2 Corners are more distinct when a viewer is inside a space as shown on the left, than when outside it.

gular room. Interestingly, monkeys did not use small cues to differentiate the geometry, but they did use larger cues. This result supports an adaptive combination interpretation of when features will be used to disambiguate geometry, because small objects are likely to move, and hence would not often provide a good cue to spatial location. By contrast, larger objects are much more likely to be stable, and thus to be useful in building a spatial framework.

Although the results with various nonhuman animal species are impressive, Hermer-Vazquez, Moffett, and Munkholm (2001) suggested that they might reflect the extensive training that was used in these experiments, which used a reference memory technique rather than the working memory design that had most clearly suggested modularity in Cheng's original experiments. They argued that only human adults, and children older than 5 years, have been shown to use nongeometric landmarks *flexibly* and *easily*, with minimal training. Evaluating the claims of a geometric module requires work either with working-memory paradigms or with paradigms in which training can be minimal, as is possible in studies of human children. Thus, evidence regarding circumstances in which very young children succeed in using nongeometric landmarks as well as geometric information to reorient is vital to the modularity debate. In fact, there is evidence that young children do use both kinds of information. In moderately large spaces, children as young as 18 months use features such as a colored wall to reorient, as well as coding geometric information (Learmonth, Newcombe, & Huttenlocher, 2001). The encapsulation result is restricted to the extremely small room used in the original Hermer-Spelke studies (Learmonth, Nadel, & Newcombe, 2002).

There are a fairly large number of data sets on children's use of featural and geometric information, at various ages and in rooms of various sizes. Cheng and Newcombe (2005) compared the available data, revealing several interesting patterns. First, although even very young children do make above-chance use of featural information in large rooms, they are not perfect users of such information. Children's performance improves with age in large as well as small rooms. Specifically, the ability to use the colored wall to choose between the geometrically identical corners in the larger space appears to improve at 5 years and then again at 6 years of age (the same age range at which the ability to use the colored wall at all appears in the small room). Second, performance in using featural information in

the larger room is better than performance in the smaller one, even at the older ages. Thus, two facts about the data need to be explained: the consistently greater difficulty of the small room, and the age-related changes that occur in each context. In addition, the age-related change in using featural information appears to be much more abrupt in the small room than in the larger one.

Newcombe (2005) has proposed that the existing data on integration of featural and geometric information can be best explained by an adaptive combination approach in which the likelihood of using the two kinds of information varies depending on factors such as uncertainty or history of cue validity. Being in a larger room may increase the likelihood of using a feature, because it increases its validity—in the real world, more distal features are more typically useful as landmarks. Alternatively or in addition, being in a room that affords more opportunities for movement may activate modes of processing that involve cue combinations not typically used in a more motorically passive situation, just as movement facilitates access to remembered spatial layouts (Rieser, Garing, & Young, 1994). Studies exploring the room-size effect, as well as directly manipulating the salience, certainty, variability, and usefulness of featural and geometric information, hold the promise of specifying how geometric and featural information are used and combined in different circumstances, and the developmental mechanisms that underlie behavioral changes in feature use in enclosed geometric spaces as well as in more naturalistic ones.

The Development of Spatial Processing from an Adaptive Combination Point of View

We have examined studies of early spatial memory and action inspired by Piaget's thinking, and others inspired by theorizing about modular cognitive architecture, arguing in each case that an adaptive combination interpretation of the findings was possible and even preferable. In this section, we examine directly how spatial development occurs from the point of view of an adaptive combination theory, specifically, the Huttenlocher-Hedges hierarchical coding approach. Because this model postulates the combination of fine-grained and categorical information, it suggests the need to investigate the starting points and development of three kinds of processing: first, encoding of fine-grained (or distance) information, second, encoding of categorical information, and third, the hierarchical combination

process itself. While all these lines of development are related, the development of spatial categorization and of hierarchical combination are especially intertwined, because the systematic biases that are evidence for combination of information also provide clues about the nature of categorical coding.

Distance Coding

Recent evidence indicates that toddlers and even infants can use extent to code location and can retain that information after movement. Huttenlocher, Newcombe, and Sandberg (1994) found that 18- to 24-month-olds used distance information to locate an object hidden in a 5-foot-long sandbox; use of such information by toddlers is also supported by the findings of geometric sensitivity just reviewed (Hermer & Spelke, 1996; Learmonth et al., 2001). Newcombe, Huttenlocher, and Learmonth (1999) found that even 5-month-old infants may code distance; after familiarization to a hiding event, infants looked longer when an object emerged from a new location in a 3-foot-long sandbox. These reactions seem to reflect knowledge infants bring with them to the laboratory rather than online learning from familiarization events (Newcombe et al., 2005). In addition, Gao, Levine, and Huttenlocher (2000) found that 9-month-old infants could encode extent in a different setting involving the length (height) of an object. After being familiarized to a beaker filled with liquid to a particular height, infants looked longer when the height of liquid in a beaker was changed.

Comparing the paradigms used by Newcombe, Huttenlocher, and Learmonth (1999) and Gao et al. (2000) is interesting. In the first situation, an infant must encode a horizontal extent between the edge of a box and the place where an object disappeared. In the second situation, an infant must encode the vertical extent from the bottom (or the top) of a beaker to a liquid surface. In the first case, we speak of encoding distance, and in the second case, we speak of encoding either height or liquid quantity, but the situations are closely comparable. In other words, along with time and quantity, distance involves the registration of magnitudes along a dimension. General notions of extent are present across species and may be fundamental to several domains of human thought (Walsh, 2003). Tasks involving extent have been shown to have a common neural basis in humans in regions in and around the intraparietal sulcus (Dehaene, Dehaene-Lambertz, & Cohen, 1998; Fias, Lammertyn, Reynvoet, Dupont, & Orban, 2003), per-

haps based on common action principles (Rossetti et al., 2004). There are close relations between visuospatial competence and understanding of number in normally developing children (Ansari et al., 2003). Children with Williams syndrome, who have pronounced spatial deficits, also show delayed understanding of counting and cardinality (Ansari et al., 2003).

The linkage between the spatial notion of distance and the mathematical notion of quantity raises the possibility of a close connection between spatial and mathematical thinking based on sharing a developmental starting point. If true, this linkage undercuts claims of domain-specific innate representations and early modularity. Humans may build on this starting point, one shared with other species, in various ways that ultimately demarcate the spatial and mathematical domains. Many of the mechanisms that lead to separate lines of development revolve around human symbolic abilities, including the use of measuring instruments for relatively exact evaluation of distance and the use of numerical notation for exact specification of quantity.

One possible interpretation of these data is that young infants possess mature spatial (and quantitative) competence. However, another possibility is that, while the starting points for spatial development are stronger than those posited by Piaget, the abilities of young children are still limited. There is in fact evidence of several specific transitions in the development of extent coding. One change, which we have already discussed, is that during the 1st year of life, location may often not be coordinated with the static perceptual characteristics of objects, but rather be taken as definitional of objecthood (e.g., Leslie et al., 1998).

Other changes occur after infancy, particularly in the period between 18 and 24 months, when there are several changes in distance coding. Prior work with infants and toddlers had involved distance coding in the context of locating a single object, hidden for a relatively brief period, located in a surrounding container. Newcombe, Huttenlocher, Drumney, and Wiley (1998) examined the development of the use of distal landmarks located at the edges of a room in which there was a centrally located sandbox. Children ages 16 to 36 months observed a toy being hidden in the rectangular sandbox, moved to the opposite side, and then searched for the toy. Half the children performed this search with visible landmarks in the room and half without visible landmarks (because a circular white curtain surrounded the sandbox). Children 22 months and older performed better when the

landmarks were visible, whereas the presence or absence of a curtain made no difference to the accuracy of children younger than 22 months. They did not seem to use the distance from surrounding objects to locate objects after movement, that is, did not exhibit what has been called place learning. These results are consistent with earlier work (Bushnell, McKenzie, Lawrence, & Connell, 1995; DeLoache, & Brown, 1983).

Sluzenski, Newcombe, and Satlow (2004) examined the ability of children aged 18 to 42 months to perform three other tasks that are basic to mature spatial functioning. In prior work with the sandbox paradigm, we had examined memory for only a single object, hidden for less than a minute. To be useful, however, spatial location memory needs to allow for representing multiple locations to support the learning of spatial relations among objects. We also need to exhibit recall after a substantial filled delay. When children from 18 to 42 months were tested on sandbox search tasks involving recall of two locations, learning a spatial relation, or retaining even the location of a single object over a filled delay, results indicated a transition from 18 to 24 months in all three abilities. A similar transition was found by Russell and Thompson (2003). Although Moore and Meltzoff (2004) found good performance by 14-month-olds after a 24-hour delay, their hiding situation involved very distinctive locations and a very highly marked hiding procedure, and they did not examine age-related change. Thus, the existing evidence, though still sparse, suggests the possibility of a general transition in spatial coding toward the end of infancy, in which a capability emerges for durable and complex memory that can support action and reasoning.

