At the teacher level, none of the teachers at the Gilmore knows for sure how to manage the kids. Ms. Li is kind but ineffective. She feels powerless to stop Reanna from being socially bullied, so she prefers to go home at the end of the day rather than try to come up with inadequate ways to stop the harassment. She remembers this type of “relational aggression” when she was in school, but even as an adult she admits she has no idea how to go about preventing it. In contrast, Ms. McCarthy chooses to punish the children for their physical conflicts—no recess for 2 weeks—instead of teaching conflict resolution and fostering connections between the kids. She relies on peer pressure to change her students’ behavior, but these students are not relating to each other in positive ways. As a result, the lessons they learn from each other will be negative ones, such as Robert blaming Jamil for causing the recess ban. Interestingly, we noticed that Ms. Li’s response bore a strong

resemblance to Reanna's strategy of withdrawing, and Ms. McCarthy's was remarkably similar to Jamil's and Robert's of pushing back.

The school adjustment counselor, Ms. Curtis, recognizes that families need to be involved if the school wants to solve student behavioral issues. But the families in this neighborhood are overstressed: Not enough economic and social supports exist to help them. As a result, they lack the time and energy to come to the school and sometimes don't understand why their participation is so important. Ms. Curtis's role in the school is reduced to seeing individual students one-on-one. Without more administrative support and funding, she lacks the resources to organize schoolwide social competence programs or develop teacher education programs on the topic of behavioral management. Furthermore, her clinical training primarily equipped her to deal with students individually; she is not sure she'd be able to organize a school program even if it was requested. What topics would she focus on? How would she help teachers and students?

From the principal's perspective, the social problems and academic problems of the students are separate. Despite paying lip service to the notion that students cannot function well academically when their social lives and relationships are a mess, Mr. Martinez prefers to focus on the immediate problem he faces: the need to get the school operating at a better level of performance. Ms. McCarthy's complaints are seen as nagging. Ultimately, both Mr. Martinez and Ms. McCarthy blame the current crop of students: "This year is worse than ever."

For better or worse, we have diagnosed a problem in the school on both the community and individual levels. We believe the problems faced by the students and teachers in this school are not unique. In diagnosing these problems, we do not want to come across as pathologizing the individuals involved; all of the teachers and staff in this school face a hard task, and trying to figure out what is best for their students individually and as a whole is daunting. Mr. Martinez is doing the best he can to turn around a failing school. Ms. Li and Ms. McCarthy just want their students to get along and respect their authority. Similarly, the school hierarchy, lack of parental involvement, and a clinical training that emphasized individual rather than systematic problem-solving prevent Ms. Curtis from making progress. Finally, Jamil, Robert, and Reanna are negotiating their social worlds the best they know how.

What can these individuals do differently in their lives? How would they know the best thing to do in a given social situation? What individual, family, school, and systemwide intervention is needed to solve the Gilmore School's distress? It seems to us that although schools have begun to learn how to solve the problem of lack of literacy skills—and they are having a tough enough time trying to do that—they are still at a complete loss as to how to manage social problems. Even if they had the funding to develop a wide-scale approach, how would a school negotiate the wide variety of programs available to them? What criteria would they use to choose?

How Can the Institute of Medicine Model Help the Gilmore School?

The second and third steps of the IOM model recommend that research should lead the way toward developing an intervention. First, by evaluating the existing literature on school climate, social competence, and youth development, the prevention program should choose a theoretical model that will guide the intervention. Next, based on a model and research, the program should design the necessary activities, hire staff, get cooperation from the site, and choose the methodology they will use to do formative and evaluative research. In the fourth and fifth steps, the program should move toward designing large-scale trials of the program and eventually provide a manual outlining the program and delineating core elements and characteristics (Mrazek & Haggerty, 1994).

The benefit of the model is that it focuses on interventions that can be implemented at a scale that will affect not only individuals but also populations beyond individuals. For instance, in this first case, the Gilmore School, our initial point of departure was the desire to improve the mental health and social development of the children in the school through thoughtful services. Over time, however, our concerns mounted as we worked with students and teachers struggling to live in and be supported in a school with a vulnerable social atmosphere. We realized we had to think beyond the individual student at the Gilmore; one-on-one interventions were not stemming the tide of behavioral and social competence issues that permeated every hallway of the school.

The strategy we articulated was to use the IOM framework to seek "mature" outside preventive interventions from a range of options, each with its own theoretical framework and evidence base. In our case,

we reviewed the literature on prevention programs (Weissberg et al., 2003) and also examined research that emphasized positive youth development programs. Rather than focus only on the risks children face, these programs seek to develop the positive influences in children's lives that can help promote positive outcomes (Catalano et al., 2002). For the Gilmore School, we needed a program that not only would help ameliorate the mental and social problems of future students of the school but that would also promote positive development among the students who were currently enrolled. In other words, we needed to focus on helping students in the present as well as in the future—combining intervention (a.k.a. "treatment") with prevention.

Some Possible Choices

What are some possible options for the Gilmore School? How should we, as the school's "doctors," the so-called experts, proceed toward making a recommendation of how the school should solve its social and behavioral problems? It is important to keep in mind that many schools are left on their own to make these types of intervention decisions. Some cities have begun school-reform programs that focus on social-emotional competence and decreasing negative attitudes and behaviors (see, e.g., the Reading, Writing, Respect, and Resolution [4Rs] program currently being evaluated in several New York City public schools). But many schools, like the Gilmore, are left to find their way through a confusing landscape of options as best they can. How do they know which programs will work? How much do the various programs cost, and what will they get for their money? These are critical questions from a practice perspective.

Researchers understand that although two programs may rest on the same fundamental research base, their approach and choice of solution may depend on their theoretical orientation, that is, a program that is based on socioemotional learning versus one that views a school as a community. Neither approach is wrong and in fact may share many common attributes, yet for practitioners it can create confusion about which one is best. The realization that even experts may have vastly different points of view about the development of social competence in children, for example, is frustrating and can lead practitioners to doubt the benefit of research.

One option for schools is to turn to CASEL. Under the current direction of Roger P. Weissberg and based in

the Department of Psychology at the University of Illinois, Chicago, CASEL partners with researchers and practitioners in the fields of social and emotional learning, prevention, positive youth development, service learning, character education, and education reform. It does not develop or market educational programs, but rather brings together the work of different researchers across disciplines to promote social and emotional learning. In 2003, it recommended 22 programs across the country that are effective in promoting social and emotional learning and providing staff development (CASEL, 2003).

Even with an array of programs to choose from, and a fairly solid guarantee that the programs are beneficial, schools need to decide which one is best for their particular situation. Should the intervention take place only within classrooms or across schools and communities? Should it work with school staff and students only, or include families? What does it cost? How long does it take to be implemented? Will it focus on conflict resolution, violence and drug prevention, the promotion of social learning, or a combination of different approaches? These are just some of the questions Mr. Martinez needs to have answered. Even though all of the programs CASEL recommends have been outcome-evaluated and are research-based, each has its own particular agenda.

Although there are many programs to choose from, this chapter focuses on four programs in depth. Our intention is not to evaluate the programs, but to illustrate the ways developmental, applied developmental, and clinical psychology research can be (and have been) integrated with other disciplines and translated into practice.

Second Step

Second Step (Committee for Children, 2005) is an elementary school violence prevention curriculum focused on developing three competencies in children: empathy, impulse control/problem solving, and anger management. Studies of Second Step suggest that students of different age groups from kindergarten through sixth grade demonstrated increased positive interactions and empathy, a decline in anxious and depressed behavior, and less disruptive, hostile, and aggressive behavior (Frey, Nolen, Van Schoiack-Edstrom, & Hirschstein, 2001; Grossman et al., 1997; Orpinas, Parcel, McAlister, & Frankowski, 1995).

Second Step's goals for children are to recognize and understand their own feelings, keep anger from es-

calating into violence, and make positive rather than negative behavior choices. In addition, Second Step aims to help teachers recognize and deal with classroom disruptions and behavior issues. Because Second Step is prepackaged and requires very little teacher preparation time, it seems easy for teachers to follow, and the recommended time commitment is 30 minutes several times a week. Products for purchase in elementary school include puppets for role-playing (e.g., the Slow-Down Snail helps children stop and think before acting or speaking), videos, and photo lesson cards. Teachers use stories as the basis of a lesson (e.g., on the theme of anger management), and visuals are used to depict children's faces in the social situation to display feelings and help young students make the link between the face, the feeling, and the story (Committee for Children, 2005).

In theory, Second Step could be utilized to solve schoolwide as well as individual problems. For instance, to change the Gilmore School's climate from one of punishment to problem solving, teachers could come to agreement around behavior management. Instead of banning recess, teachers could assign "reflection sheets" that prompt students with behavior issues to walk back through the incident and think of a better solution. This could arm the students with the skills needed to proactively address social problems and potentially change future behavior, instead of simply punishing them after the fact. As a reward, students would be given an "I am a Second Step Star" button. Signs listing the problem-solving steps would be posted in the recess area so that paraprofessionals, students, and even lunch mothers would be aware of the format. The signs would also communicate the Second Step values to visiting community members and parents.

Students like Robert would be helped by a change in the language of behavior management (emphasizing student reflection rather than punishment). Teachers and students would partner to reflect on behaviors and plans for the future, opening communication. "Reflections" help students understand why they are being singled out for behavior changes and would prevent them from feeling frustrated that they have no voice in the development of consequences.

At the classroom level, although the program includes some standardized lessons (e.g., anger management), there is also room for teachers to tailor lessons to specific conflict situations. For instance, Ms. Li could create a lesson card for the class to role-play issues of

social exclusion to expose the emotions involved and encourage empathy. The curriculum is specific about problem-solving steps that are needed to resolve the conflict productively.

Mr. Martinez and Ms. McCarthy would be pleased with a social problem-solving program that is consistent across the whole school. Progress made in the classroom could be continued at recess, in halls, and at home because other staff and families would be informed of the values and strategies the children were learning. Students of different grades would learn similar strategies and could employ them at recess and after school.

The cost of Second Step is fairly reasonable. Although kits can be purchased for each grade, a comprehensive preschool through grade 5 kit costs around \$900 (Committee for Children, 2005).

Social Development Research Group

The Social Development Research Group (SDRG) is affiliated with the School of Social Work at the University of Washington in Seattle. There are several interventions associated with SDRG; one that we consider to be relevant to the Gilmore School is the Raising Healthy Children (RHC) project (SDRG, 2004a). An 8-year intervention funded by the National Institute on Drug Abuse, RHC was designed to promote school success as a protective factor that promotes healthy child and adolescent development and prevents problem behaviors (Catalano et al., 2003). During the 2002/2003 school year, this intervention was running only in the Edmonds School District in Washington, but other districts throughout the country could presumably adapt its principles and publications. RHC, unlike Second Step, is a district-oriented program that works with all elementary, middle, and high schools within the district. It focuses its attention on parents as well as schools to promote positive development. Parents can attend workshops, such as "How to Help Your Child Succeed in School," "Raising Healthy Children," and "Moving into Middle School." During the high school years, parents are even offered home visits that reinforce the training sessions they attended earlier (SDRG, 2004a).

Teachers and school administrators, on the other hand, receive training that helps them keep the school atmosphere focused on learning, not just identification of problem behaviors. Positive social interactions are praised and students are encouraged to remain involved and work in small teams to help each other learn. RHC

research suggests that these methods provide an atmosphere in which children feel good about themselves and their ability to learn (Catalano et al., 2003).

Unlike Second Step, however, RHC is less of a packaged curriculum that schools could follow easily. The program would have to be specifically adapted to the Boston Public School district and extended beyond its current existence in a Washington-area school district. The cost of adapting RHC to the district (with the program's permission and supervision) is difficult to calculate, although funding opportunities may be available through the National Institute on Drug Abuse, other federal agencies, or philanthropic organizations. The grant-writing process and application would have to be factored into the cost and more research would be needed.

The benefits for the Gilmore School, however, could be substantial. RHC philosophies seem to be in line with what is needed at the Gilmore. For instance, part of the problem at the school is a lack of positive relationships between students and teachers (e.g., Robert, Jamil, and Ms. McCarthy; Reanna and Ms. Li). There is also a lack of clear, schoolwide standards for behavior and shared decisions about classroom management. Under RHC training, teachers would be able to begin to share strategies for creating a socially appropriate classroom atmosphere that would promote, rather than take away from, the academic learning that is supposed to take place in schools. Also, from Ms. Curtis's point of view, RHC would be beneficial because it does not limit its intervention simply to the school but works to involve parents, recognizing that it is often necessary to get parents on board when designing and implementing school-based interventions. Whether parents would attend or not, however, is hard to say, considering that Ms. Curtis is having a difficult time getting them to attend even parent-teacher conferences.

Although books and other curriculum materials are available for purchase, teachers and administrators would have to spend a substantial amount of time figuring out how the program could be adapted in the district. Although the SDRG programs and research base seems in line with the Gilmore's needs, the practical application of the program would be a district decision, involving the Boston superintendent as well his cluster leaders.

Promoting Alternative Thinking Strategies

The Promoting Alternative Thinking Strategies (PATHS; Greenberg, Kusché, & Mihalic, 1998) program is a

K–sixth-grade violence prevention program affiliated with Pennsylvania State University and sold by a commercial publisher, Channing-Bete. Named as one of 10 Blueprints for Violence Prevention by the U.S. Department of Justice and the Center for the Study and Prevention of Violence, PATHS is in place in more than 500 schools throughout the world. Like Second Step, PATHS teaches children nonviolent conflict resolution strategies, to stop and think before acting, and to manage and express their emotions. For teachers, PATHS can be easily integrated into existing classrooms, and the timing and frequency of the lessons can be adapted based on the teacher's needs. The curriculum comes with an instructor's manual as well as a curriculum guide that includes information on how to present the lessons, an overview of the important concepts to get across, and a list of necessary materials. Furthermore, PATHS is fairly cost-effective: A complete program costs around \$700 (Greenberg et al., 1998).

For the students, PATHS provides them with ways to evaluate their responses to conflict so that they can learn to prevent future incidences. For the teachers, it recommends that they stop and think about their feelings before responding with yelling or punishment or other negative strategies. Clinical trials have shown decreases in teacher reports of student aggressive behavior and increases in teacher reports of self-control as well as students' emotional vocabularies and cognitive skill test scores (Greenberg et al., 1998; Greenberg, Kusché, Cook, & Quamma, 1995; Greenberg et al., 2003). This would be good news to both Ms. McCarthy and Ms. Li. Furthermore, because the curriculum would be schoolwide, Mr. Martinez could feel confident that all teachers were following the same behavior management strategies.

Developmental Studies Center: Child Development Project

The fourth and final program we discuss is the Developmental Studies Center Child Development Project (CDP, 2003). Rather than focus on student problem behaviors, CDP tries to revamp school climate to create "communities of learners." The Developmental Studies Center provides whole-school training in social and ethical as well as academic development. The CDP's focus is on improving school design to improve students' literacy skills as well as relational connections among students, teachers, and administrative staff. It

has created a literacy program that combines decoding with reading comprehension through the use of literacy activities such as guided reading, group reading, and individual instruction (CDP, 2003). In addition, CDP works to train teachers as well as administrators in how to foster a positive school climate. Like the other programs we introduced, CDP has been evaluated for positive outcomes (Battistich, Schaps, Watson, & Solomon, 1996; Solomon, Battistich, Watson, Schaps, & Lewis, 2000).