To say that this capability may emerge toward the end of the 2nd year is not to be equated with saying what we see by 2 years is mature competence. On the contrary, there is evidence that development of the capacity to construct spatial relations may continue for some time. In particular, place learning is not complete until well into the school years, perhaps not until the age of 10 years (Laurance, Learmonth, Nadel, & Jacobs, 2003; Leplow et al., 2003; Overman, Pate, Moore, & Peuster, 1996; see review by Learmonth and Newcombe, in press). In addition, there may be earlier roots of this capability in simpler situations (Clearfield, 2004; Lew, Bremner, & Lefkovich, 2000; Lew et al., 2004).

Another change in distance coding (or coding of extent) that occurs after infancy concerns the use of a surrounding container that can serve as a standard against

which to assess extent. Such a standard was present in all the sandbox or beaker studies reviewed so far. Without a perceptually present standard, a mental standard must be imposed, and applied uniformly across a wide range of situations, to determine extent. Huttenlocher, Duffy, and Levine (2002) found that infants and 2-year-olds could judge extent only as long as a target was aligned with a perceptually available standard. They could *not* do so when a target was presented in isolation (see Figure 17.3). It was not until the age of 4 years that children could determine extent without a perceptually available standard. Beginning at about 5 years of age, children show a mixed pattern of performance in extent coding tasks. On the one hand, they can determine extent without a perceptually available standard, indicating some independence from perceptual context. On the other hand, their judgment can be affected by a misleading standard. For example, if a target object is presented in a container of a particular height, and then children are given a choice task involving containers of a different height, they do not recognize the target since it has a changed relation to the container (Duffy, Huttenlocher, & Levine, 2005). If the foil in the choice task shows the same relation to the container as the target had to its container in the original presentation, they

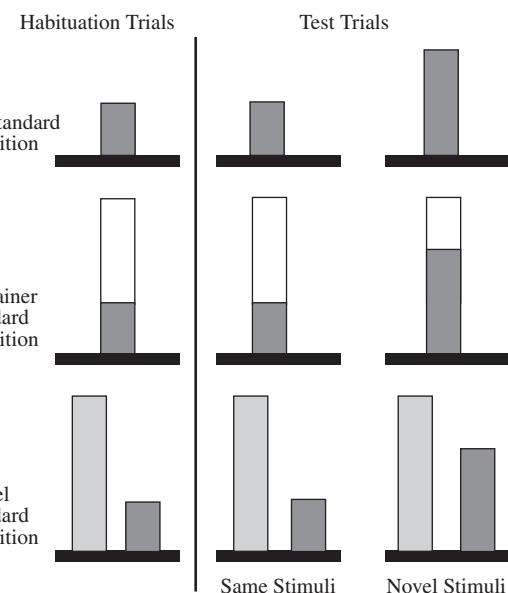

Figure 17.3 Examples of the stimuli presented in habituation and test trials in three conditions. *Source:* From "Infants and Toddlers Discriminate Amount: Are They Measuring?" by J. Huttenlocher, S. Duffy, and S. Levine, 2002, *Psychological Science*, 13(3), pp. 244–249. Reprinted with permission.

choose the foil. Thus, it appears that children initially code extent only relative to a present standard (“relative extent”). Later, they become able to represent extent relative to a constant standard (“absolute extent”), but in ambiguous situations, the present context still affects their judgments.

Development of Categorical Coding

Besides fine-grained coding of distance, the other kind of information used in spatial estimation, according to the hierarchical coding model, is categorical information. The earliest signs of categorical coding of location are evident by at least 3 months of age, in the ability of infants to dishabituate when stimuli presented in various positions above a bar are presented below the bar (or vice versa) (Quinn, 1994). A similar pattern is evident for switches from left to right of a bar (or vice versa), although, interestingly, there are no reactions to changes from one side to the other of a diagonal bar (Quinn, 2004). At 6 months, there are indications of understanding of an abstract notion of containment (Casasola, Cohen, & Chiarello, 2003).

Despite these indications of early spatial categorization, it is also clear that there is a developmental progression in the ability to categorize spatially. Categories of above and below are not formed without a bar to demarcate them (Quinn, 1994) and are not formed until 6 months of age when the stimuli shown during habituation vary in shape as well as in position (Quinn, Cummins, Kase, Martin, & Weissman, 1996). At 3 and 4 months, there is no category of between at all, and when it appears at 6 months, it is only evident with uniform habituation stimuli (Quinn, Norris, Pasko, Schmader, & Mash, 1999). This limitation is overcome by 9 to 10 months (Quinn, Adams, Kennedy, Shettler, & Wasnik, 2003). In sum, although only a few spatial categories have been examined so far, there may be gradual and protracted development in spatial categorization. The factors and mechanisms that underlie this development remain to be determined.

Development of Hierarchical Combination

In the preceding sections, we reviewed the development of the two components of the Huttenlocher-Hedges hierarchical combination model of spatial coding: fine-grained coding of distance, and coding of spatial categories. We are now in a position to take up the issue of the development of hierarchical combination of these information sources. Evidence of such combination comes

from systematic patterns of bias in spatial estimation toward category prototypes, bias patterns that in turn provide information on what categories are being used. Thus, for example, the fact that spatial estimations of the locations of dots in a circle are biased toward the centers of quadrants defined by horizontal and vertical axes suggests that those quadrants constitute spatial categories (Huttenlocher et al., 1991). The earliest evidence of hierarchical combination comes from children of 16 to 24 months, who show bias toward the center of the rectangular sandbox (Huttenlocher et al., 1994). This bias cannot be explained on perceptual or motoric grounds, as it is evident even when children move laterally along the box between hiding and search, or observe hiding and then search from an extreme end of the box. Whether hierarchical combination is evident before 16 months is unknown. The development of categorization ability in the 1st year of life may set some lower limit on the possibility of such adaptive combination. However, the process of hierarchical combination could potentially be available in principle or as a potential even before specific constituents appear.

Even if hierarchical combination is a basic cognitive process, it might be expected to change developmentally in various ways. First, the accuracy of fine-grained coding might improve, as well as its durability. Such change would be expected to reduce the weighting of category information and hence reduce the extent of bias. The research on this topic concentrates on the issue of durability, studied by manipulating the length of the delay between encoding information and being asked to estimate it. Research with adults has shown that longer delays lead to increased bias, as would be expected because categorical information should be more strongly weighted as the certainty of fine-grained information declines (Engebretson & Huttenlocher, 1996; Huttenlocher et al., 1991). Thus, one might expect that delay-related increases in bias would be more marked for younger children, if they experience more marked forgetting of fine-grained information (although whether there actually are such age differences in forgetting rates is controversial; see Brainerd, Kingma, & Howe, 1985). So far, delay-related increases in bias have been shown to be fairly constant from the age of 7 years on (Hund & Plumert, 2002).³ However, if there are in fact age-related

³There is, however, a puzzling decline in delay-related bias at age 11 in these data.

changes in forgetting, they may exist at younger ages, so this question deserves examination in children between the ages of 2 and 7 years.

Second, categorical coding might change in any one of several ways. One possible change is that categories might become more conceptual and more likely to be based on functional groupings (e.g., “the playground area”). From the age of 7 years on, children and adults show increased systematic biases when objects in a certain spatial area also belong to the same conceptual category, with the effects constant across age (Hund & Plumert, 2003). However, the effect of conceptual categories might not be present for younger children whose categories are less firmly entrenched. Relatedly, spatial categories might become less dependent on the presence of physically present boundaries. For example, a rectangular space could be divided categorically into two halves by imposition of an imaginary line down the center. Indication of such a division appears to be more likely in smaller spaces, perhaps because they can be apprehended at a single glance: children’s bias patterns showed evidence of dividing a rectangle into halves by 4 years for small spaces, although not until much later for larger ones (Huttenlocher et al., 1994). In addition, categories might not be formed in the most difficult circumstances until older ages. Hund, Plumert, and Benney (2002) found that only adults were capable of using categorical information when the locations of objects in four spatial regions were learned in a random order, so that the spatial categories were far less evident than when there was no temporal scrambling.

Third, hierarchical combination might change as information-processing capabilities strengthen. In fact, hierarchical combination seems initially to be limited to one dimension at a time. When children are asked to encode the location of a dot in a circle, they encode fine-grained location in the same two dimensions used by adults—distance from the center of the circle and angle—and they adjust the coding of distance from the center using category information. However, they do not also show categorical adjustment of angular information until 10 years of age (Sandberg, Huttenlocher, & Newcombe, 1996). This lack was not basic to encoding of angle because categorical coding and adjustment was demonstrated by children as young as 7 years when no coding of distance was also required (Sandberg, 2000). Thus, it seems likely that children have capacity limitations that prevent them from noticing or using the

central tendency of variation in two dimensions at the same time.

In summary, the principle of hierarchical combination seems to be in evidence as early as we have been able to examine it, by 16 months of age. It may well be a basic aspect of information processing, as arguably suggested by the fact that it is also shown by rhesus monkeys (Merchant et al., 2004). However, precise patterns of hierarchical combination may be expected to change with age. For instance, the components may change, as distance coding becomes more exact and/or categorical coding becomes more systematic, more conceptual, or more differentiated. Very little research has studied those questions. What we do know is that there is a basic change in late childhood in the ability to perform hierarchical combination along two dimensions at once. Acquisition of this capability may affect many other aspects of spatial functioning and is interestingly reminiscent of some of Piaget and Inhelder’s proposals about the advent of mature spatial functioning in the same time period.

Effects of Experience on Hierarchical Combination

Developmental change in hierarchical combination ought to be related to experience in the shorter run, as well as to age-related change in information-processing capacity or estimation ability. That is, when certain locations in a space are routinely clustered or more frequently occupied, categories may be formed based on these probabilities of occurrence (Huttenlocher, Hedges, & Vevea, 2000; Spencer & Hund, 2002, 2003). Formation of such ad hoc spatial categories is difficult to find in situations in which there are strongly engrained bases of organization, as in the case of the circle where it is difficult to override a vertical axis based on gravitation and a horizontal axis organized at right angles to the vertical and in parallel with the symmetry of the human body (Huttenlocher et al., 2004), or in cases where one basis of organization is around the midline of a person’s body (Spencer & Hund, 2002, 2003). In fact, forming categories based on regions of high density of occurrence may not be adaptive in cases where other boundaries can be known with greater precision. However, dynamic alteration of spatial categories has been found in certain contexts.

One situation for studying the extent to which participants alter their categorical organization of a spatial

array is when the sequential order of display of the various objects in the array initially suggests a certain organization and this order of display is then altered to suggest a different organization. Hund and Plumert (2005) displayed 20 objects in a large square box in an order that either emphasized organizing the objects by quadrant or by their relation to the sides of the box (see Figure 17.4). They found that adults could flexibly reorganize as a function of the most recent temporal structuring of the display. This finding is interesting because it indicates that the use of horizontal and vertical boundaries (Huttenlocher et al., 2004) is not inevitable; the availability of horizontal and vertical lines defining the edge of the space provides an alternative organization of some precision. However, Hund and Plumert found that children as old as 11 years displayed limited flexibility. The reasons for this limitation are unknown at present.

Another situation in which to study dynamic restructuring of spatial estimation occurs when a single location is repeatedly utilized in a spatial search situation, and then search is switched to a second location, as in the classic A-not-B task. Of course, if the A-not-B error is conceptualized as the result of a basic limitation in understanding of object permanence, as it was by Piaget, no such effects would be evident, but recent data show convincingly that biases toward location A when

searching for location B can be found in children of 2, 3, 4, and even 6 years of age, under certain circumstances (Schutte & Spencer, 2002; Schutte, Spencer, & Schöner, 2003; Spencer & Schutte, 2004; Spencer, Smith, & Thelen, 2001). The tendency is a function of the number of A trials and the number of B trials (Spencer et al., 2001), as well as the separation between the A and the B locations (Schutte et al., 2003). It does not depend on active search to location A, being evident also when children simply observe hiding at location A (Spencer & Schutte, 2004).

An interesting kind of developmental change may depend on the relative use of prototypes based on intrinsic geometry, such as that defined by the vertical and horizontal lines that divide a circle into quadrants, and the prototypes of frequency-based spatial categories formed around groups of locations that are frequently occupied in a particular situation. Hund and Spencer (2003) found that 6-year-olds were more affected than 11-year-olds by such frequency-based categories. In fact, they exhibited biases toward a frequency-based prototype that ignored categories based on intrinsic geometry. These biases involved crossing the vertical boundary that defined categories of right and left of their bodies. This kind of flexibility might be important in forming categories early in life and may be lost as experience informs about the relative advantage of using a boundary that can be known with precision (Huttenlocher et al., 2004). However, the question of developmental change in flexibility is not yet clear, as Hund and Plumert (2005) found that adults were more, not less, flexible than children in reorganizing categorical structure on the basis of changes in temporal ordering.

Summary

Fine-grained metric coding of distance and categorical groupings of spatial locations are both evident within the 1st year of life, although neither is present in its mature form. Coding of distance evolves over the toddler and preschool years by taking more account of distal objects, becoming more complex and enduring, and beginning to encompass absolute as well as relative extent. Categorical coding evolves in the 1st year to be less dependent on perceptually available demarcations and more able to encompass perceptually varied stimuli, and likely changes over the next few years as well. Hierarchical combination of these two kinds of information is evident as early as it has been assessed, at 16 months, but it too changes devel-

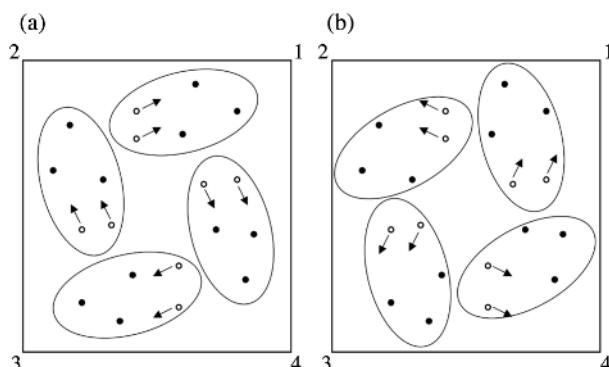

Figure 17.4 Diagram of the experimental apparatus and locations. Open circles mark the eight target locations. Arrows show the predicted pattern of displacement for the target locations. Plumert, 2005, *Cognitive Psychology*, 50, pp. 1–44. Reprinted with permission.

opmentally, over the span of a decade or so. Some of these changes likely depend on increases in information-processing capabilities, whereas others may involve decreased sensitivity to frequency-based prototypes and increasing use of preset category boundaries that can be known with great precision.

REPRESENTING SPATIAL RELATIONS BETWEEN VIEWER AND ENVIRONMENT

We have, so far, examined the development of human capability to encode spatial location. While such abilities likely differ to some extent between humans and other species (e.g., MacDonald et al., 2004), the fundamental capacity to encode location in some fashion is widely shared. The ability to manipulate such information may be more distinctively human. Although this issue has not been extensively studied, nonhuman primates have difficulty with mental rotation (Hopkins, Fagot, & Vauclair, 1993; Vauclair, Fagot, & Hopkins, 1993), and pigeons do not compute interpolated views in the same way that humans do in what amounts to a simple assessment of perspective-taking ability (Spatch & Friedman, 2003). These observations suggest limitations on the capacity of nonhuman animals to mentally transform spatial relations.

In this section, we discuss the development of mental rotation and perspective taking. We also examine the development of navigation, which in many species of nonhuman animal can be very sophisticated. Yet, there is no secure evidence that other species are capable of the kind of spatial inference that allows humans to devise new routes, that is, to get from location B to location C when they have previously traveled only between locations A and B and locations A and C (Shuttleworth, 1998). Spatial inference of the sort that allows for way finding along novel routes may share with mental rotation and perspective taking the need to construct and manipulate relations between viewer and environment.

Mental Rotation and Perspective Taking

Research over the past few decades has shown that mental rotation and perspective taking, while formally equivalent, are in fact very different psychologically. The formal equivalence is easy to appreciate; any computing machine that could move an object (or array) on its axis with respect to a viewer could also perform the computa-

tions required to move the viewer around the object (or array), and the output of (say) a 90-degree rotation of either kind would be identical. The psychological difference was implicitly appreciated by Piaget, who discussed mental rotation and perspective taking in different books (*Mental Imagery in the Child* and *The Child's Conception of Space*), conceptualizing them as part of different lines of development and as occurring at different ages. The fact that mental rotation and perspective taking differ psychologically though not logically was first demonstrated empirically by Huttenlocher and Presson (1973). They found that it is easier to select a picture showing the appearance of an object or array after imagining it rotating on its axis than after imagining moving oneself to take a different perspective on the same object or array. However, mental rotation is not invariably simpler than perspective taking (Huttenlocher & Presson, 1979). When people are asked what object in an array would be in a certain position relative to themselves following a transformation (e.g., what would be closest? on the left?), perspective taking is easier than mental rotation. In fact, with item-focused questions of this kind, children as young as 3 years show an impressive ability to work out the results of moving to take a different perspective on an array (Newcombe & Huttenlocher, 1992), although if asked to choose what picture shows the results of such movement, they do not succeed until 9 or 10 years.

Subsequent studies have confirmed these difficulty orderings (Presson, 1982), using change detection paradigms as well as more specific queries (Simons & Wang, 1998), in contexts where people are standing inside or outside an array (Wraga, Creem, & Proffitt, 2000), and with displays varying in complexity (Wraga, Creem-Regehr, & Proffitt, 2004). It has also been shown that perspective taking and mental rotation differ in terms of their neural substrates, with perspective transformations associated with increased activity in left temporal cortex and mental rotation associated with changes in activity in parietal cortex (Zacks, Vettel, & Michelon, 2003), and that perspective taking and mental rotation are separable abilities when analyzed in terms of patterns of individual differences (Kozhevnikov & Hegarty, 2001). Other work has decomposed the action of moving around the perimeter of an array, as one does in a perspective-taking task, into its rotational and translational components. It appears that rotation is much more difficult to imagine than translation (May, 2004; Presson & Montello, 1994; Rieser, 1989).