CDP's focus on literacy as well as social development would appeal to Mr. Martinez, as he is primarily focused on raising students' performance on academic tests. In addition, CDP staff provide development and consulting services to assist in implementation, relieving the Gilmore staff from having to worry about adapting a packaged curriculum to their school. However, to successfully implement CDP, a school must commit over several years to its program and to ongoing professional development. Furthermore, the cost to the school is individually negotiated with the school and the district, depending on the program elements that would be used and the type of support, services, or materials that are required. Mr. Martinez would need to explore whether CDP was cost-effective compared to the other programs. Yet, CDP also provides assistance in identifying grants that could be available for schools and districts and even offers a grant-writing service to help schools apply for them (CDP, 2003).

Implementation

Each of these four programs is research-based. That is, they have not only been empirically evaluated with regard to positive outcomes, but their ideas, models, and implementation rest firmly on solid theoretical and empirical foundations in academic disciplines such as social psychology, developmental psychology, and even cultural anthropology. Yet, although each has been acknowledged as a top program in the United States, the founders, practitioners, and researchers affiliated with each intervention are not equally invested in the management process of implementing the interventions in school systems.

In the process of development, each intervention (and their founders, both practitioners and researchers) had to decide where it wanted to spend its time and energy. Research and practice do not always go hand in hand;

it is extremely difficult to design and implement programs, run training sessions, and sell products while also initiating new practice-inspired research projects, writing grant proposals, and managing data collection and analysis. Once the effectiveness of a program has been proven, its dissemination usually depends on a committed principal investigator who decides to replicate the study with larger samples over time, works with policymakers to ensure a steady stream of funding, and pushes for implementation. In the world of academia, program implementation, even for the most well-regarded research, is not always praised; there is an expectation that researchers must continue to break new ground conducting research and publishing findings (Rotheram-Borus & Duan, 2003).

So each program we presented had (at one time or another) decided what type of "social development" intervention it wished to be. Would it become market-oriented, for example, geared toward meeting the needs of school systems? Or would it contract the business to outside vendors and concentrate on designing and researching future interventions and doing basic research? Among the four programs we have discussed, there is a split down the middle. For instance, Second Step and Developmental Studies Center are business-oriented, market-driven programs. They are not affiliated with any one particular university; Developmental Studies Center conducts its own practice-driven research while contracting with school systems to provide both curriculum materials and professional development. With excellent random assignment outcome evaluations already under its belt (Solomon et al., 2000), Developmental Studies Center has recently turned its attention to doing research that is more formative, focused on identifying the best practices that create a sense of community in schools (Schaps, 2003). Second Step, on the other hand, hires outside researchers to conduct independent evaluations. This research, like that of Developmental Studies Center, is primarily driven by the needs of practice. At this point in their evolution, both programs are geared toward issues of implementation, be it marketing and selling social skills "products" or promoting positive school climates with teacher professional development.

PATHS and SDRG are structured differently. They are affiliated with universities and are less hands-on than Second Step and CDP. The PATHS research base, for instance, is considered one of several middle

childhood projects in the Prevention Research Center (PRC) at Pennsylvania State University. Currently, the PRC seems less interested in trying to sell a curriculum or work with school systems to implement it, and more interested in continuing to do both applied and basic research (PRC, 2003).

The ways and means of implementing SDRG are not obvious when you visit the organization's Web site. Like the Prevention Research Center, the Social Development Research Group is located in a university and is a collaboration of researchers sharing common research goals. For these programs, success is not measured by selling a curriculum; instead, like most university-based research programs, they live off grants, doing practice-oriented research on system change and writing publications. The most recent intervention program at SDRG, for instance, is a 5-year study designed to test the effectiveness of the Communities That Care system, an intervention designed to reduce violence, drug abuse, and dropout while fostering healthy development by working at the community level (Hawkins & Catalano, 2003). The outcome research will be funded by several federal agencies (i.e., the National Institute on Drug Abuse and the National Institute on Mental Health) and will involve the participation of treatment and control communities across seven states (SDRG, 2004b).

So, what program did the Gilmore eventually choose? As it turned out, the Massachusetts Department of Public Health awarded \$5 million to the Boston Public Schools to implement a district wide violence-prevention program. Senior administrators decided that Second Step was the best fit for the targeted schools in the city. Funds were used to bring in professional development from Second Step and to hire "social skills coaches," akin to literacy coaches, and certain schools, including the Gilmore, were selected to participate. Second Step was implemented in the district until the money ran out a few years later. Currently, neither Second Step nor any other prevention program is in use at the Gilmore. Second Step's principles seem to have disappeared, like many other reform efforts that fail to thrive in urban schools. Although Second Step may still be used in other Boston schools, at the Gilmore we have not seen it in action, nor has it been spoken of by any of the teachers in recent years.

The ending to this story suggests that the implementation process at the Gilmore was less than ideal. Unfor-

tunately, this may be all too common in "disorganized" schools, where there are schoolwide discipline problems, high rates of suspension, low student attendance, and low faculty morale (Gottfredson, Jones, & Gore, 2002). It is disappointing, yet not surprising, that mental health intervention programs are often less successful precisely in the contexts where they are most needed. The implementation of school-based programs can vary widely from school to school and even from classroom to classroom. When the Resolving Conflicts Creatively program was implemented in New York, for example, some teachers taught the program frequently and with fidelity to program goals. Other schools and teachers did not embrace the program as enthusiastically. The dosage and level of buy-in of the program at the classroom level had an effect on the success of the program at the student level (Aber, Brown, Chaudry, Jones, & Samples, 1996; Aber et al., 2003; Brown, Roderick, Lantieri, & Aber, 2004).

Recently, Wandersman and his colleagues (Wandersman & Florin, 2003; Wandersman, Imm, Chinman, & Kaftarian, 2000) have come up with an approach to program implementation, Getting to Outcomes (GTO), that suggests positive outcomes depend on several factors. They have devised a fairly comprehensive list of accountability questions that need to be asked before, during, and after program implementation and they map out the steps from conducting a needs assessment to evaluation program success and sustainability.

It is important, for example, to look at who makes the decisions about implementation. One of the problems at the Gilmore was the extent to which the school bought into the program. It was unclear, for instance, whether Second Step was a program that met the school's needs (as the faculty and staff would describe them), or whether it was something that someone else (in this case, the district) told them they had to do. One question that should be asked, therefore, is What is the best process for working with schools and communities in the decision-making process?

For instance, although the teachers and administrators at the Gilmore clearly needed help, they tended to respond to individual crises as they emerged rather than develop plans to anticipate and solve behavioral problems at a school level. When the district sent Second Step to the school, it is doubtful the faculty saw the program as one with which they needed to partner. Too often, outside programs are viewed either with skepti-

cism (as yet another reform effort with which schools must comply and that will go away eventually) or as a magic bullet that will immediately and easily solve all their problems. The Gilmore may also have realized that not all schools in Boston received Second Step and felt like the poorly performing sibling in the school district family. Assessing a school's readiness to participate in prevention programs seems to be an important preliminary step to implementation that is often overlooked (Brown, Roderick, Lantieri, & Aber, 2004; Wandersman et al., 2000).

A second important issue Wandersman et al. (2000) point out is that all prevention programs need to have diverse streams of funding. By relying entirely on funds from the Massachusetts Department of Public Health, the Boston school district seemed to have set themselves up for disappointment: The program ended when the funding ran out. Sustainability is a term we hear often in the field of mental health, particularly as it applies to prevention and evaluation, and the challenges of sustainability are evident in the failure to keep the program in place at the Gilmore.

Sustainability, however, refers not only to funding, but also to the ability to train teachers and faculty successfully in the program. Ideally, if the school embraced Second Step fully, and if the program was successful, the teachers would not need any additional funding or coaching to continue the program at the school. The program's pedagogy would be embedded in the day-to-day classroom practices of the teacher and reinforced by the overall school climate. The school would then "own" the program and in time maybe even forget that they learned these ideas from Second Step in the first place. Clearly, then, extensive training and skill at the teacher and school level is needed for prevention programs to achieve desired outcomes (Brown et al., 2004; Gottfredson et al., 2002). However, this can be especially challenging in environments where teachers have experienced burnout, are skeptical of new ideas coming from the top, and where typical classrooms are characterized by off-task time and poor student attendance (Gottfredson et al., 2002).

Urban schools face tough issues at the individual, district, and national levels. We hope the Gilmore School's case points to the persistent gap that still exists between research and practice and the challenges we face when we try to bridge this gap. There is a strong need for ap-

plied researchers to work in close and ongoing partnership with the sites where they work.

The Tension of Research, Practice, Service, and Training

When we first began working with the Gilmore School, we, too, had our own agenda. On the one hand, we wished to provide a training site—a practicum—for master's-level practice-focused students who wished to gain experience working in schools and with children. On the other hand, we also wished to gain a foothold within the school to further our own research. Basic research in clinical and developmental psychology, after all, needs not only participants but also new ideas. The Gilmore, along with other schools in the Boston system, was an active environment within which we could conduct research.

Like many similar research/practice partnerships, our plan may seem colonialistic. We intended to "take" from the Gilmore—to do research within its walls—and in return we would "give" service provided by our interns under supervision. Both parties agreed to the idea; in fact, the Gilmore administration was happy with the quid pro quo approach. The organizations that provided funding for our project literally and figuratively bought into our plan, as did all the necessary university organizations (e.g., human subjects review) through which any research project has to progress.

Although we intended to work within the Gilmore doing research, truthfully the opportunity to provide a practicum site for master's-level interns was a primary goal. From Mr. Martinez's perspective, the Gilmore would receive both the practical experience of free (or at least, no direct cost) interns and the expert advice of a university partnership. Mr. Martinez's teachers, however, were skeptical of our arrival. They questioned what "services" interns could provide in 1 year—would they be helpful, or would their presence translate into more work for the teachers? The status of a university partnership was not a plus for the teachers; they felt they were under enough scrutiny to improve children's academic performance without interns and/or researchers giving more advice or taking their time.

At the time, it did not occur to us exactly how the Gilmore would contribute to our thinking or be more than a context in which to provide service and conduct research. In the years since we first entered the

Gilmore, however, we have begun to question the stance with which we entered the partnership. We also began to wonder about broader, discipline-wide assumptions regarding the relationship of research to practice. In the fields of child and adolescent psychology (and psychiatry), how can the experience and knowledge of the practitioner, whose primary mission is the healthy development and education of children and adolescents, best be integrated with the expertise of the researcher, whose primary mission is to generate fundamental knowledge about development during childhood and adolescence? Can we serve in both these roles? What part, then, does the applied researcher play?

We realized that certain basic issues, such as knowledge about the development of pathways of individuals from different social backgrounds, or the relationships among thought, language, and action in social relationships, are of interest to both researchers and practitioners alike. However, although both groups share a common interest in improving outcomes for children, very often the communication among these professions—how one can learn from the other—could be improved. As a discipline, we need to connect the researcher's scientific knowledge of childhood and adolescence with the practitioner's everyday experiential and clinical knowledge of children and adolescents. We need the practitioner's role of "consumer" and the researcher's role of "knowledge producer" to shift to one of true "partner," each learning and teaching one another.

To bridge this gap, in our second case we continue to examine how researchers build connections with practitioners and policymakers, using the Gilmore School as our context. However, we shift our focus from the first case, where we put ourselves in the position of the practitioner: specifically, diagnosticians and prescribers of research-based interventions. Now, we take the perspective of practice-based researchers, whose interests are both fundamental and applied. As applied developmental psychologists, we are interested in the degree to which the promotion of self and social awareness as individual competencies in childhood can serve as psychosocial protectors against negative life outcomes such as mental illness and prejudicial attitudes, as well as ways to optimize human development and potential. As fundamental researchers, we are interested in studying psychological and social development in all its complexity. Often, the fundamental researcher receives inspiration from practice to study social processes and problems, while the applied re-

searcher focuses on ways to design and evaluate approaches to solve them. Yet, in both instances, we are interested in the interdisciplinary and interprofessional collaborations that best serve the interests of children growing up.

Nothing which is true or beautiful or good makes complete sense in any immediate context of history;
therefore we must be saved by faith.

—Reinhold Niebuhr (1952)

CASE STUDY 2: PRACTICE-EMBEDDED RESEARCH—MOVING FROM RESEARCH TO PRACTICE TO POLICY AND BACK AGAIN

The second case in this chapter tells the story of our current intellectual journey from research, to practice, to policy and back again to research. By using our own work as examples, we do not intend to aggrandize our initiatives but to demonstrate why we conceptualize the partnership of research and practice in the prevention field differently from the way many researchers, as well as practitioners in this field, tend to think about it. It has often seemed to us as though our expedition—from research to practice to policy—has been like a metaphorical set of travels along a tidal river.

Over the past 30 years, a loosely formed collaborative we call the Group for the Study of Interpersonal Development (GSID) has studied the development of social and ethical awareness in children and their links to social action and conduct, always in conjunction with efforts to promote them. Our earliest efforts focused on the psychological treatment of those youth who already were burdened with severe psychiatric disorders and psychological problems (Selman, 1980; Selman & Schultz, 1990). Subsequently, we adapted these approaches to youth who were identified (targeted) as at risk for these psychological difficulties (Selman et al., 1997). For the past decade we have focused on primary or universal prevention, often working with students in schools (Selman, 2003; Selman & Adalbjarnardottir, 2000; Selman et al., 1992, 1997). Like the four programs profiled in the first part of this chapter, we were researchers embedded in practice, although less driven by the needs of practitioners as oriented toward them.

Our most recent preventative strategy was to integrate the promotion of children's social competence di-

rectly into the heart of mainstream education—into the academic literacy practice—as a way to prevent social isolation and miscommunication (Selman, 2003). Up until this point, our model had been used to understand one-on-one social interactions between two individuals, for example, interpersonal development. By moving our ideas into a curriculum, we hoped to scale up our intervention and see if and how it applied to intergroup development, that is, children’s understanding of relations within and between groups such as those from different cultures and identity groups.

Our method of delivery was to identify high-quality children’s literature, in particular stories that have powerful social themes, and to design research-based teachers’ guides for these texts.³ The books were chosen to appeal to students who come from diverse backgrounds, and the guides focused on exercises to promote students’ social understanding and skills. Books were selected and accompanying guides were designed for grades K–6 (Selman, 2003).

In the late 1990s, we began working with Angela Burgos, a fifth-grade teacher at the Gilmore, as she implemented the literacy curriculum that incorporated reading comprehension, vocabulary, and writing skills as well as a heavy dose of social skills training and social awareness promotion. We wanted to know whether our framework was effective, whether it would be supported by evidence, and whether it would have a detectable effect on practice. We were primarily concerned with steps 1 through 3 of the IOM model: We had an idea about the scope (incidence and prevalence) of the problem, we wished to explore it in depth, and we had designed several pilot studies to begin the research process. As part of our partnership with the Gilmore, the school became the context in which we would explore our ideas.