The explanation of these complex patterns turns on understanding the frames of reference involved in each task. For example, the classic Piagetian task of selecting a picture that shows the view of an array from a different perspective is difficult because the correct picture shows the elements of the array in the currently available external framework, not the framework as it would be transformed by actual physical movement. Physically moving to a new vantage point makes this task much easier, both because the movement transforms the framework and because dead reckoning mechanisms support the computation of new views. Asking a specific question about the viewer-array relation is easier because it isolates the relation of central interest, reducing the conflict between actual and imagined framework. Imaging the array rotating on its axis involves transforming the relations of the array to the external framework, so that there is no conflict between frameworks. In addition, people often concentrate on one element of the array in performing such a mental rotation, thus simplifying the task.

The developmental sequence from 3 to 10 years has been exhaustively investigated; for more complete reviews, see Newcombe (1989, 2002a) and Newcombe and Huttenlocher (2000). In brief, perspective taking can be seen in incipient form as early as 3 years of age (Newcombe & Huttenlocher, 1992), with mental rotation appearing a year or two afterward. However, variant forms of the task remain difficult at these ages and develop slowly, with good performance on some versions not being evident until 10 years or so. Sequences of this kind leave a powerful impression that the emergence of capabilities follows a complexity ordering, so that tasks that adults perform more slowly and on which they make more errors appear later in children's repertoires. By 3 years, there may be no fundamental lack in understanding the possibility of mentally transforming relations between the viewer and the environment, yet there may be important limitations on the ability to do so in particular performance situations, with the idea of conflict in frames of reference a key aspect of determining when tasks are easier versus harder.⁴

⁴ Such limitations should not be dismissed as uninteresting in the face of early basic ability; they are very functionally relevant and determine children's capacity to take on everyday tasks (Newcombe, 2002a). Thus, they deserve concentrated study with a view to maximizing competence and minimizing the extent to which some children develop less than optimal ability to perform these tasks.

Thinking in terms of the conflict among frames of reference also allows us to explain certain problems children have with spatial tasks other than mental rotation and perspective taking. A prominent example is that children have great difficulty copying the arrangement of elements on a tableau, when the two arrays are not aligned (Laurendeau & Pinard, 1970; Piaget & Inhelder, 1948/1967; Pufall & Shaw, 1973), in finding hidden objects in misaligned models (Blades, 1991), or in indicating positions on misaligned maps (Liben & Downs, 1993). Vasilyeva (2002) showed that 4-year-old children could utilize objective frames of reference when the temptation to use egocentric frames was reduced, but that they failed when there was conflict between the objective and the egocentric frames.

Navigation

We treat navigation after mental rotation and perspective taking, despite the fact that navigation is relatively unproblematic when a visible beacon marks the spot one wishes to reach, as when a church's spire is visible above the surrounding houses. However, reaching an unseen location is more challenging and may sometimes depend on spatial inference of the same kind that occurs in mental rotation and perspective: the construction and manipulation of relations between viewer and environment. Such operations are important in many settings, although they are not always necessary because it is sometimes possible to reach unseen locations by engaging in sequential beacon following. That is, one can go first to one visible landmark that marks an interim step on the journey, then to a second beacon visible from the first beacon, and so on. Such a system is generally called route learning, and seems to be available even to young children, although improvements in noticing landmarks and constructing routes occur with age through the elementary school years (Siegel, Kirasic, & Kail, 1979; Siegel & White, 1975).

Returning to the ability to navigate to unseen points when no route is known and where it may be necessary to conduct inference based on constructions of multiple spatial relations, it has been claimed that children gradually develop a knowledge base that allows for such inference. This knowledge base is often called *survey knowledge* of the environment and has also been termed a *cognitive map* (Siegel & White, 1975). However, the existence of such representations has been controversial, at least in nonhuman animals, and has been more assumed

than extensively studied in children. The most basic indication of integrated spatial knowledge is the ability to go from one point to another, without having previously traveled this route, based on navigation involving a third point. For example, if you can go from your home to school, and also from your home to the park, going directly from the school to the park would indicate spatial inference. Studying this ability in the situation depicted in Figure 17.5, in a blind child of 2.5 years, Landau, Spelke, and Gleitman (1984) argued that human spatial inference is a basic capacity that is evident early in life and is not dependent on visual input. Although this study has been criticized on methodological grounds (Liben, 1988; Millar, 1994), and a replication with a larger sample of blind children and with sighted children wearing blindfolds indicated that one must be skeptical about very early ability for spatial inference (Morrongiello, Timney, Humphrey, Anderson, & Skory, 1995), the data from the Morrongiello study did show that spatial inference is possible by the age of 4 years, with accuracy in-

creasing with age to 8 years. Using a somewhat more complicated situation, Hazen, Lockman, and Pick (1978) found that 3- and 4-year-olds had a very limited ability to draw spatial inferences, but 5- and 6-year-olds did appreciably better.

We should consider further the bases of spatial inference in these paradigms. In the Landau et al. and Morrongiello et al. work, children cannot see the environment, either because they are blind or because they are blindfolded. In the Hazen et al. work, children are sighted and not blindfolded, but because the rooms have doors and roofs, they cannot relate their locations visually to each other or to an external framework. Thus, in these studies, spatial inference has to be based on dead reckoning—on memory for distances traveled and on the angles of turns. Studies of blindfolded adults doing simple integration tasks based only on dead reckoning (e.g., traveling outward from a home base, taking a turn and traveling further, and then being asked to point to home base) show that performance is reasonably accurate, but that even adults show at least a small amount of error in such simple tasks (Fukusima, Loomis, & Da Silva, 1997; Rieser, Guth, & Hill, 1986). Furthermore, the ability to perform such tasks improves from the preschool period to adulthood (Rieser & Rider, 1988, 1991). Thus, it is not surprising that spatial inference based on dead reckoning is difficult for young children and develops over the school years.

What about spatial inference in situations in which external frameworks are available? In the home-school-park example, if neither park nor home is visible from the school, then walking or pointing to the park from the school would be evidence of a spatial inference, arising from an integrated representation created by the availability of common external landmarks during travel of previous routes. Although there have been many studies in which children and adults have been asked to point to unseen locations in a neighborhood or on a campus from a particular vantage point (e.g., Anooshian & Kromer, 1986; Anooshian & Young, 1981; Cousins, Siegel, & Maxwell, 1983), none of these studies included a means of assessing whether the relations queried had ever been directly experienced. Thus, it is unknown to what extent they probed spatial inference. After several years spent living in a certain environment, it is possible that all possible pairs of locations have been traversed directly. Research on spatial inference in novel environments is oddly rare. In one of the few such studies, Heth, Cornell, and Flood (2002) found that 6-year-old children were

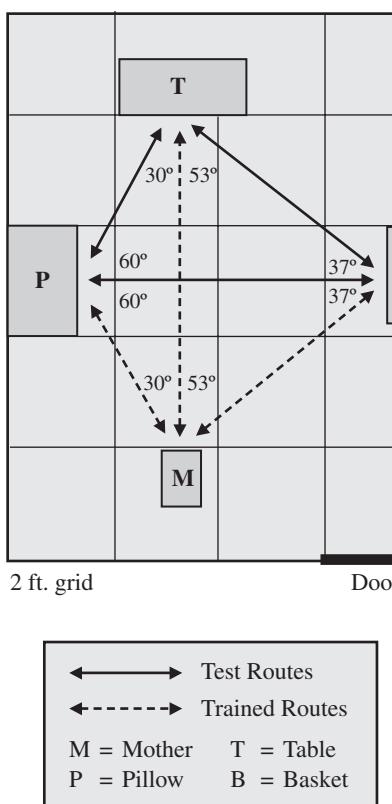

Figure 17.5 Layout for task. Source: From "Spatial Knowledge in a Young Blind Child," by B. Landau, E. S. Spelke, and H. Gleitman, 1984, *Cognition*, 16(3), pp. 225–260. Reprinted with permission.

able to point to where they started a 1-km hike across an unfamiliar campus after completing it. The performance is impressive given that they had not been told to keep track of their movements, and that the route was very long and traversed only once. However, the children's error, while better than chance, was still substantial at 54 degrees. Adults' error was 30 degrees. In addition, because children were not disoriented, their success could have been based on dead reckoning as well as on spatial inference.

Though sparse, the data suggest that the origins of spatial inference lie in the preschool period, with considerable refinement in the accuracy of inference over the school years. It is possible that spatial inference follows a similar developmental trajectory to transitive inference. After all, transitive inference has been shown to depend on the construction of an ordered spatial array from verbal statements (Huttenlocher, 1968), so spatial inference and traditional transitive inference seem quite similar. A considerable body of evidence on transitive inference suggests that, while it may first be evident in the preschool years, it appears more clearly and reliably as children move into the elementary school years (Chapman & Lindenberger, 1992; Halford & Kelly, 1984). In turn, transitive inference from verbal statements appears to depend on working memory (Oakhill, 1984; Perner & Aebi, 1985), which also develops considerably across the school years (e.g., Gathercole, Pickering, Ambridge, & Wearing, 2004). The same reliance on working memory is likely to be true for specifically spatial inference.

Navigation based on spatial inference may also improve in ways that are linked to the changes in hierarchical coding that we noted in a prior section. Children do not use categorical coding to correct fine-grained coding on two dimensions simultaneously until 9 years of age (Sandberg et al., 1996), and they do not divide even a 5-foot-long sandbox into halves for categorical coding until about the same age (Huttenlocher et al., 1994). These changes increase the accuracy with which spatial information is coded and therefore could affect the extent to which a set of spatial locations can be sensibly combined.