When we entered this partnership and we adapted the developmental framework—a guide for understanding children’s social development—to a practice-based method of literacy instruction, this represented to us a modest flow from theory to evidence, then to practice, and then back up the river again to theory. We had made this kind of journey twice before; in fact, the theory

of peer relationships and interpersonal development stemmed from years of going back and forth between practice and research (Selman, 2003).

This time, we started in the knowledge pool at the confluence of developmental, cultural, and social psychology and flowed down toward the delta of practice. Specifically, we were interested in exploring whether our framework of children’s social development could help promote students’ comprehension of stories they read during language arts classes. Could the lessons students learn from reading literature that deals with social justice, for instance, influence their own lives? Alternatively, does their own understanding of social issues influence their comprehension of these stories? These were the questions that guided our research in the Gilmore School.

As we demonstrated in our first case, when we entered the Gilmore—expecting to apply our model, provide service, collect some data, and return upstream to our laboratory for analysis—we were unprepared for the reality of doing applied research in schools in today’s educational climate. For example, we ran into a confluence of political and policy issues, such as the increasing focus on literacy standards, the No Child Left Behind Act, and the economy of the state of Massachusetts and its influence on school budgets. A multitude of political and research agendas were waiting to divert funding and attention away from our interests. The day-to-day decisions faced by the Gilmore School, like many schools across the United States, not only would affect the individual students and teachers within the school, but were representative of the wider concerns facing the educational community and the role of developmental and cultural psychology in contributing to this field.

We did not, however, hold the conviction that we were the experts. We did not naively believe that our research could remain “uncontaminated” by political, economic, and social forces. Although intellectually we understood that contexts such as family, neighborhood, and environment played a role in the development of social competence, we knew we did not fully comprehend the extent to which a school’s climate, the concerns of its teachers, and the complexity of a school system could have an impact on the children. We viewed developmental psychology as the domain of the individual, not the school system, but hoped through the application process to learn more about the link between the two.

Nevertheless, in our work at the Gilmore we experienced an identity crisis that was relevant to ourselves as

³Our partner in this endeavor was Voices of Love and Freedom (VLF), a literacy-based character education program based in Boston under the direction of Patrick Walker. See Selman (2003) for more information on VLF.

well as the larger field of child psychology. Were we basic researchers who happened to work in a school? Or were we applied researchers with a strong theory and research knowledge base? These are simple questions to ask, but not so easy to answer. Although many of us in the field of developmental psychology might be reluctant to admit there is a gap between these two identities, we often run into instances that challenge this assumption. In the field of social development, for example, there are many well-published applied researchers whose research interests center on designing, applying, and evaluating prevention and intervention programs. The work of this group of researchers is highly prized by practitioners because they can easily translate their research into practices that may quickly and directly improve the lives of children. On the other hand, a different group of researchers may do groundbreaking basic research in cognitive science that could someday have implications for improving practice, but they have little expertise in talking with teachers about how to improve students' social competence, little knowledge of social policy, and little experience in working with children. Which type of research is more valuable in today's environment? What type of researcher did we wish to be? Could one be both?

This case is designed to reframe this dichotomy. Instead of choosing sides in the debate, we have struggled to maintain both identities. Doing so has not been without its challenges, as we will point out, but we have found that the rewards of bridging this gap have far outweighed the problems. By keeping a foot in both camps, we have learned to appreciate what both the applied and the basic researcher bring to the field.

From Research to Practice: The Integration of a Theory of Interpersonal and Intergroup Development into a Literacy Curriculum

We worked with Angela Burgo's class for several months in the late 1990s as she implemented the literacy/social skills curriculum. Following the IOM model, we collected data (step 3) in the form of videotaped classroom discussions, teacher interviews, and homework. The following passages come from one of the books we selected to use in this approach. The excerpt is from a novel chosen for fifth grade, *Felita*, by Nicholasa Mohr (1979, pp. 36–37), which tells the experiences of a third-grade Puerto Rican girl and her family living in New York City in the late 1950s:

I stood on the stoop, watching the group of girls I had seen from my window. They had stopped playing rope and were now playing hopscotch. . . . They were having a good time, using bottle caps and keys to toss on the chalked squares. Hopscotch was one game I was really good at.

"Hi! Hey you!" a girl with short brown hair and glasses wearing blue jeans called out. "You wanna play with us?"

The first chapter of the novel introduces the young narrator, Felita, and her friends and family, who live in a neighborhood in Spanish Harlem. Although Felita is reluctant to leave this neighborhood, her parents are intent on moving to a place with better schools and safer streets. In Chapter 2, Felita and her family move to a new neighborhood where few Puerto Rican families live. Once there, Felita faces the awkwardness of making new friends and attending a new school. Understandably, she is nervous. She begins to play hopscotch with some girls on her street in the new neighborhood, but their parents do not welcome this new girl from a strange (Spanish-speaking) family into their community. The children's initial friendliness turns into hostility and aggression once they fall under the influence of their parents, and a painful confrontation takes place.

The other girls all huddled together with the grown-ups. They all spoke in low voices. I waited. Were they coming back to play? They all stared silently at me. . . . Suddenly I felt frightened and all alone. I wanted to get home, upstairs, where I would be safe with Mami. . . . Now the adults and girls were standing in a group beside the stoop steps. As I approached my building, I lowered my eyes and quickened my pace. I figured I would walk around them and get up the steps as fast as I could.

Thelma quickly stepped in front of me, blocking my way. "Why did you move here?"

"Why don't you stay with your own kind?" Mary Beth stood next to Thelma.

As I tried to get by them the other three girls ran up the stoop and formed a line across the building entrance. I turned toward the grown-ups. Some were smiling. Others looked angry.

"She should stay in her own place, right, Mama?"

"Can't you answer? No speak the English no more?"

The grown-ups laughed.

". . . so many colors in your family. What are you?"

"Her mother is black and her father is white."

"They ain't white . . . just trying to pass!"

"Niggers."

"Shh, don't say that."

"All right, spicks. God only knows what they are!"

"Let me through!" I screamed.

"Nobody's stopping you." Mary Beth and Thelma stepped aside.

I took a deep breath, tried not to cry, walked up the stoop, and began to push past the other three girls blocking the entrance.

"Watch it!" They pushed back, shoving me down a couple of steps.

"Mami!" I looked up at the window. No one was there. "Let me go by!" I shouted.

I pushed again. I felt a sharp punch in my back and a fist hit the side of my face. Then a wall of arms came crashing down. I began to cry hard.

"Mami . . . Mamita . . ."

"Here now. That's enough!" a man said.

"Let her go," a woman shouted. "She knows now she's not wanted here. Girls, let her through."

As I ran past, someone pulled at my skirt and I heard it rip. I ran up three flights of stairs, crying until I was safe inside my apartment. I made sure the front door was bolted behind me. I ran right into Mami's arms.

The first day *Felita* was introduced, Ms. Burgos encouraged her students to consider, "What is a neighborhood?" The class had a conversation about what it means to be part of a neighborhood and what it would feel like to move to some place new and unfamiliar. They drew pictures of their own neighborhoods, pinned them up on the wall, and learned from Ms. Burgos about the history of Puerto Rican immigration to specific communities in the United States. The children engaged with the book and connected it to their own personal experiences.

A few days later, Ms. Burgos asked her students, "How do you think Felita feels about moving to a neighborhood where there are no Puerto Rican families?" The question, and the discussion that developed, was particularly meaningful to this class of Spanish-speaking bilingual students, most of whom were recent immigrants. During the next 2 weeks, the students participated in learning activities centered on incidents like the one described earlier in Chapter 2, as well as those in Chapter 3, when Felita and her family painfully decided to move back to their old neighborhood because they could no longer endure the discrimination.

From the beginning, Angela Burgos's class was riveted by Felita's story. We discovered that to the fifth graders in the class, *Felita* did not always read like a work of fiction. For these children, whose school is

in a neighborhood that had one of the highest immigration rates in the city, and who were referred to as the "Spanish class" by other fifth graders in the school, Felita's tale was relevant and personally meaningful.

As observers in this classroom in Boston, we saw how powerfully the children engaged in the story, and how the teacher connected the novel to her students' personal lives. We also realized that children seemed to vary in their understanding of the characters' motivation and had different suggestions for dealing with the conflict. Some children supported the family's decision to move back to their old neighborhood. Others felt they should have stayed and fought the discrimination. These observations led to the formulation of several questions: What accounted for the variation we observed? Were some of the students more sophisticated in their understanding of the issues faced by Felita's family? If so, how could we systematize and validate our intuitive observations of developmental differences among the students in the class?

When we first developed a strategy for promoting social competence in the literacy curriculum used by Angela Burgos, we relied on a theoretical model of psychosocial understanding grounded in developmental theory and basic empirical research. The model delineates children's developing awareness of the linkages between the challenges or risks they face (e.g., the risk Felita takes in challenging her persecutors) and the important social relationships in their lives (e.g., Felita's family and the community in the new neighborhood; Adalbjarnardottir, 2002; Levitt & Selman, 1996; Levitt, Selman, & Richmond, 1991; Selman & Adalbjarnardottir, 2000). It analyzes the development and connection of three psychological components of social awareness:

1. The *general level of understanding* individuals have about how social risks influence and are influenced by social relationships (social knowledge).
2. The *repertoire of interpersonal strategies* individuals have available to manage these challenges (social skills).
3. The *awareness individuals have of the personal meaning* these challenges and relationships actually have for themselves: how they understand the actions they take as they relate to the quality of the personal relationships they seek to form and maintain (social relationships and values).

This theoretical model asserts that the greater one's capacity to integrate the social perspectives of oneself and others in the context of dealing with life's social challenges, the better the chances of successfully navigating social relationships (Selman & Schultz, 1990; Selman et al., 1997). Figure 10.2 depicts the connection among the components of the model in visual terms. The broadening of this figure with age suggests that with development, awareness within each of the three components becomes more differentiated. It also suggests that, with development, the components themselves become more integrated with one another, but that there can be regression as well as progression.

Each of the three components of this developmental model—the social understanding, social strategies, and awareness of the personal meaning of relationships and their risks—helped us to define questions in the teacher guides and subsequently analyze the children's responses. For example, we created reading comprehension questions that probed for each of the three theoretical components within the model. One set of reading comprehension/social awareness questions specifically investigated the students' *understanding* of

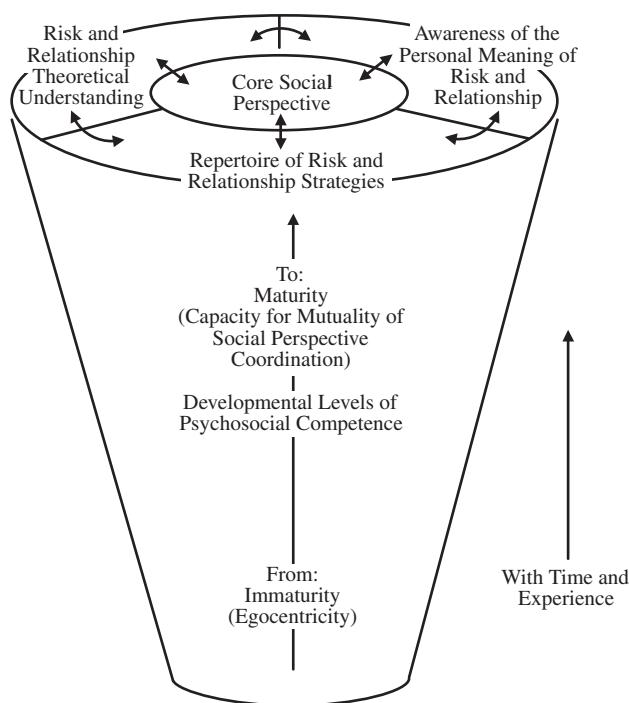

Figure 10.2 A developmental view of risk and social relationships: An analysis of three psychosocial competencies.

the connection between the social relationships and living conditions in Felita's two neighborhoods by asking the students to consider: "How are Felita's new and old neighborhoods alike? How are they different?" A second kind of reading comprehension/social awareness question focused on students' awareness of the *strategies* the family had available to deal with the conflict in which they found themselves, for example: "What is the problem Felita is facing? What can Felita and her family do to deal with the way the people in the new neighborhood treat them?" Finally, a third reading comprehension/social awareness question evaluated how the students interpreted what *personal meaning* the events in the story had for the characters—and for themselves. How did they understand Felita's dilemma when, in conversation with her grandmother, she grappled with her decision to run away from the confrontation in the neighborhood? "Felita says to her abuelita, 'I never said anything to those girls. Never. It was as if they were right, because I just walked away, you know?' What does Felita mean?"

Once we collected the responses from the students, we explored the possibility that the students' ability to understand fictional social experiences was a window into their ability to think about, negotiate, and make meaning of the social risks and relationships in their own lives. We hypothesized that students who displayed more sophisticated social perspective-coordination—the ability to connect multiple viewpoints and think deeply about the actions and motivations of the characters in the book—would also display a richer understanding of the texts they read (Dray, 2005; Selman & Dray, 2003). For example, we observed differences in the way children understood the question about differences between the two neighborhoods (the social understanding question).

Frederico, a boy with limited English proficiency, wrote the following response:

The kitchen was almost alike. The bilden [building] was desein [designed] like the other bilden. The street of the new neighborhood was clean.

Amalia, a shy girl in the class, wrote:

They are alike in the neighborhood because both the neighborhoods had a school and some stores. They are different in that in the old neighborhood she got friends and in the new neighborhood she doesn't.

Claudia, a soft-spoken but assertive student, wrote:

The things that the new and old neighborhood had in common were the stores, schools and building. The difference was the people's attitudes and how they treated other people just because they speak Spanish.

As we attempted to make sense of these responses, they became our data. Because we believed we could identify differences in the ways the children responded to this question, we tackled the question of how to code the responses both developmentally and culturally. For example, with respect to developmentally oriented coding, each of these students' answers was to some degree accurate. As Frederico pointed out, Felita's new neighborhood is cleaner, and it is true that Felita's family originally moved in part because of the better physical qualities of the new neighborhood. But we noted that Frederico was focused on the impersonal qualities that contrasted Felita's old and new communities: the buildings and the streets. He did not refer to the social relationships in the story: Although the family did indeed move to the new neighborhood for the benefit of better living conditions, they moved back because of the negative social conditions (the prejudice and discrimination they experienced). Frederico's response did not (according to our coding scheme) capture the arguably more important definition of a neighborhood.

Now, compare the responses of the two girls, Amalia and Claudia. Amalia wrote, "In the old neighborhood she got friends and in the new neighborhood she doesn't." Her response acknowledged that it is the relationships among the people in each neighborhood that were most important in the story. Unlike Frederico, she was able to express her knowledge of relationships more explicitly, if not more clearly. However, we found it intriguing that Amalia looked at the people in each neighborhood from a self-referential perspective: They were either Felita's friends or they were not her friends. Claudia, on the other hand, suggested that the people in the new neighborhood *had beliefs* and *acted* in ways that prevented Felita from making friends: "The difference was the people's attitudes and how they treated other people." Whereas Amalia implied that someone is either a friend or not (as if by magic), Claudia's response suggested that she understood that the characters' internal beliefs (their attitudes) drove their actions (how they treated people).

She further implied that perhaps these attitudes and actions were influenced by the perception of the group Felita belonged to, a group seen by parents and kids in the new neighborhood as being different and unwelcome. From our theoretical perspective, Claudia's response displayed a more complex understanding of how people become friends and the importance of trust and actions in forming relationships. By enlarging her view to encompass intergroup relationships, she indicated a more sophisticated social awareness.

From Practice Back to Research: The Theory and Promotion of Social Awareness

What do we mean by "social awareness"? Until now, our theory had been successful in investigating social relationships, usually one-on-one interpersonal relationships such as friendships (Selman & Schultz, 1990; Selman et al., 1992, 1997). But, as we realized that some children displayed an interpretation of the text that went beyond a *social* understanding to a *societal* understanding, we reexamined our original ideas. What if the theory of social development that had attempted to explain children's understanding and strategies within friendships could be expanded to help explain their understanding and strategies for solving questions of social justice? This was a shift for us from not just using research to support effective practice, but allowing practice to inspire theory and research.

For example, we found that two other students took their analysis of the neighborhood differences one step further. They pointed out qualities they believed the girls in Felita's new neighborhood lacked. The words they used to describe these qualities were striking to us:

They are alike because they both are calm neighborhoods. They are both different because the people there (in the new neighborhood) have a hard heart and they make spanish people miserable. (Juan)

In the old neighborhood they have the hopscotch game. The houses are the same sides. [In the new neighborhood] kids don't respect adults. There is no respect for each other. There are selfish people. (Rosario)

Rosario and Juan, unlike Amalia and Claudia, looked beyond specific actions and attitudes to identify the important internal and enduring feelings of the

people in both neighborhoods that contrasted them: respect, selfishness, and “hard hearts.” Juan, for instance, demonstrated to us that he perceived correctly that the girls’ dislike of Felita originated from their dislike of anyone Spanish. Unlike Amalia, Juan’s understanding of the conflict went beyond just seeing the girls as being “friends” or “not friends.” He was able to express a level of awareness that included a cultural perspective on the qualities of the neighborhoods. Similarly, Rosario captured an essential meaning of prejudice: that people do not respect each other’s differences.

As we examined the responses to *Felita*’s reading comprehension questions, we focused on several developmental research questions: Were the students able to describe how the people in the neighborhoods differed in their attitudes toward Spanish speakers? To what did they attribute these differences? Did they see it simply as a problem of Felita “having friends” or “not having friends,” or did they really understand the complexity of prejudice in the story? We began to write our answers down, and in doing so, we began to create a set of rubrics designed to code social awareness (Selman & Dray, 2003).

It is important to step back for a minute to consider the broader implications of these data. In the IOM model we discussed earlier, research and theory feed into practice: The flow goes from the knowledge pool of research to the delta of practice, with practice being the beneficiary of good research. But here our primary prevention program (the literacy infused with social awareness curriculum) was hit midstream with a whirlpool, so to speak. Our original theory of interpersonal development did not easily map onto the intercultural and intergroup responses given by the children. So we did not try to force it to fit; instead, we listened to our data and attempted to make sense of what the students described to us.

From Awareness to Practice: How Children Learn Strategies of Coping with Discrimination

Thus far, we have analyzed how the children comprehended the differences between the two neighborhoods using a developmental analysis. Next, we questioned how they would solve the discrimination the family faced in the new neighborhood. We did not as yet know how their understanding would translate into actions:

How would the students solve the problem Felita and her family actually faced?

Embedded into the curriculum were exercises that allowed the students to practice their social problem solving and interpersonal negotiation skills. One worksheet was called, “ABC: Ask, Brainstorm, and Choose.” The students were instructed to “ask” what the problem is, “brainstorm” different ways to solve it, and then “choose” the solution that is best in this particular situation. This type of exercise is fairly common to conflict resolution curricula and is similar to the “stop and think” exercises of Second Step (Committee for Children, 2005).

One kind of fundamental social-cognitive research that underlies this type of exercise conceptualizes the link between social thought and action as a series of information-processing steps, from defining the problem to evaluating the outcome (Coie & Dodge, 1998; Dodge, Pettit, McClaskey, & Brown, 1986). This approach attempts to understand or predict behavior at any particular moment; it is in this sense *proximal*.⁴ Our developmental method tends to examine both conduct and the way children make meaning of it over time and is thus more *distal*. These two approaches are not mutually exclusive but instead are complimentary in their methods of explaining behavior in the moment and over time and across children (Selman, Beardslee, Schultz, Krupa, & Podorefsky, 1986).

As part of our data collection, we videotaped the students as they role-played and worked through the exercises. As we expected, the students’ responses to *Felita*’s dilemma were illuminating. After about 3 months in Ms. Burgos’s class, the students trusted their teacher enough to say what was on their mind—what they really thought as opposed to what they thought she wanted to hear. The class had been instructed to work through the ABC exercise on their own for homework and they would discuss the exercise as a group the following day. That morning, Ms. Burgos called on one student, Luis, to present to the class his homework assignment from the night before. We were on hand with our video recorders to capture the responses and the ensuing discussion.

Luis read the first question on his homework assignment, “What is the problem Felita is facing?” He paused

⁴As recounted by K. A. Dodge in 2004 in personal conversation with the first author.

for a moment and then declared, “Felita is facing the problem of living in the new neighborhood and getting insulted by other people.” Then Luis read the next question on the sheet, “What advice would you give to Felita to deal with and cope with the difficult situation?” Luis briefly looked up from his homework before replying, “I would advise Felita to ignore everybody and get on with her life.”

On the videotape, it is clear this suggestion went over with the rest of the students like a lead balloon. An awkward silence fell over the class as Luis’s classmates exchanged knowing smirks and eye rolls. In the class discussion that followed, under Ms. Burgos’s careful guidance, we found that most of the students disagreed with Luis’s suggestion to ignore the provocation. Instead, most of the students strongly felt Felita’s family should do something—anything—in response to the discrimination they experienced.

What strategies did the students choose to handle this conflict? Based on the videotapes and their homework assignments, we identified four thematic groups of responses:

1. *Fight back:* If someone pushes you, push them back (e.g., “call the police,” “beat the bullies up for doing that,” “ask friends from the old neighborhood to help beat up the bullies”). Most of the boys fell into this category.
2. *Retreat:* Walk away from these situations (e.g., “move back to the old neighborhood,” “play with friends in the old neighborhood,” “move back to Puerto Rico”). Many of the girls fell into this category.
3. *Ignore:* “Felita should ignore the problem.” Only Luis chose this strategy.
4. *Organize:* Rally support to protest the injustice. “Have a celebrating differences day.” One girl, Juanita, suggested this option.

Any researcher in social psychology could interpret these children’s responses based on his or her own theoretical and interpretive framework. A clinical perspective, for instance, would look to Luis’s biographical life experiences to help explain his reaction. We knew, for instance, that in fact Luis had lived in a homeless shelter and had been exposed to life on the streets. Using this type of analysis, Luis’s response may be considered adaptive in that he learned that the best strategy to resolve conflicts is avoidance. From a cultural or gender

perspective, it is worth paying attention to how the girls tended to cluster together around the theme of “go back to the old neighborhood,” whereas most of the boys preferred the “beat up the bullies” strategy. Cultural psychologists would note, too, that these children are Latino and either are recent immigrants or children of immigrants. That type of analysis would look to the cultural values and preferences rooted in these children’s own lives, and their family histories, for explanations of their behavioral strategies. It would also compare Angela’s class to other classes.

Using our framework, we began by identifying two main themes in the responses: “forget about it” and “push them back.” The “forget about it” category (the left column in Figure 10.3) included a range of options: move back to the old neighborhood, ignore the girls and maybe they will leave you alone, and walk away from the conflict and reflect on it so that you can make a better decision in the future. We called these responses “self-transforming” because they recommended that Felita and her family walk away from the situation (at least at first) by avoiding it, moving back to the old neighborhood, or giving the situation some time and thought.

In contrast, the “push them back” category (the right column in Figure 10.3) included responses in which Felita and her family would take outward action toward the girls and the families in the community.

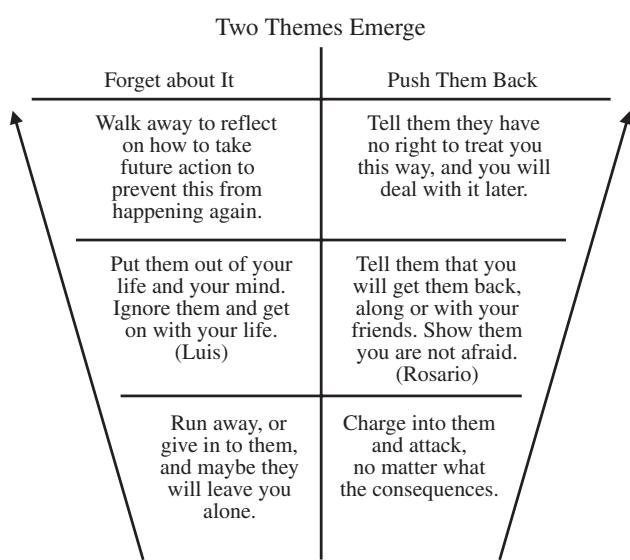

Figure 10.3 Developmental and thematic framework.

These actions ranged from “beat them up immediately” to “get friends from the old neighborhood to beat them up” to “tell them they have no right to treat us this way.” Using either words or behavior, this group of responses preferred taking action rather than spending time reflecting on or avoiding the conflict.

However, there is also variation within each thematic group. From our developmental perspective, some responses seemed to be more mature than others. For example, comparing the responses in the “forget about it” column, we felt that reflecting on the problem was more appropriate than ignoring it. Similarly, talking over the problem within the community (a “push them back” option) was preferable to beating them up. Therefore, the widening of the cone in Figure 10.3 reflected by the side arrows illustrates a broadening of perspectives being taken into consideration and a subsequently more developmentally mature social understanding of the problem and strategy.

Why This Type of Analysis Matters

Our interpretation of the students’ responses to the reading comprehension questions was intriguing for several reasons. First, it offered a new insight into our preexisting theory: that how children develop an understanding of interpersonal relationships could be broadened to include an awareness of cultural and societal forces. We could identify differences in the children’s understanding of Felita’s story, and our model of understanding the development of social relationships could classify these differences.

Second, our method of assessing social awareness—through reading comprehension questions in literature—offered a new way to study how children comprehend social situations. In addition to observing behavior and conducting interviews, we could investigate how children make meaning and negotiate social situations through their responses to questions about fictional characters in novels. Combined with the more traditional methods of assessment, this was another tool in the study of the development of social competence, one that integrates well with practice.

Finally, the application of a developmental theory of social awareness (and research that supports it) to the fields of language arts and literacy was important because it suggested the possibility of mutually supporting literacy and social awareness development in children. Of course, the idea that multicultural literature can be

used to teach children about their own lives is not new.⁵ A variety of programs that teach social skills through literacy have been integrated into schools recently (Developmental Studies Center, 2004; Educators for Social Responsibility [ESR Metro], 1999; Leming, 2000; Narvaez, 2001; Walker, 2000). For many schools, the programs may be a solution to their dilemma of needing to promote literacy, yet not wanting to sideline social skills. If we could come up with a way to assess children’s social awareness reliably, then we could work as a discipline toward promoting it. Instead of literature simply being the vehicle through which social relationships are introduced, it could become a mechanism for deepening understanding.

However, these ideas are not without challenges. For instance, we still do not know whether what we captured was a more developed awareness of interpersonal and intergroup relationships, or simply more advanced literacy skills. Literacy researchers, for example, would point to the bilingualism of the students as a factor in their understanding of the novel; perhaps Rosario had better language skills than Frederico and therefore could read and communicate her ideas more fluently in English. In our analysis, we primarily interpreted what we believed the children meant to say. We hypothesized that although many students, including those who were bilingual, would not be sophisticated enough in their writing or reading skills to use the word “prejudice,” they knew when they experienced it. However, not everyone would agree with this interpretation. Whether children’s social awareness can be disentangled from language and literacy remains to be seen.

Finally, even if we could conduct research that would adequately disentangle the effects of language and literacy skills from the reading comprehension assessments, and if we found ways to validate that in fact we were capturing social skill and understanding, we wondered about the implications of this type of analysis. Would practitioners adopt it as an effective method of teaching

⁵ See, for example, the Developmental Studies Center’s programs, such as Character Development and Academic Competence through Literature; the Yale University School Development Program developed by James Comer; the Collaborative for Academic, Social and Emotional Learning at the University of Chicago, Illinois; and the Reading, Writing, Respect, and Resolution program based out of the Educators for Social Responsibility in New York City.

social skills? How would this method of assessment fit within the more traditional psychological methods of behavior observation, measurement, and interviews? What level of professional and teacher development would be needed to teach the awareness that we considered to be essential? We decided these were important questions to be explored.

From Policy to Practice: Where the Promotion of Social Awareness Fits within Educational Policy in the Field of Literacy

We decided to first tackle the question of language and literacy. Could existing research in reading comprehension explain what we identified in the students' responses—their social awareness? How should we begin to validate our coding? To answer these questions, we needed to do some research in the field of language and literacy—not the usual home of social developmental psychologists.

We discovered that the field is one of the most closely watched and researched domains in education. Faced currently with one of the largest growth spurts in immigration in the history of the United States, the demands of the labor market for jobs requiring a literate workforce, and a widening gap between the wealthy and the very poor, policymakers (and politicians) have responded to these changing social demographics with a focus on academic achievement for all (Bronfenbrenner, McClelland, Wethington, Moen, & Ceci, 1996). The importance of creating a literate nation has become one of, if not the most important goals of education (Hill & Larsen, 2000; MacGinitie & MacGinitie, 1986; Sarroub & Pearson, 1998; Snow, Burns, & Griffin, 1998).

We also discovered that reading comprehension is an important area of research and practice. Although decoding has been acknowledged as a critical step in reading development, researchers and practitioners have come to realize that even the most fluent readers do not necessarily comprehend well (Snow & Sweet, 2003). Good comprehenders not only are skilled decoders but also can navigate different types of texts (Walpole, 1999). When students read fiction, they need to learn how to make inferences about characters' motivations and feelings. They also need to comprehend plot developments that result from characters' actions (Oakhill & Yuill, 1996). Students with good comprehension actively make connections between what they currently read and their background knowledge. They monitor

their own understanding and work to make meaning of the author's ideas (Spires & Donley, 1998; Vacca & Newton, 1995).