The fact that children's ability to navigate improves in many ways over the first 12 years or so of life (e.g., Cornell, Heth, & Alberts, 1994) is associated with an increase in the home range that they are allowed to travel without supervision (Hart, 1979). Causality here may run in both directions; parents allow children to

travel further when they appear competent to do so, while further travel may foster navigational ability. In addition to the age-related changes in spatial inference that we have been stressing, navigational prowess may increase as children develop specific strategies such as looking around at turns to note the view that will be seen on a return trip (Cornell, Heth, & Rowat, 1992) or selecting salient landmarks for rehearsal, especially landmarks located at turns (Allen, Kirasic, Siegel, & Herman, 1979).

In summary, spatial inference based in integrating dead reckoning information is likely first evident in the preschool years; inference based on integrating information using common external landmarks is little studied, but was perhaps seen at 6 years (the youngest age tested) in one study. However, we do not know what allows for the emergence of these abilities. Improvement in spatial inference and in navigation is considerable over the school years, and is likely linked to multiple lines of development, including reasoning in general, the accuracy of spatial coding, and the use of strategies such as looking around at turns. It is striking that there is much that remains unknown about navigation, an area of spatial functioning of considerable practical importance that has been intensively studied in nonhuman animals. Although navigation was the focus of a great deal of research a few decades ago, attention to it declined, in part because of the focus on infancy and the origins of knowledge question. It may now be time to return to its examination, which can be richly informed by recent advances in allied fields.

USING SYMBOLIC SPATIAL REPRESENTATIONS

Our species may be unique, or at least very distinctive, in our capacities for mental rotation, perspective taking, and spatial inference. Another distinctive kind of human spatial competence rests on our ability to represent situations symbolically and to communicate with each other using language and nonlinguistic symbolic systems such as maps. In this section, we begin by addressing the development of nonlinguistic spatial communication, and then proceed to discuss spatial language. These two varieties of spatial communication present very different patterns of advantages and disadvantages, and very different challenges in acquisition.

Maps and Models

As a device for communicating about spatial relations, maps and models differ from language in two ways. They must necessarily incorporate metric relations, which are optional in language, and they must show all depicted relations simultaneously, which is impossible in language. However, while maps and models have similarities, there are distinctions between them. Although there are many unclear cases and exceptions, generally speaking, maps are flat and models are three-dimensional; maps use arbitrary symbol-referent relations and models are more iconic; and maps deal with larger spaces and models with smaller ones.

Research on the development of understanding and using models and maps has been marked by the same kind of controversy evident in other research on spatial development, with some investigators arguing that mapping abilities emerge slowly in a fashion tied to the construction of spatial understanding as described by Piaget (Liben & Downs, 1993) and other investigators suggesting that mapping has an innate basis (Blaut, 1997; Landau, 1986). However, in this research area, a third tradition has been prominent. Investigators using a Vygotskian perspective have analyzed maps and models, as well as other culturally transmitted tools such as navigation systems, as artifacts that build on distinctively human capabilities, either innate or constructed ones, in a fashion that is heavily dependent on social interaction. Newcombe and Huttenlocher (2000) pointed out that, while the Vygotskian perspective fits the existing data reasonably well, a notable lack in the literature is investigation of the sporadic and variable exposure to mapping systems that is common in our culture. This situation has yet to be remedied, although a pioneering investigation by Szechter and Liben (2004) has shown that investigation of spatial input is feasible and valuable. These investigators observed parents explaining a graphically challenging book called *Zoom* to their 3- and 5-year-old children. They found substantial variability, even in a small middle-class sample, in the extent to which parents used helpful strategies, and found cross-sectional correlations of parental explanation strategies with children's spatial comprehension.

Although we are just beginning to get data on how symbolic spatial abilities are transmitted to children, we have a reasonably good, and continuously strengthening, body of descriptive data on the typical ages and sequences of emergence of mapping competence in chil-

dren growing up in the cultural conditions of modern industrialized societies. The sequence begins at about the second birthday and involves appreciation of two aspects of maps and models: that elements in them stand for objects in the world (element-to-element correspondence) and that distances in them stand for distances in the world, although subject to a scaling factor (relational correspondence). Element-to-element correspondence has been the focus of a well-known research program (e.g., DeLoache, 1987, 1995) in which children are asked to find an object they have seen hidden in a model in a larger room (or vice versa). These studies have shown that in the use of information acquired in a model to guide search in a room, there are typically abrupt transitions that are not linked to memory for the location, which is always high. Rather, children seem to have (or not have) a representational insight that one element can stand for another (DeLoache, Miller, Rosen-gren, & Bryant, 1997). The exact age of this transition is somewhat variable and depends on factors such as iconic resemblance and the extent of differences in scale, but children younger than 2 years typically have great difficulty with even the easiest versions of the task, whereas children of 3.5 years and older succeed even in difficult contexts. Element-to-element correspondence of a completely arbitrary kind (e.g., X marks the spot) may appear slightly later. There is some evidence of success in children as young as 3 years (Dalke, 1998), but the ability strengthens from 3 to 6 years (Newcombe & Huttenlocher, 2000).

Relational correspondence seems, on the face of it, to be more difficult than element-to-element correspondence. Indeed, from a Piagetian perspective, scaling depends on proportionality and hence should not be evident until well into the elementary school years. However, Huttenlocher, Newcombe, and Vasilyeva (1999) have shown that 4-year-olds, and some 3-year-olds, can use a small map of a five-foot-long sandbox, in which a dot represents a hidden toy, to find the toy with great accuracy. Of course, this is a simple situation involving only one object and a single dimension. In the two-dimensional case, still with only a single location at issue, 5-year-olds succeed and 4-year-olds show the same kind of bimodal performance exhibited by 3-year-olds in the one-dimensional context (Vasilyeva & Hutten-locher, 2004). Children's performance was affected by the degree of rescaling required, with higher accuracy when the referent space was closer in size to the map. This fact may partially explain why 4- and 5-, and even

6- and 7-year-olds, show difficulty with scaling when dealing with maps or models of large spaces (Liben & Yekel, 1996; Uttal, 1996). These more difficult situations also involve the need to locate many objects at once, and hence to rescale many distances.

Overall, the data suggest that the ability to comprehend the relation between distance in a map or model and distance in a real-world space may be present earlier than proportional reasoning of a formal kind, but that there is only gradual emergence of the ability to use this insight in complex situations. The basis for early relational correspondence is not yet clear. Huttenlocher et al. (1999) suggested that relative coding of distance might be involved, but in this case, degree of rescaling should not be important, or at least not more marked than it is in simple memory for location in smaller versus larger spaces. However, Vasilyeva and Huttenlocher (2004) found that performance on a scaling task could not be completely accounted for by the difficulty of a nonscaling task. It is possible that early rescaling is based instead on a simple stretching of encoded distances and that error increases as more stretching is required.

Element-to-element and relational correspondence are not all that is required for map and model use. Other requirements include the ability to relate aerial or oblique views to eye-level views, the ability to align maps physically or mentally, and the ability to use maps to guide navigation. The first ability appears at a younger age than one might expect. By the age of 25 months, children lifted up so as to be able to view a barrier arrangement that separated them from their mothers could use this information to head for their mothers in the direction that was open (Rieser, Doxsey, McCarrell, & Brooks, 1982). They could do this even after having viewed the apparatus from a side perspective different from the view they had from the ground in direction as well as elevation. However, 21-month-olds failed to use information gained from an overhead view. The reason for this remarkable developmental transition is still unknown.

Alignment of maps is notoriously difficult, at least when it must be done mentally. Even adults struggle to answer questions that involve dealing with misalignment (Levine, Jankovic, & Palij, 1982). One reason for the problem may be that alignment of map and world involves mental rotation of the map (Scholnick, Fein, & Campbell, 1990; Shepard & Hurwitz, 1984). Children begin to show some success in simple situations involv-

ing misaligned maps by the age of 5 years (Blades, 1991; Bluestein & Acredolo, 1979) but difficulties persist into the school years (Presson, 1982).

Using maps for navigation involves the combination of all the skills discussed so far. Children as young as 4 years can use maps to guide navigation in simple situations (Scholnick et al., 1990; Uttal & Wellman, 1989), but have difficulty dealing with misalignment (Bremner & Andreasen, 1998). Children of 6 years can use maps in larger and more complex spaces, where there are many alternative ways to go and where rescaled distance information must be used (Sandberg & Huttenlocher, 2001). However, children of 5 and 6 years rarely turn the map into physical alignment with the space (Vosmik & Presson, 2004). Instead, they succeed when they can "look ahead," planning what they will do for several turns, while looking at an aligned map (Sandberg & Huttenlocher, 2001; Vosmik & Presson, 2004).

Spatial Language

There are at least three ways in which human language is not particularly well suited to the communication of spatial information. First, it is difficult to capture metric knowledge without using technical terms. Instead, language naturally groups space into categories, such as "front" and "back." Second, ambiguity can arise in speaking about space because various frames of reference are possible for many spatial terms, so that "front" can mean two different locations depending on the system in use. Third, language is sequential, so that speakers must select a specific order in which to mention the spatial relations in a scene. Fortunately, although these issues are potential impediments to effective communication, adult speakers and listeners generally cope well with spatial description, in part through the use of various strategies and linguistic devices. For example, spatial-linguistic categories, like other categories, are structured so that terms refer to areas that have prototypic centers, albeit unclear boundaries (e.g., Crawford, Regier, & Huttenlocher, 2000; Franklin, Henkel, & Zangas, 1995; Munnich, Landau, & Dosher, 2001). Thus, while from a logical point of view, describing a location as in "front" may only communicate spatial information approximately, there is a general assumption that one means the prototypical front unless otherwise specified. When necessary, speakers supplement their use of a term such as *front* by saying things like "in front but a bit to the left" or "the hole is three yards in front of

you." In the first case, they graduate the category; in the second case, they add metric specification in a case where it may be crucial. In another example of adroit use of strategies to use language to communicate about space, speakers often specify which of the different possible frames of reference they are using, in ways that are structured by politeness rules and conventions (Carlson-Radvansky & Radvansky, 1996; Schober, 1993, 1995). Sometimes speakers even mix frames of reference to maximize the chances of comprehension (Taylor & Tversky, 1992b). The comprehension of spatial layouts from verbal description is often, though not always, as good as that obtained from visual experience such as viewing environments and maps (e.g., Avraamides, Loomis, Klatzky, & Golledge, 2004; Taylor & Tversky, 1992a, 1992b, 1996).

Given this picture of mature competence, the developmental issue is how children acquire terms for spatial categories, conventions regarding frames of reference, and rules for structuring sequential linguistic description of spatial scenes. The first problem has generated the most controversy, as it involves the classic question of the relation of language and thought. One answer to the question is that the way a particular language carves up the spatial world into categories influences children's developing spatial understanding (Bowerman, 1996; Choi & Bowerman, 1991). For example, because Korean has special language that denotes to the relation of "tight fit," children search for a referent for the term and construct the corresponding category. An alternative answer is that children have already acquired an understanding of the spatial categories that may potentially be linguistically marked by the time they begin to acquire the corresponding linguistic terms (Mandler, 1996). In this view, children in all linguistic communities know about tight fit before they learn language, although only some of them will be exposed to a linguistic means of referring to this concept.

Research suggests that an intermediate position may be most appropriate. Infants of 9 to 14 months apparently categorize both contrasts that are lexicalized in their language and contrasts that are not, suggesting the prior existence of spatial understanding and favoring Mandler's point of view (Hespos & Spelke, 2004; McDonough, Choi, & Mandler, 2003). However, adults seem to pay little attention to contrasts that they do not routinely lexicalize (McDonough et al., 2003), suggesting that language may ultimately influence spatial conceptualization, leading to the atrophy of concepts that

are not used in language. Although this phenomenon is analogous to the loss of phonemic contrasts not used in one's native language, it may be easier to overcome; simple manipulations of context have been found to lead people to pay attention to spatial meanings that they do not linguistically code (Li & Gleitman, 2002; see also Levinson, 2003, and Levinson, Kita, Haun, & Rasch, 2002, for an opposing view).

We know a good deal about our second and third questions: how children learn to select frames of reference and how they learn to structure their spatial descriptions and direction giving. In both cases, there is a fairly protracted developmental course, so that children as old as 8 years or so may not be effective users of the conventions adopted by adults (Allen, Kirasic, & Beard, 1989; Craton, Elicker, Plumert, & Pick, 1990; Gauvain & Rogoff, 1989; Plumert, Ewert, & Spear, 1995; Plumert & Strahan, 1997). Children in elementary school may also have difficulty in constructing spatial knowledge from verbal descriptions (Ondracek & Allen, 2000). These abilities may appear late because of the social skills that are required: taking the listener's point of view and recognizing communication failures. Efficient referential communication about nonspatial matters is also rare in the early school years, although explicit training can help overcome the difficulties (Sonnenchein & Whitehurst, 1984). Another reason for protracted development of these skills may be the demands these tasks make on working memory capacity (Ondracek & Allen, 2000).

INDIVIDUAL DIFFERENCES IN SPATIAL DEVELOPMENT

People often talk about how they are good (or bad) at fitting objects into the trunks of their cars, putting together electronic equipment, or finding their way in strange cities. Such matters have a strange fascination, for example, gender differences in tasks such as these are a staple of cartoons and comedy routines. But individual and gender differences in spatial ability are not trivial curiosities. They have real-world importance because they predict interest and success in occupations such as engineering, drafting, piloting, surgery, computer science, mathematics, and the physical sciences (Shea, Lubinski, & Benbow, 2001; for an overview, see Hegarty & Waller, 2005). Given these relations, understanding how children develop a range of abilities in spatial tasks becomes a crucial goal. Knowledge about

the mechanisms involved could help us devise methods to maximize the availability of a set of cognitive skills that is more and more important in an increasingly technological society. Variability in spatial performance is theoretically as well as practically important. For example, an adaptive combination model of spatial development uses variability in its description of development, as do other contemporary approaches to developmental change (Siegler, 1996). As another example, some of the debates over the nature of mature spatial competence, such as whether representations are orientation-specific or orientation-free, may be clarified by considering individual differences (Friedman & Miyake, 2000). However, despite the practical and theoretical importance of understanding the development of individual differences in spatial skill, research on this topic has been peripheral to the study of cognitive development, and it has been pursued primarily as a branch of psychometrics, using correlational rather than experimental techniques.

There are several reasons for this state of affairs. Within the cognitive development community, there has been intense interest in constructing a dense and detailed account of normative development. This concentration leads to the neglect of individual differences for reasons both theoretical and practical. On the theoretical side, there is the assumption that much of spatial development is canalized and that variability in performance is truly error variance rather than meaningful information. This assumption is very common when investigators consider very early developments in infancy and preschool, and research on this period has been especially fascinating for cognitive developmentalists over the past few decades. Although the proposition may be correct, it is also possible that children who develop earlier ability to retain spatial information over delays or to rescale information from maps are in fact displaying meaningful strengths. Recently, there have been demonstrations of such linkages in other domains of cognitive development, for example, findings that variations in habituation to human intentional action at 14 months are related to the development of theory of mind in preschool (Wellman, Phillips, Dunphy-Lelii, & LaLonde, 2004) and that variations in speech perception at 6 months of age are linked to language development at 2 years (Tsao, Liu, & Kuhl, 2004). On the practical side, it has been difficult to assess the assumption of canalization and to integrate the study of normative development and individual differences because the

techniques used in studies of normative spatial development have never been adapted for use in the study of individual differences. Experiments often involve a small number of trials, and hence would have uncertain reliability and be difficult to use with confidence in longitudinal analyses.

The difficulty in uniting the two disciplines of psychology (Cronbach, 1957) does not derive only from the disinterest in individual differences in the cognitive development community. In addition, there are difficult problems within the psychometric tradition that has established the methods and agenda for the study of individual differences over the past century (Hegarty & Waller, 2005). Paper-and-pencil tests, especially those suitable for group administration, do not do a good job of assessing skills that involve three-dimensional objects or navigation in large-scale environments. For example, the Guilford-Zimmerman Test of Spatial Orientation attempts to simulate being in various positions in a moving boat using only small thumbnail sketches of the prow. Factor analysis, especially exploratory rather than confirmatory factor analysis, gives an unclear and ever-changing picture of the structure of spatial abilities, in part because it is at the mercy of the characteristics of the tests included in the battery under examination and in part because it ignores the fact that people may vary in the strategies they use to solve different items on the same test. Recent efforts to use virtual reality for testing and to study strategy directly are encouraging, but have not yet progressed far enough to provide techniques that can be relied on.

In summary, the study of individual differences seems poised to begin a mutually productive interaction with cognitive psychology and cognitive development, although there are currently only a few harbingers of what can be accomplished. Some promising methodologies and strategies are beginning to emerge, including virtual reality techniques, the adaptation of developmental research paradigms to the assessment of individual differences, and the close analysis of strategies as well as performance levels.

Given these problems, it is tempting to conclude this section simply with the hope that future research can address these issues. However, there has been enough interesting study of the development of sex-related differences in spatial ability that it seems important to review this topic, if only briefly (for fuller reviews, see Halpern & Collaer, 2005; Newcombe, Mathason, & Terlecki,

2002). We should begin by examining the state of the descriptive facts regarding the nature and development of sex-related differences.

First, looking at sex-related differences in adults, it has long been clear that there are large male advantages on many spatial tests, most notably, tests of mental rotation and tests that require defining a horizontal or vertical line while ignoring distracting cues (Linn & Petersen, 1985; Voyer, Voyer, & Bryden, 1995). These differences are diminishing with historical time for some tests (Feingold, 1988), but are maintaining or even increasing their size in the case of mental rotation (Voyer et al., 1995). As well as showing higher means, males also often show greater variability (Hedges & Nowell, 1995), which increases the predominance of men at very high performance levels. More recently, there have been findings indicating that males may also be more skilled at using geometric information regarding distance and direction in navigation, and in using maps to gain geographical knowledge (Halpern & Collaer, 2005).