Yet, despite knowing what good reading comprehension looks like in action, trying to teach it well or assess it effectively remains a challenge (Snow & Sweet, 2003). Trying to disentangle children's content knowledge (what they actually read about) from their reading skill in assessments is no easy task. In fact, our attempt to figure out how much of what we captured was social awareness versus literacy skill is similar to questions of background knowledge and comprehension confronting literacy assessments.

The Massachusetts Comprehensive Assessment System (MCAS) is one example of how reading comprehension has become an indicator of acquired literacy skills. In the Commonwealth of Massachusetts, as in many states, the recent educational reform movement has focused much of its considerable energy and funding on improving academic achievement by raising literacy standards. MCAS exams are used to identify areas of improvement in individual students, teachers, schools, and districts. Across the state, teachers, principals, and superintendents work hard to prepare students for the yearly MCAS exams. "Teaching to the test" has become an everyday phrase, and teachers not only admit to structuring curriculum and classes according to the MCAS standards, but are in fact expected to do so. The exams are a fact of life in Massachusetts, and a bar all students (including Angela Burgos's) have to jump over to move to the next grade and to graduate. A single test has become a very high-stakes measure indeed, for students, parents, and school professionals.

Outside of Massachusetts, the Stanford Achievement Test (Harcourt Educational Measurement, 1997) is a widely used national measure that evaluates writing and reading comprehension across grade levels. It attempts to assess how well the student understands the story as a whole, connects relationships among ideas, considers why and for whom the story was written, comprehends character's motivations, and understands setting and plot. Assessments such as the MCAS and the Stanford series have broad goals. But often, the objectives of the assessments are distilled into short-answer reading comprehension questions that rarely probe beyond the main idea of a paragraph or passage (Sarroub & Pearson, 1998).

For example, in Figure 10.4 the Stanford Nine (Harcourt Educational Measurement, 1997) tries to determine

<p>Reading Selection: <i>Faster Than the Wind</i>, by Lois Grambling.</p> <p>Somewhere near you lives a boy like Peter. Peter is in the fourth grade. It takes him a long time to do his work at school, and often he needs help with it...But Peter always does his best. His family taught him that.</p> <p>Every afternoon when school is over, Peter runs to his house... Peter likes to run. He feels good when he runs, because his legs do what he wants them to do. His arms and feet do too. The wind hits his face and blows his hair. When he runs, Peter feels as if he is flying...</p> <p>One day, Peter's big brother told Peter that he should try out for the school track team. His brother said the team needed fast and steady runners...All that day, Peter thought about it...The next day, Peter ran over to the track field to try out for the team.</p> <p>Some things are different for Peter...Peter gets home from school late now, but his family doesn't mind. They're proud of Peter, who may be slow at doing some things, but is faster than the wind when he runs.</p>
<p>Comprehension Question: Peter's family says that he is faster than the wind. What does that mean? How do you know that?</p>
<p>Coded Responses (with our corrected spelling) from low (bottom) to high (top) levels:</p> <p>"That means in figurative language it means that he can run very fast. I know that because it would be impossible for a human to run faster than the wind."</p> <p>"Faster than the wind means he runs very very fast. Because he runs and so if he runs fast his parents use that expression to say he is a fast runner."</p> <p>"Peter can run very fast. It is a comparison."</p> <p>"It means that he runs fast because he runs everywhere and he runs on the track team Peter likes to run. Because I read the story and that's what it says Peter runs fast also because he like to run and has good practice at it."</p>

Figure 10.4 An analysis of a short-answer reading comprehension coding rubric from the Stanford Achievement Test 9/e scoring guides. *Source:* From *Stanford Achievement Test Series*, ninth edition, [Technical data report], by Harcourt Educational Measurement, 1997, San Antonio, TX: Author.

if children in the fifth grade can understand the meaning of a “figurative phrase” such as “run faster than the wind.” Reading comprehension requires being able to understand literary devices such as figurative phrases; if children cannot utilize these expressions, they will not learn to communicate deeply. We applaud instruction guided toward developing children’s capacity to read well, but we cannot help but feel something can be added to the type of assessment represented by the Stanford Nine approach.

One difference in our approach is our theoretical and practical perspective. A social awareness approach focuses on the comprehension of the *understanding, management, and personal meaning* of the powerful challenges inherent in the social and societal relationships in fictional as well as biographical stories. Therefore, our method of assessment needs to be based on narratives where these challenges in social relationships are the primary themes. Traditional measures of reading comprehension contain elements we consider particularly important, such as understanding character motivations, traits, and thoughts (Vacca & Newton, 1995). However, our coding and analysis also tries to capture how deeply the student can see beyond the literal meaning of a text and grasp the personal meaning of the social situations experienced by the characters.

Developmentally speaking, we argue that fifth grade is an important time for learning the kind of social issues raised by texts such as *Felita*. Every day, the students in Angela Burgos’s class experience conflicts with each other, with their family, and with students in other classes. It is inevitable that such experiences engage the students’ energy and their attention. We cannot ignore this energy; their ideas about relationships will affect their social behavior. Instead of avoiding socially charged themes, as traditional assessments may try to do, we embrace them.

Of course, there are risks to the approach we advocate. For instance, children have to read across different subject areas and need to comprehend texts about science as well as about social relationships (Snow & Sweet, 2003). We don’t want to overemphasize our approach and ignore the need for a balanced research agenda in reading comprehension. Our method is not the only way, nor is it all these students need for literacy skills.

A second concern is that we may misdiagnose students using this method of assessment. For example, we could underestimate what they are capable of understanding, or we may mistake differences in cultural beliefs about social issues for variation in social and cognitive development. It is important that we understand and research the ways people from various cultures and backgrounds, with diverse beliefs and values, would infuse *Felita*’s story with different meanings and interpretations.

These risks and prospects suggest a challenge for research and theory. The potential pitfalls and opportunities suggest the need for a next round of research to fill in the picture of what students at different ages and

from different backgrounds understand of social issues in stories. We need to return to the area of fundamental research to consider the issues that were raised when we moved into the world of practice.

Reviewing the Map: The Institute of Medicine Principles in Light of the Two Cases

The two cases we have provided, the Gilmore School and Angela Burgos's classroom, are snapshots from the first two phases of our journey from research to practice, and from practice to policy. We return now to our original topics: the role of the Institute of Medicine's Prevention and Intervention Cycle (Mrazek & Haggerty, 1994) and the relationships between practice and research, both fundamental and applied.

In the first case, the school in distress, we illustrated how basic research in psychology (clinical, developmental, social, and/or cultural) can be integrated into programs that may help turn a school around in its approach toward social behavior and school climate. We introduced four programs that are very successful in integrating research with practice. All rest on a foundation of theory and research and all have been outcome-evaluated. By describing the people at the Gilmore to you, we hoped to illustrate how practitioners experience the everyday world of social relationships in school and the challenges they face in trying to sift through research to find the answers to their essential problems.

The second case, the story of Felita and our interpretation of the children's reading comprehension questions, illustrates how even basic research can be, and should be, influenced by contextual issues such as classroom atmosphere and systemic issues such as educational policy. With the current focus on academic standards, social development and character education programs are often sidelined or integrated into content areas such as history or language arts. In our example, reading and social development seem to be a natural fit. But without a structured research plan of how the children's responses and participation in the program can be assessed, we will never know how influential are books about multiculturalism, prejudice, or interpersonal conflicts on the development of children. Nor will we know how to assess the role of teachers. We must have faith that basic research, no matter how modest in relation to the forces of practice, will be of some value. Therefore, our own research agenda has changed direction, becoming more basic as opposed to applied, and

we are currently engaged in designing a new pilot study that may help us disentangle more clearly the role children's literacy skills play in understanding stories of social justice.

In its report on prevention research, the IOM recommended that comprehensive initiatives in this field be guided by five principles (Mrazek & Haggerty, 1994). Consider the two cases we have described in light of each of these characteristics. The first principle is to have clearly specified theory-linked hypotheses to guide both the intervention and the methods of evaluation. Both cases fit this requirement. In the case of the Gilmore School, each intervention program we described had its own underlying research base in the risk and resilience field; all shared an interest in promoting children's social and emotional competence and reducing the risks of conduct disorder, violence, and other social behavioral problems. In the second case, Angela Burgos's class, our working hypothesis was that literacy programs that focus on reading, writing about, and discussing books with powerful social themes and issues will promote better abilities in fundamental academic skills such as reading comprehension and writing. We also believe these programs may improve children's abilities to deal with adversity, risk, and injustice in their lives, such as negotiating conflict, developing self- and social awareness, and expressing their own point of view. In both cases, these theory-driven hypotheses were not just tested once, but require both the continual design and implementation of a range of practices as well as ongoing basic research.

The second IOM principle is that interventions should strive to randomly assign participants to well-defined conditions, where there are clearly specified manuals to guide the intervention and methods to constantly monitor the fidelity of the way the intervention is provided or delivered (Mrazek & Haggerty, 1994). This guideline may work better in models where the target participants are individuals with identifiable disorders or risk factors, although with enough resources evaluation studies at the classroom or school level can be undertaken (Solomon et al., 2000).

The third principle is that potential participants in intervention (or clinical) trials should be fully assessed prior to their (random) assignment to one of the conditions in the study. In addition, once under way, the study should have well-specified measures of expected outcomes that are objectively rated. Here we see an interesting difference in the cases. In their research, the

investigators of each program profiled in the first case set up two conditions, participation and nonparticipation, and explored the evaluation literature for the kinds of measures that could objectively (with validity/reliability) measure the effects of each program. The best available measures in the field were imported into the study for use, and the outcomes captured.

In the second case, the pilot work has neither compared results across different conditions (steps 3 and 4) nor gone to the literature for validated measures. Instead, we went in a different direction from that suggested by the evidence in step 3. Rather than move to step 4, we returned to the empirical domain to explore our ideas, construct new hypotheses, and develop measures that could be used in a field where few objective and validated measures previously existed. We then began working on another pilot study to test the measures and our research methods. In other words, the feedback loop to step 1 occurred earlier than the feedback loop outlined in the IOM cycle. Before moving to steps 4 and 5, we needed to spend more time circling between identifying the problem, reviewing literature, and conducting pilot studies.

The final principle of the IOM model is that evaluations should continue beyond the immediate end of the intervention trials (Mrazek & Haggerty, 1994). This is a principle important not only to the model but to all research-based practice that thinks about both individuals (and populations) in developmental terms. At the Gilmore School, for example, we need to know whether cases of conduct disorder diminished over time for those who participated in the school-based prevention program Second Step. In addition, we need to better understand the economic and contextual factors that influenced its implementation. In the literacy classroom, on the other hand, we also must investigate what happened to students who got a good dose of social awareness mixed in with their reading program. In both cases, we want to know if the students were in better shape, academically and socially, than they otherwise might be 3, 5, or 7 years down the line.

Most likely, the IOM model suggests the final principle primarily to find out whether an intervention with any immediately positive effect has some kind of staying power or whether the effects strengthen or weaken over time. These compelling practice-driven questions need to be answered if they are to turn into policies. Nevertheless, this recommendation does not assume

there is some definable end to the intervention/prevention. For instance, the approaches suggested in both cases are really long-term interventions. In the case of the school-based prevention programs, there is evidence that school and individual problems cannot be solved in the short term and that the prevention needs to be ongoing. In the case of the promotion of social awareness, the ideal method of choice is to infuse this approach at every grade level. It is not a circumscribed intervention implemented in a relatively short period of time. In fact, the intervention probably should be adopted for at least 6 years, for example, from kindergarten through fifth grade, with appropriate teacher professional development, for it to be considered implemented with fidelity.

In both cases, longitudinal follow-up studies are essential. All the interventions we presented in both case studies target school-age children, and children are in school from ages 6 to 17. Clearly, there are developmental differences in how children across this age range understand the nature of and make meaning of social interactions in school. We need to study what this process looks like across ages as well as contexts such as school, social class, and cultural background. We also need to know the effect of teacher training and family and contextual interventions. Only with further, long-term, longitudinal research can any of these issues be explored thoroughly.

Nothing we do, however virtuous, can be accomplished alone; therefore we must be saved by love.

—Reinhold Niebuhr (1952)

Enlarging the Map: Connecting the Institute of Medicine Principles to the Public Policy Circle

The cases in this chapter also point to the necessity of integrating public policy into our discussion of the IOM research cycle. Initially, our point of departure was the desire to improve the mental health and social development of youth through thoughtful services. At the Gilmore School, this concern grew from our experience working with children and teachers struggling to live in and be supported in a school with a vulnerable social atmosphere. The strategy we presented was to seek outside preventive interventions from a range of options, each with its own theoretical framework and evidence base. We witnessed how the Gilmore strove to adapt to a new era of educational policy changes

that enormously influenced their decision in choosing and implementing a prevention program. In the second case, our goal was to pilot-test a theory and a research-based approach to the promotion of social awareness. Our intervention did not have an empirical outcome seal of approval. Even so, we still found ourselves having to negotiate national policies on literacy assessment and instruction to do research on children's social development. Instead of being cases that simply addressed the relationship between knowledge and practice, in both instances we moved quickly to having to consider issues of policy.

In thinking about the interaction among research, practice, and policy, we have found a framework initially articulated by Julius Richmond, former U.S. surgeon general, to be very useful as a guide to locate the kind of integrative work we both describe and do, the movements we have made, and to plan our next steps. This map not only locates the work of our cases on a larger landscape, but it needs to be considered as a way to view explicitly how this kind of work evolves over time.

Throughout his 60-year career, Richmond, a pediatrician by training, traveled across the worlds of research, practice, and policy in the fields of child development and child health. He has analyzed how members of the child development professions, be they researchers, practitioners, policymakers, politicians, or advocates, can be more effective in influencing public policy. In several articles, Richmond presented a three-factor model to guide child health public policy (Richmond & Kotelchuck, 1983; Richmond & Leaf, 1985; Richmond & Lustman, 1954). To explain it, we will refer to Figure 10.5.

There are three territories, Richmond claims, with which those of us who want to impact public policy in child development must gain some familiarity: (1) the analysis and development of a scientific knowledge base, (2) the analysis and development of a social strategy, and (3) the analysis and development of political will. The three must work together to develop and implement public policy.

For example, a knowledge base provides the scientific foundation on which to make health care policy decisions. Health care policy requires basic research before we can make progress toward the eradication of disease. In addition, however, Richmond and his colleagues suggest that the knowledge base must also in-

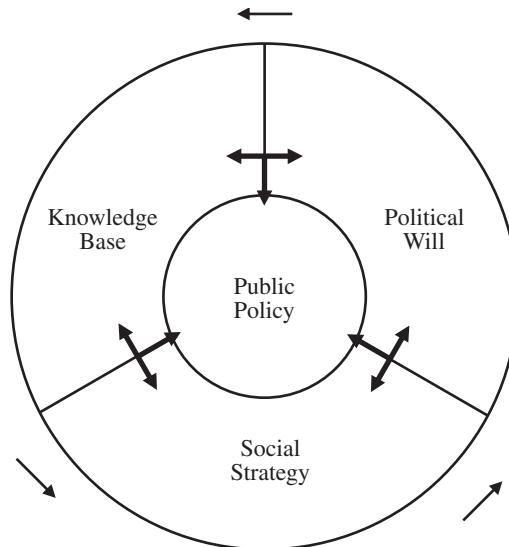

Figure 10.5 Three-factor approach to policy: The Richmond Model.

clude an understanding of the social and economic factors that encompass the health risk, the culture in which the problems exist, and the delivery systems (such as prevention programs) that work to ameliorate the risks. In other words, two kinds of knowledge are necessary: knowledge provided by the basic researcher who does fundamental research on questions related to children's mental health (e.g., the risks they face) and the expertise of the applied researcher who refines and evaluates the context and systems of delivery (i.e., the prevention programs that may work to ameliorate those risks). Without an understanding of both the health risk and the process by which our efforts will make a difference, policies will proceed incrementally in many different directions.

However, basic and applied knowledge are necessary but not sufficient to sway public policy. Knowledge must work hand in hand with social strategy. A social strategy, as defined by Richmond, is a national or international blueprint of how our goals should be accomplished. As a field, child psychology must work across disciplines and domains and bridge gaps between basic and applied research to come to agreement about the steps we should follow to achieve our policy goals. Social strategy is not in itself policy; it is simply the outline and plan of a child health or education policy (Richmond & Kotelchuck, 1983).

Finally, even when we have a strong knowledge base in an area and a blueprint for change, transformations in public policy depend on political will. How committed are we as a society to develop new programs or reinvent old ones? We need to create a process by which constituencies will be created and resources are generated to accomplish our child-care goals.

Developmental psychology as a discipline that contributes to prevention science and practice needs to contribute to the movement among all three domains, as suggested by the bidirectional arrows linking knowledge, strategy, and political will in Figure 10.5. We need to value each domain and acknowledge the contributions each make to the other. Furthermore, when activity in one domain is weak, it needs to have resources invested to strengthen it. No matter where one starts in Figure 10.5, one should not abandon that experience as one moves to a different area. Engagement in all three territories must come together before one can really influence the development and implementation of public policy.

In our case of applied social development, we now know that academic skills alone will not suffice to ensure that children will have successful lives. We realize that supportive schools lead to better academic performance (Goodenow, 1993; Larson & Richards, 1991; Wentzel, 1996; Zins, Weissberg, Wang, & Walberg, 2004), but how does one raise the consciousness among the public or decision makers that high standards in education need to include standards of social understanding and ethical conduct? How can we influence the policies faced by the Gilmore? What are the next steps our field needs to take to deepen our knowledge, map out our social strategy, and invigorate the political will?

These are critical questions our field needs to address. However, as we grappled with them in our own work, we came up with a different question we believe we needed to answer first: In Richmond's model, what role does practice play? Where is the "practice" in the three fields of the model? Is the practitioner simply the person who carries out the work of the knowledge base, or the facilitator in our research studies? Does the practitioner help map social strategy or contribute to political will?

Let us now return to our second case, the students in Angela Burgos's class at the Gilmore School and their responses to reading comprehension questions, to de-

scribe the challenges we faced when our knowledge base met the politics and practice of implementation.

The Journey from Practice and Policy Back to Research: Reversing the Direction of the Feedback Loop

While analyzing the data Angela Burgos's students provided, we realized that gaps in our own knowledge base required that we return to the domain of basic research to explore social awareness more deeply. But to do basic research, we had to stay within practice, in Angela Burgos's classroom. We grappled with fundamental ideas about what children understand by continuing to do applied yet basic research—by doing what we call "practice-based" research.

For example, we found that the most challenging question the students faced originated in Chapter 3 of the book. Several weeks after moving back to her old neighborhood, the character of Felita talked with her grandmother about the conflict with the neighborhood girls:

"Abuelita, I don't want Mami or anybody else to know that I . . . I feel like this."

"Like how, Felita?"

"Bad . . . and like I can't stand up for myself."

"Well, then I promise you, nobody will know but us, yes?" She smiled and hugged me real tight.

"It's about when I lived in that new neighborhood and what happened to me." I told Abuelita the whole story, just like it happened. "Probably Mami told you already, but I don't think she really knows how I feel."

"Now what makes you say that?"

"Abuelita, I never said anything to those girls. Never. It was as if they were right, because I just walked away, you know?" (Mohr, 1979, p. 59)

We were intrigued by this part of the story, where Felita grapples with her own actions and reactions while talking to her grandmother. We wondered, what was the personal meaning of the incident for Felita? Do the students understand why Felita is upset? To explore these ideas, our reading comprehension/social awareness question was this: "Felita says to her Abuelita, 'I never said anything to those girls. Never. It was as if they were right, because I just walked away, you know?' What does Felita mean?"

This question does not just require the students to look back at a passage in the story. Rather, it probes for

the levels of awareness children have of the social world around them. In a developmental framework, the responses offered insight into how the students thought about social relationships generally and Felita's situation specifically. How, then, do we interpret the students' responses—their "thoughts"?

Most students fell into one of two groups. Some believed Felita meant she was sorry she had run away from the physical confrontation with the girls, because now they thought she was chicken. Others thought Felita was upset because the girls rejected her for no good reason—she did nothing wrong. However, a small number of students believed that what most upset Felita was how she herself reacted to the neighborhood kids, and how they in turn judged what *they* had done as a function of her reaction. One student, Juanita, wrote, "Felita means when she says, '[it] is as if they were right because I just walked away you know.' She means that they had the reason . . . to beat her up because she walked away and didn't say anything while she was leaving." Although Juanita's sentence is grammatically confusing at first, she catches something most of the other children missed: Juanita realizes that Felita thinks that, because she walked away, she implicitly validated her attackers' view of their discriminatory behavior. The girls believe "they had the right" to act the way they did.

Developmentally speaking, Juanita's comprehension represented to us a deeper level of social awareness as well as a deeper level of reading comprehension, and we believe it is a level that we should strive to promote in all students as they move across the elementary grades. When we talk to educators about this analysis of how students interpret *Felita*, many initially agree with us. However, as soon as we recommend using findings like these to create developmental social awareness benchmarks, patterned after literacy benchmarks, the resolve of these educators quickly evaporates. They say, "Whoa, you can't do that." Why not?

Educators usually object for one of two reasons. One group tends to believe this type of assessment might *underestimate* the student's social awareness, or worse, that it will not recognize that there are alternative, and equally sophisticated, ways to express deeper social awareness. They are concerned that a developmental approach will incorrectly label the level of the student's expressed awareness as some fixed ability of the child. In other words, they mistakenly confuse, and hence fear,

the organization of responses to classify the emergence of social awareness as a kind of *absolute* diagnosis of fixed abilities.

On the other hand, other educators have argued that even an accurate assessment of students' social awareness will not tell us how children will act when faced with similar situations. These educators want a clear path of action—a right choice—that students will know needs to be taken. They are concerned especially with giving credit to the student who develops the capacity to express an understanding of the social situation but may not ultimately "do the right thing." In other words, our approach may not emphasize absolute virtues and values. This group mistakenly confuses the ability for *reflection* with an inability to *see* the right course of action.

Frankly, we are not saying that a single method or measure can fully assess the social competencies of any particular student. Nor should we expect to predict how students will themselves behave based on what they say a character should do. The method we used in the *Felita* example accepts the limits of words to express thoughts, and subsequently, of thoughts to predict actions, and we need to acknowledge that the analysis of our observations captures only the depth of awareness that a particular student (or group of students) expresses at a particular time in that single assignment. It does not generalize to students' social development overall. Despite these limitations, however, we believe it is possible to use this approach to develop a method of measuring social and ethical awareness. The *Felita* example demonstrates why such an assessment is essential if we continue to integrate the promotion of social and ethical awareness in elementary school language arts programs.

For instance, reconsider Juanita's interpretation of Felita's comments alongside the other students' interpretations. It is very likely that Felita actually *did not* want to be seen as chicken and *did* want to be friends with the kids in the new neighborhood. However, the other students expressed less depth of awareness about why Felita later struggled with her decision to walk away and why she said to her grandmother, "It was as if they were right." Unlike the other students in her class, Juanita is aware that Felita was less concerned about looking like a chicken or losing friends and more concerned about the interpretation her antagonists would make of her not challenging the girls' opinions of Spanish people.

Accountability and Assessment

We believe the development of research-based standards for measuring students' level of social awareness will enable teachers at all grade levels to better determine how well students have acquired a deeper understanding of social and ethical issues. But the research on assessment will need to move quickly to catch up with policy. For example, as part of a network in the state of Illinois, a consortium on risk and prevention recently helped to define a set of social and emotional learning standards for students in grades K to 12 (Illinois State Board of Education, 2004). The standards focus on three goals for each of five "benchmark" levels: early elementary (grades K to 3), late elementary (grades 4 to 5), middle/junior high (grades 6 to 8), early high school (grades 9 to 10), and late high school (grades 11 to 12). The three broad social and emotional goals are to (1) develop self-awareness and self-management skills for school and life success, (2) use social awareness and interpersonal skills to establish and maintain positive relationships, and (3) demonstrate decision-making skills and responsible behaviors in personal, school, and community contexts.

However, standards are meaningless unless we come up with ways of effectively measuring whether students attained them. This is where we feel practice-based research can make a contribution. If teachers or schools were able to use carefully selected children's literature that reiterated themes from personal identity to social responsibility, they would be able to analyze students' responses to key questions to study how social awareness grows in each student over time.

In addition, if teachers had an empirically validated map that located students' responses to meaning-oriented questions about social awareness on a developmental continuum, they could determine how well the whole class understands the complexity of social issues via a particular book in the literacy program and be able to assist those students who need additional help in developing and understanding their own social awareness. The teachers we have worked with have been fascinated by the prospect of interpreting their students' writing beyond a straight literacy analysis. They well understand that promoting social awareness requires students to understand the meaning these characters make of social events in their lives. They know that students cannot—or will not—always say what they mean, but that practice sharing their thoughts about difficult social is-

sues through writing and discussion is an essential step toward making that connection. Frameworks that organize their students' responses would be very helpful to this practice.

Teachers also know that fostering students' mature social conduct, either in the moment of a critical incident or in relationships over time, is not something that happens as a simple and direct effect of promoting their capacity for social awareness. Both social awareness and social actions fluctuate, and they continue to change depending on conditions in the social atmosphere. But systematic analysis of children's writings on these matters provides one necessary scale for assessing those changes and fluctuations, even if it should not be used as the only indicator.

When students write about what Felita means, the material can be used in multiple ways: as worksheets for teachers to use to evaluate their literacy and social awareness skills, by teachers to assess the classroom culture with respect to intergroup conflict and its resolution, by the district for outcome or program evaluation, and by researchers as data to study basic questions such as the connection or disconnection between social awareness and social conduct or between language and thought. In addition it can be used, in conjunction with teachers and practitioners, to help come to agreement on the topic of what is social development. Practitioners can and should use our research (or at least our research methods) as a basis for coming up with their own knowledge and standards of social developmental growth.

All these initiatives, taken together, constitute what we mean by practice-based research. We did not have to retreat upstream to the usual laboratory location of the basic researcher to create knowledge. Instead, we tried to commit to doing the type of rigorous scientific theory building and research that is necessary to understand children's social competencies while also being sensitive to the needs of the teachers and the complexities of the Gilmore School. Of course, this process is far from easy. It is difficult to relinquish control of our standards of what is developmentally mature or best for the Gilmore School and allow practitioners to engage with us in a dialogue about what is appropriate for their classroom, their school, and their students. But if we had not been willing to listen to what the children told us in their own natural context, and work with Angela Burgos and the other practitioners in the Gilmore School, we would not have been able to gain the inspiration we

needed into our own work to move it to the next level of its own development.

Developing Our Knowledge Base: Triangulating Research with Practice

The need to link research to practice is a rhetorical mantra in the field of child psychology that has been repeated often enough to lose much of its meaning. Of course we must link research to practice, we say. We make our regular obeisance to this truth, then go back to doing whatever research (or practice) we were doing before. It may be that the phrase “linking research to practice” is too common and hackneyed to be rescued at this point. Instead, we will argue that there are at least three ways that one could be working at the intersection of research and practice, three possible conversations between researchers and practitioners that could and should take place. They are represented in Figure 10.6, the research-practice triangle.⁶

In this triangle, researchers live at points A (applied) and B (basic), and practitioners live at P (practice). Clearly, however, there is movement along the sides of the triangle from one point to the next. An easy path to understand is between B and A—between the basic researcher doing work in a discipline (e.g., ways to assess and test hypotheses about the social development of children) and the applied researcher. Those who travel along this route apply theory and research to practical matters (e.g., the interpersonal competence of children at risk for depression) or work with applied researchers to design and evaluate interventions. We call this type of work *practice-oriented research*.

A second, fairly easy path to understand is between A and P—the path of the applied researchers who bring their work into the day-to-day life of practice, such as schools, teachers, and hospitals. Often, the type of researcher who bridges this gap lives in two camps, with a primary home in the applied research world and a second home in the practice world. We call this *practice-driven research*; it is akin to our first case, where the Gilmore School was in distress and needed a research-based prevention program. This type of work may also

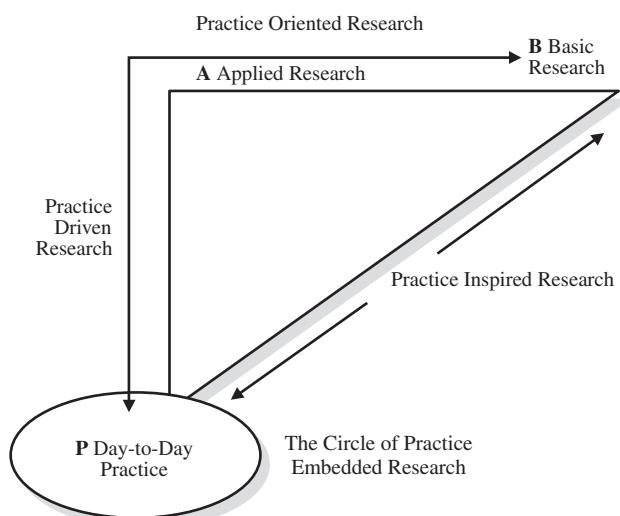

Figure 10.6 The practice-based research triangle.

be called evidence-based practice, when the emphasis is on the P to A direction, for example Second Step’s need for evaluation. It is also represented in part by our second case study, when we entered Angela Burgos’s classroom with an intervention program and stayed there to do applied research.

The last connection, between P and B, is often the most complicated to grasp and by far the most difficult path to traverse. We think of this link as *practice-inspired research*. It is the partnership that is possible when the basic researcher meaningfully integrates the ideas and concerns of practice and reconceptualizes his or her own research (and theory) based on this new knowledge. In Angela Burgos’s classroom, for example, when we realized that our preexisting theory did not account for the complexity of children’s thoughts about social issues and certainly did not take into consideration their cognitive language and literacy skills, we returned to the drawing board. We are currently engaged in the process of doing new pilot work that seeks to integrate the knowledge contributed by practitioners, language and literacy researchers, and our own field of social development in an effort to better understand how children make meaning of stories about social justice.