Second, in terms of development, it is likely that sex differences exist by the age of 4 years, the earliest age at which it has been possible to devise a test that taps the areas in which sex-related differences are found in adults (Levine, Huttenlocher, Taylor, & Langrock, 1999). Other investigations have only found clear evidence of sex-related differences emerging at around the age of 9 or 10 years (Johnson & Meade, 1987; Kerns & Berenbaum, 1991), and meta-analyses consistently show that sex-related differences increase in size over childhood and adolescence (Linn & Petersen, 1985; Voyer et al., 1995). However, the question of earliest appearance and developmental course is difficult to address with current assessment instruments. New assessments taking advantage of recent work in normative cognitive development might be very helpful in addressing these issues.

Sex-related differences in spatial skill, especially in mental rotation, are among the largest gender differences we know. There have been many efforts to explain why they occur, and the area has been a contentious one for biology versus environment debate. Several hypotheses emphasizing biological factors have waxed and then waned in popularity over the past few decades. For example, Waber's (1976) hypothesis that higher spatial ability is related to later timing of puberty has not been substantiated by subsequent research (see

meta-analysis by Newcombe & Dubas, 1987). Hypotheses involving sex-related differences in lateralization of brain function have received only weak support from studies using behavioral techniques to assess lateralization (Voyer, 1996). More direct assessment of neural substrates of spatial tasks using imaging techniques may allow better evaluation of the lateralization hypothesis. Current studies of this kind have sometimes shown sex-related differences (Roberts & Bell, 2000), but many studies have not assessed the question, and samples so far have tended to be small and unrepresentative. Possibly the strongest evidence exists for the hypothesis that sex steroid hormones are the proximate cause of sex-related differences in spatial abilities, although even there the evidence is mixed, precisely which hormones are important is unknown, and the shape of the curve relating hormone levels to performance is not yet defined (Collaer & Hines, 1995; Halpern & Collaer, 2005).

Although the proximate biological mechanisms that may underlie sex-related differences are not yet known, sociobiology has provided a ready explanation for the ultimate reason for this sex difference. Actually, there are two explanations, both focusing on the reproductive advantage that might accrue to men for having higher spatial ability. One explanation focuses on the fact that men are generally the hunters in hunting-gathering societies, and hunting seems to require spatial skill in several of its component activities, including tracking animals, aiming at them, and fashioning the weapons with which to take aim. The protein obtained from hunting helps to ensure the survival of a man's children, and prowess in hunting may also enhance a man's access to women (who wish to have their children provisioned by a skilled hunter). In addition, aiming may come in handy in any struggles for dominance with other males over sexual access to females.

The other explanation for sex differences derives from elegant observational and experimental evidence of voles, a small mammal that comes in two varieties. One species, the prairie vole, is pair-bonded while a very similar species, the meadow vole, has a mating system in which females occupy territories, and during the mating season, males make the rounds of females, attempting to reach as many as possible in time to impregnate them. Strikingly, spatial ability (assessed by the ability to navigate mazes) is equal for males and females in the pair-bonded prairie vole, but male meadow voles surpass

females at spatial tasks—during the mating season only, when the part of their brain that supports navigation (the hippocampus) actually enlarges to meet the reproductive challenge (Gaulin & Fitzgerald, 1989).

There are, however, problems with both kinds of sociobiological explanations (see also Jones, Braithwaite, & Healy, 2003). Looking first at hunting and gathering, gathering may require quite long trips away from home base to find various kinds of edible vegetation in their respective ripening seasons. While it is true that animals move while vegetation sits still, humans are unsuited to swift pursuit of most game animals, and much hunting by our ancestors may have consisted of setting traps, or waiting at waterholes, rather than tracking animals over meandering paths. In terms of manufacturing artifacts to use in hunting and gathering, spatial skill is required to weave or make baskets or pottery, as much as for fashioning arrows and spearheads. Lastly, while the aiming component of hunting success is a kind of action in space, it does not appear to be a spatial skill—success in hitting a target may not be related to success at mental rotation (Hines et al., 2003). In terms of extrapolating to humans from the vole studies, a major problem for a sociobiological approach is that human females, unlike female meadow voles, live in social groups rather than occupying widely separated home territories. Impregnating many females probably depends more on abilities such as charm or stealth than on the ability to find one's way among a cluster of huts.

We should also ask why, from an evolutionary point of view, sex differences would exist in a trait that has adaptive significance for both sexes when there is no obvious metabolic cost for that trait. Most sex-specific traits that enhance reproduction are for attributes such as growing antlers or ornamental tails, physical features that are cumbersome and costly for the body to produce. Males have these features only because they enhance their ability to do combat with other males and/or attract females. There is no reason both sexes should not have a trait that is useful in a wide variety of settings unless its possession exacts costs. Of course, developing high levels of spatial ability might exact some kind of cost; however, we currently have very little idea of what the trade-offs might be.

So far, we have not discussed environmental factors that may contribute to sex-related differences in spatial ability. Correlational analyses show that there are small but reliable relations between participation in spatial activities, many of which are sex-typed masculine, and

spatial ability (Baenninger & Newcombe, 1989). However, these correlations could be the product of self-selection of activities based on ability, rather than arising from the activities causing increases in ability. Some spatial sex differences are decreasing over historical time (Feingold, 1988), presumably for environmental reasons, but differences in mental rotation seem to be increasing (Voyer et al., 1995). Increasing as well as decreasing size in sex-related differences may indicate environmental causation. Although it is commonly assumed that society is becoming more egalitarian, there has been little direct examination of change in social factors that may affect mental rotation ability. Increasing computer usage in the past decades may influence increasing sex-related differences, as males are more likely to use computers in general and to engage in spatially demanding computer activities, including games, than females (De Lisi & Cammarano, 1996; Funk & Buchman, 1996). Approximately 75% to 80% of video game sales are generated by males (Natale, 2002). Computer use is related to spatial skill (De Lisi & Cammarano, 1996; De Lisi & Wolford, 2002; Okagaki & Frensch, 1994; Roberts & Bell, 2000; Saccuzzo, Craig, Johnson, & Larson, 1996; Sims & Mayer, 2002; Waller, Knapp, & Hunt, 2001).

Malleability of spatial skill is a central issue that is often overlooked in the fascination with sex differences (as well as overlooked more generally in the fascination with individual differences in intelligence, Ceci, 1991). Even though sex differences are substantial, levels of spatial ability do not seem to be biologically fixed. Several sorts of training can enhance spatial performance (Baenninger & Newcombe, 1989, 1995; Loewenstein & Gentner, 2001; Newcombe et al., 2002), including input during schooling (Huttenlocher, Levine, & Vevea, 1998). Like other intellectual abilities, and possibly more so, spatial ability has increased in the past century faster than the gene can change, in what has been called the *Flynn effect* (Flynn, 1987). It is true that training effects are often equivalent for males and females, so that sex differences do not disappear (Baenninger & Newcombe, 1989). However, the training effects are also substantial in size, often larger than the sex-related differences themselves, so that trained females do as well as or better than untrained males. If we want to maximize the human capital available for occupations that draw in spatial skill, such as mathematics, engineering, architecture, physical science, and computer science, it is vital to understand

how to educate for spatial skill, rather than focusing solely on the explanation of sex differences.

SPATIAL DEVELOPMENT IN NON-NORMATIVE CONTEXTS

Spatial development is the product of the interaction of biological and environmental factors that affect it. Some researchers have focused on genetic variations, which can sometimes lead to specific patterns of cognitive impact in which spatial ability seems particularly affected (e.g., Williams syndrome, Turner syndrome).⁵ Studying syndromes of this kind has been based in part on the hope that we can gain information about the mechanisms and architecture of cognitive development from the fractionation that occurs when normal development goes awry. Other researchers have examined sensory impairments that can limit spatially relevant input, most notably visual impairments. Studying the effects of sensory limitations is potentially useful in elucidating what environmental input normal development rests on, and it can help resolve the issue of whether critical or sensitive periods exist during which input is essential for normal spatial development.⁶ In this section, we concentrate on Williams syndrome and visual impairment as examples of research that can have considerable relevance for understanding spatial development in normally developing children.

⁵There are also two other interesting classes of syndromes. One category is diagnoses where there is diffuse slowing of cognitive progress but with indications of differentially larger spatial problems that may depend on hippocampal dysfunction. Syndromes in this category include genetic problems such as Down syndrome (Pennington, Moon, Edgin, Stedron, & Nadel, 2003) and environmental effects on prenatal development such as fetal alcohol syndrome (Uecker & Nadel, 1996). A second interesting diagnostic category is children with problems in cognitive development presumed to have a strong genetic basis, where spatial skills are relatively spared, for example, autism (Caron, Mottron, Rainville, & Chouinard, 2004).

⁶Not all sensory impairments have deleterious effects on spatial ability; in particular, there is reason to think that children with deafness may develop enhanced spatial competence, perhaps as a consequence of signing (Emmorey, Kosslyn, & Bellugi, 1993).