We have taken the risk of introducing these terms—practice-oriented, practice-driven, and practice-inspired research—to replace the old adage “Link theory and research with practice.” It is the connections between the points of the triangle in Figure 10.6 that are important. The three research-practice paths have allowed us to think in alternative ways about our own work and the

⁶We would like to thank our colleague Catherine Snow for participating in the creation of this triangle and helping us to articulate the practice-research issues we describe in this chapter.

gaps that exist among applied research, basic research, and practice. It is not simply the task of the applied researcher to connect basic research and practice—we must find ways as a field to integrate the knowledge each brings to the domain (in our case, social development) to move forward in developing our knowledge base. Finally, we need to decide as a field how we wish to influence public policy, to create a road map for social change, and to develop the political will necessary to make that change happen.

The circle surrounding the P (practice) in Figure 10.6 also points to the merit of introducing one last term and making the case for its importance. We call this circle the zone of *practice-embedded research*. Practice-embedded research can be either applied or basic, but its fundamental feature is that it is research, as exemplified by our second case of Angela Burgos's classroom, which is located directly in the heart of the practice. Keeping in mind that in our case the social development of the child is nested in context, the social atmosphere of the classroom and school, the triangulation in Figure 10.6 of practice (P), applied research (A), and basic research (B) helped us to see that the zone of practice-embedded research is less well populated by researchers than we would like and yet probably is the area that needs to be the most integrated by researchers if child development practitioners (educators, clinicians, youth workers) are to embrace the evidence-based approaches researchers have convinced policymakers are so important.

Figure 10.6 also clarifies two matters that are obscured in the IOM model and not detailed in the Richmond model. First, although less often traversed, in this triangle there is a direct route between basic research and practice, although the waters around P are not ideal for basic researchers who seek calm and control to do their research. Second, if there was more two-way traffic along this path, it might reduce the amount of time it takes to make the translations that usually follow a path from B to A to P.

In applied research, practice is often the locale where good formative evaluation is conducted in the shifting tide between efficacy and effectiveness trials. We argue that it is also an area well suited to descriptive basic research work, for example, in social development, on what theories children at different ages and from different backgrounds have about racism and prejudice, or what they think the causes and consequences of these social phenomena are, as expressed in the natural and authentic context of the classroom. Although practice-

embedded basic research may be a slower process, and it may take longer to publish in conventional research peer-review journals, we believe there is much to be said for basic researchers spending more time embedded in the circle of practice.

CONCLUSION

This chapter used a case study approach to discuss the connections among research and practice, risk and prevention, and social and academic (specifically literacy) development. We have used two complementary cases. One focused on the story of a school at risk and how it reached out to preventive interventions offered by a group of program developers who were informed by innovative applied developmental research. The other case focused on a team of academics and how we found in the Gilmore School not only a place to do applied research but also an inspiration for our own basic research and theory building.

We also presented two intervention/prevention models for the future of the discipline of psychology, specifically social development as it connects to the field of risk and prevention. The first model, the IOM paradigm, is a linear model, or in our metaphor, a downstream-upstream model, in which discipline knowledge flows down along a river from a mountain reservoir and either settles in among the practice or takes the problems and ideas inherent in the practice and returns upstream to do applied research (such as program design or implementation) or more basic research.

In contrast, the Richmond model is a partnership or integrative model. It describes an approach that encourages a commute and conversation across three domains: the knowledge base, the social strategy, and the political will. In Richmond's model, the social strategy component is not synonymous with practice; it represents neither the practice nor the applied research that will achieve desired outcomes. Instead, it represents the wider social processes that need to take place in order for the knowledge base to have an effect in conjunction with political will on policy: the “scaling up” that is necessary to achieve societal and systematic change. Similarly, political will is not specific policies that effect change but rather the momentum that needs to gather within and behind substantive knowledge and research about a problem (i.e., poverty, health care, violence) to make a lasting change in society.

We argue that the latter model is more effective than the former for influencing policy, but also that we need a triangulation of conversation within our own knowledge base between the points of applied and basic research and practice. For one thing, the power and effect of research within a knowledge base on social and societal problems is often much weaker than the researcher in the thick of the research might suspect. It is unlikely, in any field, that any one empirical study in a journal article will have a major impact. As a result, basic researchers must have faith, in Niebuhr's sense of the term: a genuine desire to continue to grow the knowledge base within a particular discipline despite the realization that any individual contribution most likely will be modest, even if and when it attracts temporary attention. We continue to have faith, however, that over time the evidence will build up.

As researchers, both applied and basic, we also continue to hope: to persist within a discipline where progress is measured not in even increments but rather fits and starts. Enduring progressive social policies are rarely implemented in the lifetime of one professional generation; instead, it takes a continuous stream of individuals, each having hope as well as faith that his or her contribution will be beneficial. Even if, as Niebuhr says, "nothing worth doing can be done in one lifetime," the process of engagement with others toward a common cause is mutually transformative, inherently developmental, and worth doing.

Finally, both researchers and practitioners need love: the continued formation and development of ongoing partnerships that work together to promote both applied and basic research and effect change. If nothing else, in the years of doing applied research we have learned that one group can't do it alone. Researchers need practice in the same way that practitioners need research. Ultimately, applied and basic researchers as well as practitioners belong to the same camp in the Richmond model: We all contribute to the knowledge base of our domain, whether by conducting experimental research in laboratories, working with teachers in schools, or providing direct service to children.

We can envision a time when the story of the two cases we presented in this chapter might someday come together—when the basic research on social awareness we do in the Gilmore might actually help the school with its day-to-day problems. But, at this moment in time, we want to use the images these two cases project as a background to end this chapter with some tough questions

our analysis of these cases raised. There are three themes that speak to professional roles for the future. The first illuminates the gap between practice and applied research, the second demonstrates the disconnection between applied and basic research, and the third exemplifies the gaps between basic research back to practice (the biggest gap to bridge).

Although the connection between applied research and practice might in theory be the easiest to traverse, it has its own set of problems. As we pondered the dilemma of the Gilmore School and the prevention and intervention programs designed to ameliorate the school's problems, we questioned how we would go about bridging the gap between practice and applied research in developmental psychology. For instance, do you have to be a practitioner first to develop effective intervention programs?⁷ Are the gaps between the two groups more easily bridged by those who have worked in both domains? We believe the answer to this question is no, but more applied developmentalists need to find work commuting between applied research and practice in the same practice context.

There is a precedent for this model in academic medicine. Teaching hospitals are settings for both research and practice. Clinical investigators do research on the problems faced by individuals and also direct the practices that provide services for them. But hospitals (and federal agencies such as the National Institutes of Health) have to offer strong incentives to practitioners to pull them away from practice to clinical research. In our first case of the Gilmore School, if it had been an affiliate of a school of education, then the principal, Mr. Martinez, could have had research objectives as well as practitioner duties. Although this may not be realistic across all elementary schools, perhaps it is not so unrealistic to have a few such principals and schools in place. Advanced training in (applied) developmental psychology would be one good kind of training experience for a clinical investigator (or a school practitioner). Experience in practice would help the applied researcher foresee problems of implementation; experience in research

⁷For an accessible story of one psychosocial investigator in the field of prevention, in this case child and adolescent depression, who began in practice as a child psychiatrist, learned risk research in order to study epidemiological risk factors, designed a pilot intervention, conducted a random assignment efficacy study, and moved toward the challenge of effectiveness studies, see Beardslee (2002).

would help the practitioner do a better job of understanding issues of accountability and evaluation.

There are also tensions affiliated with the connection between basic and applied research. In Richmond's model, the knowledge base includes both basic research about the health problem and understanding of the influences of contextual factors and the effectiveness of different preventive measures. Too often, however, when we think of the knowledge base of a domain, we tend to consider only the scientific, cognitive, or biological issues that need to be fully explained before we can begin to think about the surrounding context and/or systems of prevention that will help ameliorate the problem. As represented by the IOM model, for instance, the flow of knowledge seems to indicate that the applied researcher should first learn from the basic researcher, then apply research to practice, and then immediately evaluate it, not necessarily swim back upstream to the area of basic research.

Applied researchers can be frustrated by basic researchers who seem disconnected from real-life needs and concerns; correspondingly, basic researchers may not be concerned with the applications of their work and/or may be unwilling to consider doing research that is too messy or contaminated by practice and applied settings to test fundamental hypotheses. Our questions to bridge this gap are therefore these: How does one keep doing both basic and applied research at the same time, and even in the same place? What kind of value has to be given to applied research in the area of basic research, and what type of basic research, albeit messy and sometimes not very experimental, can and should be published, simply because it contributes novel ideas taken from applications? What kind of bridges can we build across institutions and departments (e.g., from a school of education to the department of psychology or to the interdisciplinary field of human development) to create places where conversations about similar topics are encouraged?

Finally, we are left with the gap between practice and basic research. Too often, practitioners fail to recognize or value the contribution of research that is at first glance far removed from the day-to-day issues they face. For example, they may overvalue the insights provided by their peers and underestimate the knowledge provided by research. Or they are so focused in the moment, on the daily needs of their students, children, or clients, that they are not willing or able to step back to look across a field of research to find out where they should go or what

they should do next. Similarly, basic researchers may be so concerned with the perhaps minute process of conducting their own research that they cannot distance themselves enough to recognize the valuable contributions practitioners can make to their work. Alternatively, they may follow a research agenda of their own, instead of being reconnected to what is actually needed by the field.

Of course, sometimes the nearsightedness of both practitioners and basic researchers is exactly what the field requires. We need basic researchers to follow seemingly incomprehensible trains of thought because often this creativity (or simple doggedness) can lead to the next big breakthrough. We also need practitioners to be responsible for the daily needs of our society, not lost in some abstract world of their own. But without some kind of dialogue, or at least recognition of the value of each to the other, our field (on a macro level) will never fully traverse the practice-research triangle. As in the Richmond model, the discipline needs to constantly move among the three points to make progress in expanding our knowledge base. With this type of knowledge development, we will move confidently forward into the realms of social strategy and political will to affect the type of change that will move the fields of risk, prevention, and social development into the future and create sustainable, well-considered policy changes.

This chapter provides an overview of the various disciplines that have contributed to the conceptualization, diagnosis, and treatment of learning disabilities, with a focus on the field of developmental psychology and representative contributions of this discipline, including a life-span approach. Developmental changes in expression of learning disabilities are illustrated with cases.

The contributions of linguistics and psycholinguistics are also emphasized. The unresolved issues related to defining learning disabilities for purposes of practice

Grants R01 HD25858 and P50 33812 from the National Institute of Child Health and Human Development (NICHD) supported the preparation of this chapter and much of the research reported in it.

and of research are highlighted. Recent approaches to differential diagnosis of specific learning disabilities are discussed, and research on effective prevention and treatment of learning disabilities is reviewed. The chapter ends with current challenges for the field of learning disabilities with respect to research and practice. The unresolved controversies are related to definition and effective service delivery in schools.

I am not being facetious when I characterize my line of research as studying a phenomenon—dyslexia—that schools do not believe exists and that the experts cannot define. Despite these challenges, progress is being made on the research front across the world, but many obstacles remain in translating this scientific knowledge into educational practice, for which cases in this chapter serve as reminders.

LIFE-SPAN APPROACH

Biologically based learning problems may respond to treatment but persist over development in changing forms of behavioral expression. What is initially a problem in *phonological awareness*, *phonological working memory*, and/or *accurate phonological decoding* (e.g., Liberman, Shankweiler, & Liberman, 1989; Snowling, 1980; Stanovich, 1986; Vellutino & Scanlon, 1987; Wagner, Torgesen, & Rashotte, 1994) may resolve or persist but is likely to become a problem in *automatic word recognition* and/or *reading fluency for text* (Biemiller, 1977–1978; Blachman, 1997; Breznitz, 1987; Kuhn & Stahl, 2003; Levy, Abello, & Lysynchuk, 1997; Perfetti, 1985; Wolf, 2001; Young, Bowers, & Mackinnon, 1996) and *spelling and written expression* (Berninger, Abbott, Thomson, & Raskind, 2001). Despite early intervention, some reading and writing problems persist (Bruck, 1992, 1993; McCray, Vaughn, & Neal, 2001; Pennington, Van Orden, Smith, Green, & Haith, 1990; Shaywitz, Shaywitz, Fletcher, & Escobar, 1990; Singleton, 1999) across development.

Case Illustrating Behavioral Expression in Early Childhood

Susan's dyslexia was first evident to her teachers at the end of second grade. A bright girl with superior oral vocabulary and background knowledge, she once told her second-grade teacher that she thought the other children were missing the nuances in the stories they read and

talked about. It was only when the research team asked her to pronounce real words on a list outside story context or pseudowords that can only be decoded based on letter-sound knowledge that the nature of her reading problem was apparent: Her reading was overly dependent on guessing at words in context and on memorizing a few words without understanding how to decode unfamiliar words. These are the hallmark signs of dyslexia early in schooling. Because her school did not recognize these hallmark signs in first grade and provide appropriate instruction, Susan's written language learning came to a standstill in third grade.

Case Illustrating Behavioral Expression in Middle Childhood

Sean had the same problems as Susan in the primary grades but received special education that emphasized phonics and oral reading. He learned to read, but his oral reading was not fluent and his silent reading was slow. In addition, his written work was peppered with misspellings that reflected omissions of sounds, additions of sounds, transposition of sounds, and plausible spellings (but not for the specific word used). He often did not complete written assignments satisfactorily. However, because he could read silently with reasonable comprehension, the school dismissed him from special education services. The school did not understand that the hallmark features of dyslexia during middle childhood are persisting reading rate, spelling, and written expression problems in students who have learned to decode sufficiently well to read silently with adequate comprehension. Without additional explicit instruction in these skills, Sean floundered in the regular program.

Case Illustrating Behavioral Expression in Early Adolescence

Sam, who is in eighth grade, has the hallmark signs of dyslexia in adolescence: impaired executive functions for self-regulation of reading, writing, learning from lectures, and completion of long-term assignments. Many schools provide explicit instruction for dyslexics when they are in the early grades, but not in middle school and high school, when they would benefit from systematic, explicit language arts instruction that prepares them for the reading and writing requirements across the curriculum, study skills, note taking, and

test taking. Sam, like many other adolescents with dyslexia, does not receive any explicit instruction related to his learning disability but does receive pull-out services to help him with his assignments in the regular program. However, the school wants to dismiss him from all pull-out services for special help because he passed the state's high-stakes writing test. Both Sam and his parents wanted him to continue to receive special education because he is barely passing most of his written assignments in the regular program. However, according to his school, his learning disability does not have an adverse impact on his performance in the regular program because he receives Ds and that is satisfactory progress. Moreover, because he asks too many questions and does not always raise his hand when answering questions, the school recommended that he be placed in a program for students with behavioral disabilities. They do not think that Sam's verbal IQ in the very superior range, his history of Attention-Deficit/Hyperactivity Disorder (ADHD), or test results using research-supported measures and diagnostic procedures showing that he has dyslexia and dysgraphia are reasons to reconsider dismissing him from special education. His parents are advised by special education officials that if they do not agree, they should hire a lawyer and go to a court hearing.