Williams Syndrome

Williams syndrome (WS) is a rare genetic defect occurring about once in 20,000 births. People with WS have certain distinctive physical characteristics and also have an unusual cognitive profile. When cognitive research on WS began, investigators were impressed with the extent to which language and face processing were spared in WS, despite severe impairments in spatial ability (Bellugi, Marks, Bahrle, & Sabo, 1998; Bellugi, Wang, & Jernigan, 1994). More recently, evidence has emerged suggesting that there are actually a variety of deficits in language acquisition and processing in WS individuals (e.g., Grant, Valian, & Karmiloff-Smith, 2002; Thomas & Karmiloff-Smith, 2003), as well as some abnormalities in categorization and conceptual understanding (Johnson & Carey, 1998). Such data have led to the recognition that WS does not provide a strong example of modularity in development, as initially seemed possible (Mervis, 2003; Paterson, Brown, Gsodl, Johnson, & Karmiloff-Smith, 1999).

As with language, careful analysis of the spatial deficits in WS is revealing a complex picture of just what kinds of spatial ability are affected. Severe problems are evident when WS individuals are asked to copy designs by drawing or using blocks (Bellugi, Bahrle, Neville, Doherty, & Jerigan, 1992; Hoffman, Landau, & Pagani, 2003; Mervis, Morris, Bertrand, & Robinson, 1999). In addition, it has been shown that WS children show an intriguing early difficulty in guiding saccades using extraretinal information, a limitation that may impair their exploration of the visual environment (Brown et al., 2003). However, face recognition, which certainly requires spatial analysis, appears to be normal, although there is some controversy about the issue (Tager-Flusberg, Plesa-Skwerer, Faja, & Joseph, 2003). Similarly, WS individuals show an intact ability to perceive biological motion (Jordan, Reiss, Hoffman, & Landau, 2002). For spatial language, which is an interesting area given relative strengths in language and selective deficits in spatial skill, there are conflicting reports. Landau and Zukowski (2003) argue that there are limited effects of WS on spatial language, on the basis of data about how children with WS described motion events. They found that encoding of figure and ground objects and manner of motion was excellent in WS individuals, and their command of path information was surprisingly spared if somewhat fragile. However, Phillips, Jarrold, Baddeley, Grant, and Karmiloff-Smith (2004) report that WS

individuals perform poorly when asked to comprehend sentences that involve spatial prepositions.

Most of the spatial skills discussed in this chapter are still unstudied in WS, including encoding of distance, use of spatial categories, hierarchical combination, mental rotation, perspective taking, navigation, and the use of maps and models. This surprising lack likely stems from the initial use of psychometrically derived and clinical batteries to study cognition in these children, as well as from the focus on the language development of these children and the language-space interface. Research on this population holds promise, however, for helping to understand the structure of spatial skill and for helping us analyze the various strands in spatial development.

Visual Impairment

The spatial capacities of blind individuals appear to be central to two intertwined questions about spatial development: the extent to which it depends on innate capacities, and the ways in which it may depend on crucial input at certain periods in development. In an early philosophical argument for an innate basis for human spatial knowledge, Descartes proposed that a blind person who sequentially explores shapes and their interrelations would unify the impressions gained in this manner within a spatial framework that utilized metric properties derived from Euclidean geometry. Many years later, experiments with animals showed that visual experience is essential to normal development of visual cortex and visual perception (e.g., Wiesel & Hubel, 1965). Subsequent work with infants born with congenital cataracts has confirmed the existence of such sensitive periods in humans, and has clarified their duration and nature (e.g., Le Grand, Mondloch, Maurer, & Brent, 2001, 2003; Maurer, Lewis, Brent, & Levin, 1999).

Neither Descartes' speculations nor the experimental work on the effects of deprivation on the development of visual processes directly address the role played by an innate spatial framework versus the role played by visual experience in spatial development. While it might not appear difficult to address this topic, efforts to date have not resulted in a clear answer to the question of how, and how well, people born blind or with visual impairment develop spatial representation and navigation (see reviews by Millar, 1994 and Thinus-Blanc & Gaunet, 1997). In part, uncertainty arises because the causes and timing of vision loss may vary, large samples

of individuals who are similar in these variables are difficult to assemble, and, even within apparently homogeneous groups, there appear to be large individual differences in spatial skill.

One of the most debated topics within the literature on vision loss is the capacity for spatial inference. We have already examined the report that a young blind child can, as predicted by Descartes, unify her spatial experience so as to permit inference (Landau et al., 1984) and subsequent findings that, contrary to this hypothesis, spatial inference develops slowly in both blind and sighted children (Morrongiello et al., 1995). Some studies of adults with blindness suggest that people who suffered vision loss early have limited capabilities for spatial inference, compared both with sighted people and with people who suffered late vision loss (Rieser, Guth, & Hill, 1986). Rieser et al. argued that vision provides the best means of learning to calibrate optic flow with the experience of walking. Support for this hypothesis was found in data showing that early loss of broad field vision produced effects on spatial inference comparable to the effects of early blindness (Rieser, Hill, Talor, Bradfield, & Rosen, 1992). By contrast, early acuity loss did not have such detrimental effects, nor did late field loss. Such a pattern is compatible with the view that calibration of kinesthetic cues and optic flow in the first 3 years of life is crucial for normal spatial inference ability. Work of this kind that is developmental in nature holds great promise for understanding the starting points and key inputs for spatial development in much more analytic detail than we possess at present.

WHAT LIES AHEAD?

There is no better testimony to the current richness and excitement of research on spatial development than that this review has had to be selective in the topics covered and has only scratched the surface of many important issues in the developmental literature and, especially, in the research traditions of allied fields. We have touched only briefly on research about adult spatial cognition, individual differences, and the development of children with genetic or sensory impairments. Also, we have said almost nothing about research on nonhuman animals, research using neuroscientific techniques, or computational modeling of spatial skills. In general, our impression is that focus on the content area of spatial adaptation has led to a burst of interdisciplinary inter-

change of ideas and techniques that bodes extremely well for the development of rich theoretical understanding of this domain.

Although we have addressed a multitude of specific research questions in this chapter, we have emphasized a few major themes. First, we have suggested that the nativism-empiricism debate should be reconceptualized as the search to understand the starting points for cognitive development, the nature and timing of crucial environmental input, and the precise specification of how children use environmental input at specific points in their development from their initial starting points. Second, we have argued that an adaptive combination approach to spatial development is a powerful tool for understanding its nature and that a modular architecture is not necessary to explain the basic phenomena in this area. Third, we have attempted to highlight the distinctiveness and power of human abilities to transform and symbolically represent spatial information, and have suggested that culturally transmitted tools may be especially crucial to optimal development in this area. Fourth, we have noted that research on individual differences is crucial to a full understanding of spatial development, but that it is still very poorly integrated into most work on cognitive development. Similarly, and lastly, we have noted the enormous promise of research on spatial development in children with abnormal genetic inheritances or whose environmental stimulation is limited by sensory deprivation, especially to the extent that common conceptual and methodological tools can be used in research on normative and abnormal development.

A few research areas have not yet attracted the attention they deserve. An issue that is largely unexplored is the contribution to spatial development of various kinds of experience, many of them ubiquitous and expectable, but some of them variable and even rare. For ubiquitous and expectable input, the problem is that deprivation experiments cannot be conducted with humans. The need for more research on the effects of various kinds of visual and exploratory experiences on spatial development can often be filled through research with nonhuman animals. For example, there have been experiments evaluating the effects of rearing in the dark (Tees, Buhrmann, & Hanley, 1990) or with deprivation of social interaction (Pryce, Bettschen, Nanz-Bahr, & Feldon, 2003) on spatial development. We should use research with nonhuman animals when possible to investigate the interplay of spatial learning, activity, and exploration in

human development. In addition, we can more vigorously pursue research with human children who have naturally occurring cases of limited sensory input, such as various kinds of visual loss. This line of work needs to occur in closer contact than has often been true so far with the literature on normative spatial development.

With respect to variable and rare kinds of spatial input, we have an opposite kind of problem—long hours of naturalistic observation may yield very few interesting instances of spatial input. In contrast, studies of input to language acquisition are relatively easy, because talk is common and can be easily recorded for later transcription and analysis. One promising line of attack on this problem is to construct contexts that elicit spatial discussion in at least some parent-child dyads (Szechter & Liben, 2004). Another possibility is to train parents to record relevant examples of spatial interactions with their children, as recently done for quantitative development by Mix (2002).

Another area that we need to know much more about is individual differences in the normal range. One question here is whether the variation we see in studies focused on normative development is meaningful or represents true error variance. Researchers in cognitive development often assume that the variability in their studies is error variance, but this assumption has rarely been tested and may be false, as suggested by recent longitudinal findings in other domains (Tsao et al., 2004; Wellman & Liu, 2004). Insofar as the variability in cognitive-developmental experiments represents meaningful information about differences among children, we have the opportunity to develop more sensitive and more analytic assessment instruments for use in tracing early individual differences than has been possible from psychometrically derived tests that are not ideal for adults and that are even less well suited to developmental work in the downward extensions that have been made of them. A focus on assessment is hard and sometimes boring work that has historically been difficult to fund, but it is essential to progress on understanding why some children develop much greater spatial abilities than others.

Although these issues are important and difficult, our dominant mood is optimistic and our forecast is that the coming decade will see great advances in our understanding of spatial development. In particular, this progress will come to the extent that we can sensibly utilize techniques and concepts from allied fields to support our common goals.