Sam's own story about his learning problems at different stages of his schooling is reproduced in Figure 11.1. Readers are encouraged to read this story before reading the rest of this chapter in order to understand what it is like to have dyslexia from the perspective of an affected individual during the school years.

Case Illustrating Behavioral Expression in Young Adult Years

Sharon was the first in her family to complete a college education, which she paid for by working many jobs. She did reasonably well but had an enormous struggle learning foreign languages, which has been well documented by researchers (e.g., Ganschow & Sparks, 2000) as the hallmark feature of dyslexia during the college years. Her university graduation was held up because she could not meet the foreign language requirement. She tried three times, twice with one language and once with another language (and even spent a year living in that country to learn the language). She was told by her department that there was no point in being evaluated by the disabled student services on

campus because disabilities affect physical skills like walking and using one's hands. She had had a history of reading rate and spelling problems, but the public school she attended refused to evaluate her because she was so bright. Our research team evaluated her in her early adult years (3 years after she should have graduated) and documented that she met research-supported criteria for severe dyslexia. Based on the test results, we obtained permission for her to substitute an alternative course for the foreign language requirement. By the time this volume is published, she should have her undergraduate degree.

At the end of this chapter, these cases are discussed again from the perspective of how their literacy development might have been different had appropriate educational programs been in place. Appropriate educational programs include both diagnostic assessment and differentiated instruction.

SIGNIFICANCE OF LEARNING DISABILITIES FOR CHILD PSYCHOLOGY

Five domains of development have proved reliable and valid in understanding and assessing child development: cognitive and memory, aural receptive and oral expressive, gross and fine motor, attention and executive function for self-regulation, and social-emotional (Berninger, 2001). Children with mental retardation (global developmental disability) fall outside the normal range in each of these domains of development. Children with Pervasive Developmental Disorders (including Autism Spectrum Disorder) fall outside the normal range in two or more of these developmental domains. Some children have primary impairment in one developmental domain (e.g., primary language disorder). Children with mental retardation, Pervasive Developmental Disorder, or primary language disorder will have some difficulty with learning academic subjects and are unlikely to achieve at the population mean. However, there are other children who are generally within the normal range in most areas of development, but who have a specific kind of learning problem, a learning disability. If unidentified and untreated, learning disabilities can significantly impair a child's overall cognitive and social developmental functioning.

One in five children has some kind of learning disability. The most frequently occurring developmental

I'm forty years old and in the eighth grade, I have dyslexia and dysgraphia. I am going to tell you about what it is like, up until kindergarten I was fine, I was running around just like everybody else my age. Then in first grade that changed. Every body else was learning to read and write, I could write letters but not put them in to words or read what everybody else could. I felt really stupid and everybody else called me stupid kid. After a month of not being able to read and write the school put me in a special class with four other kids to try to figure out how to read and write.

In forth grade I continued to be in the group because I still couldn't read or write very well. I felt stupid even though I was better at math and science than everyone else. No body else was as bad as I was in every subject. I couldn't figure out why I just couldn't do it. It would take me twenty to thirty minutes to read a single paragraph and I couldn't figure out why. In the same amount of time somebody else could read five pages. Nobody could read what I had written not even my self.

That summer I was diagnosed with dyslexia and dysgraphia at the University of Washington. I was able to go to the summer program for dyslexics and it made reading a bit better and easier. Fifth grade was easier because I knew I was smart and my teacher helped me with computers and let me do video reports instead of a paper.

The next summer I went over to the university. It helped me with spelling. That helped me with the next year so that language arts was ok when it came to papers. Seventh grade was good I enjoyed all my classes because there was a lot of short stories.

~~University~~

The University therapy made me feel that the dyslexia and dysgraphia was being erased away. In fifth and sixth a teacher worked with me to cover it up and my mother continues to work with me on that. The school in seventh and eighth grade didn't help at all. Currently the school has considered my IEP and my reaction to that was that I didn't want to be stupid again. I'd like to read, write and spell fine but I can't.

Figure 11.1 "My Story," told by eighth-grader with dyslexia, dysgraphia, and ADHD (Inattentive subtype).

disorder of childhood is specific learning disability in children whose development is otherwise in the normal range. Sometimes a child's problem may be specific to one academic domain (reading, writing, or math). Sometimes a child's learning problem is in aural/oral language, nonverbal reasoning, or social cognition, which affects school functioning even though none of these is a subject in the school curriculum. Sometimes a child has disabilities in more than one domain. The focus of this chapter is on learning disabilities that affect written language. Learning disabilities that are specific to reading and/or writing are among the most frequently occurring learning disabilities in school-age children and youth and have received the most research attention. Dyslexia, which was used to illustrate the

changing developmental expression of a learning disability across schooling, is only one kind of learning disability.

MULTIDISCIPLINARY STREAMS OF KNOWLEDGE ABOUT LEARNING DISABILITIES

Federal special education law in the United States specifies that multiple disciplines should be involved in the assessment and educational planning of students with learning disabilities. Some other countries (e.g., Canada and England) have comparable laws for identifying and educating children with learning disabilities. Multiple

disciplines have also contributed to both research and clinical practice in the field of learning disabilities. These include neurology, experimental cognitive psychology, special education, linguistics, psycholinguistics, speech and child language, clinical and school psychology, and developmental psychology.

Neurology

Neurologists were the first to identify the extreme difficulty some otherwise normal children have in learning to read. One of the most informative introductions to the pioneering contributions of neurologists at the end of the nineteenth and beginning of the twentieth century is “The Historical Roots of Dyslexia” (Shaywitz, 2003, chap. 2). Neurology continued throughout the twentieth century to contribute, primarily through clinical studies (e.g., Orton, 1937). Now in the twenty-first century, this field continues to contribute through the use of *in vivo* brain imaging (scanning the brains of living children and adults as they perform cognitive and language tasks; for review, see Berninger & Richards, 2002).

Experimental Cognitive Psychology

Beginning early in the twentieth century, psychology contributed to the available literature by developing scientifically defendable paradigms for investigating mental processes involved in reading (e.g., Huey, 1908/1968). By the middle of the twentieth century, the psychology of reading had generated a wealth of knowledge about teaching children to read (e.g., Bond & Tinker, 1967; Gates, 1947; Gray, 1956; Harris, 1961), and this knowledge was transmitted in many (but not all) teacher training programs. Many schools had reading specialists who were well trained in reading (often with 60 to 90 graduate credits) and who were available for assessment, consultation, and small group instruction in local buildings. Decisions about who to test and teach and about how to work with teachers was left to specially trained professionals who were allowed to function in a flexible manner without burdensome regulations and paperwork. Unfortunately, not all schools had access to such professionals. Parents often had to turn to services outside the public school if their child had a specific learning disability in reading or writing.

Special Education

By the early 1960s, a national political movement led by parents was gaining momentum. Parents wanted to understand why schools could not teach children who had normal intelligence to read and write. This movement led to a parent-organized, landmark conference in 1963 in Chicago where Samuel Kirk (Kirk & Kirk, 1971) first proposed the label “learning disabilities.” Following that conference, parents of children with learning disabilities partnered with parents of children with mental retardation to mount a national effort in the United States that culminated in the 1975 federal legislation, Public Law 94-142, that guarantees a free and appropriate education for all students with educationally handicapping conditions. Because professionals could not agree about how to define what a learning disability is (inclusionary criteria), the federal law defined it on the basis of what it is not (exclusionary criteria: It is not due to mental retardation, sensory acuity or motor impairment, lack of opportunity to learn, or cultural difference).

To support this new field of special education, the U.S. Department of Education provided funding for training programs for special educators, model demonstration projects, and research on teaching special populations of students with educationally handicapping conditions. (See Torgesen, 2004, for the history of the field of special education; see Johnson & Myklebust, 1967, and Kirk & Kirk, 1971, for a description of early conceptualization and practices in special education.) However, because “appropriate” was not defined on the basis of developmental and educational science, this legislation has often resulted in costly legal proceedings and adversarial relationships between parents and schools, without resulting in better academic achievement of students with learning disabilities. In fact, meta-analyses indicate that special education for students with learning disabilities has not been effective (e.g., Bradley, Danielson, & Hallahan, 2002; Steubing et al., 2002), especially in reading (Vaughn, Moody, & Schumm, 1998).

One reason for the relative ineffectiveness of special education is that special education teachers are not given much preservice training in the psychology of teaching reading; they also are not taught instructional practices that cover all reading and writing skills in the general education curriculum in a grade-appropriate manner from K to 12. Currently, many preservice teacher training programs advocate philosophical approaches (e.g.,

constructivism, which advises against explicit instruction) that are not consistent with what research in developmental science and educational science during the past 3 decades has shown is effective in teaching students with specific learning disabilities—namely, explicit instruction to bring language processes into conscious awareness. (See Berninger & Winn, in press; and Mayer, 2004, for shortcomings of constructivism in contemporary educational practices.) There is a myth that explicit instruction is skill and drill, but that is not the case (see Berninger, Nagy, et al., 2003, for examples of explicit instruction for developing linguistic awareness in reflective ways that are intellectually engaging).

Moreover, paraprofessionals, most of whom do not have specialized training in teaching reading or as much professional preparation as general educators, are increasingly providing instruction for students with learning disabilities. Many schools hire reading specialists trained outside professional preparation programs and in primarily a single method. There is unlikely to be a single program that meets the needs of all students. Children with specific reading and writing disabilities are more likely to learn to read and write if taught by professionals who are skilled in differentiated instruction; that is, they can construct programs that address all the necessary reading and writing skills at a specific stage of reading or writing development and individualize, if necessary, for specific students in group learning settings (Berninger, 1998).

In short, there are a number of unresolved problems in identification and service delivery for students with specific learning disabilities. It may not be possible to achieve the desired goals by simply legislating them; these goals probably require educating the educators as well as teaching the affected individuals (Berninger, Dunn, Lin, & Shimada, 2004; Berninger & Richards, 2002).

Developmental Psychology

In contrast to special education, which is an applied discipline, developmental psychology is a scientific discipline that contributes relevant basic knowledge to understanding learning disabilities. These contributions, which are discussed later in the chapter, include understanding rule-learning deficits; multiple levels of language; automaticity, fluency, efficiency, and timing deficits; comorbidities, normal variation, gender differences; nature-nurture interactions; life-span approaches;

prevention and treatment validity; and randomized, controlled longitudinal experiments. Many of these contributions draw on earlier and concurrent contributions from linguistics and psycholinguistics.

Linguistics and Psycholinguistics

Linguistics specifies how speech is represented in English orthography in a rule-governed (not purely arbitrary) way and documents the morphophonemic nature of English (e.g., Venezky, 1970, 1999). Although spelling units (typically one or two letters in length) generally represent speech sounds, called phonemes, in a predictable manner (alternations or a set of rule-governed options such as the /k/ and /s/ sound associated with the letter *c*), not all spellings are perfectly predictable. Much of the predictability of American spelling relies on the morphology as well as the phonology of the language; for example, *signal* preserves the spelling of the stem *sign*. It has also been well established that knowledge of alphabetic principle (one- and two-letter spellings that represent the phonemes) can explain the acquisition of one- and two-syllable words of Anglo-Saxon origin that occur with high frequency in reading materials in the lower elementary grades (for reviews, see Balmuth, 1992; Ehri, Nunes, Stahl, & Willows, 2001; Rayner, Foorman, Perfetti, Pesetsky, & Seidenberg, 2001).

However, knowledge of morphology is critical to the acquisition of the *longer, more complex written words* that occur with high frequency in reading materials from mid-elementary school through high school and college (Carlisle, 2004; Carlisle & Stone, 2004; Carlisle, Stone, & Katz, 2001; Nagy, Anderson, Schommer, Scott, & Stallman, 1989; Nagy, Osborn, Winsor, & O'Flahavan, 1994). From fourth grade on, students encounter in their school texts an increasing number of complex words in terms of sound-letter relations and internal structure (i.e., syllabic or morphemic structure; Carlisle, 2000; Carlisle & Fleming, 2003; Nagy & Anderson, 1984). Students who earlier struggled with mastering alphabetic principle because of difficulties in phonological processing (Liberman et al., 1989) face additional challenges in learning to recognize specific words automatically: (a) creating and linking precise phonological and orthographic representations (Ehri, 1992; Perfetti, 1992), and (b) encountering low-frequency written words frequently enough (White,

Power, & White, 1989). Students who were earlier taught phonics and may have learned letter-sound correspondences in alphabetic principle, word family patterns (e.g., -at in pat, bat), and syllable types (e.g., open and closed, vowel teams, silent e, r-controlled, and -le) may need additional strategies to deal with the complexity of English orthography (Schagal, 1992), especially in content area texts, which may have spellings unique to word origin (Anglo-Saxon, Latinate, or Greek), complex word structures, and unfamiliar, low-frequency words.

Another contribution of linguistics was demonstrating that most language knowledge is implicit (unconscious), but learning to read requires explicit instruction that brings this implicit knowledge to conscious awareness (Mattingly, 1972). Programs of explicit instruction in word decoding that draw on alphabetic principle and morphological structure have been developed by Henry (1988, 1989, 1990, 1993, 2003) and Lovett and colleagues (e.g., Lovett et al., 1994, 2000). Both programs require children to manipulate units of phonology, orthography, and morphology (see Figure 11.2). Both programs combine explicit instruction and strategy instruction and practice, which a meta-analysis showed

was the most effective approach for improving reading skill (Swanson, 1999).

Henry's (1990, 2003) program focuses on reading and spelling words from different etymological backgrounds: words of Anglo-Saxon, Romance, and Greek origins. For each word origin, students are taught linguistic units in written words (i.e., letter-sound correspondences, syllable types, morphemes). Before receiving such instruction, third, fourth, and fifth graders had letter-sound knowledge but little knowledge of syllable or morpheme patterns; the third and fifth graders who received the morphophonemic training linked to word origin improved significantly more in reading and spelling than those who received only basic phonics (Henry, 1988, 1989, 1993). Lovett (e.g., Lovett et al., 1994, 2000) validated methods to improve the word-reading skills of students with reading disabilities: PHAB/DI (direct instruction in sound analysis, blending skills, and letter-sound correspondences), WIST (four word identification strategies: using analogy, seeking the part of the word you know, attempting variable vowel pronunciations, and peeling off affixes), and Combined PHAB/DI and WIST (Phonological and Strategy Training Program [PHAST]). Clinical studies showed positive gains in reading both trained and untrained (transfer) words (Lovett, 2000).

However, the concept of how knowledge of morphological structure in low-frequency words can help students read content area texts from the fourth grade on is less widely understood. Analysis of the number of distinct words in printed school English showed that students encountered more than 88,000 "distinct" words in texts through ninth grade (Nagy & Anderson, 1984). About half the words in printed texts through ninth grade occur once in a billion words of text or less (e.g., *inflate*, *extinguish*, *nettle*), so knowledge of word-formation processes becomes necessary (Nagy & Anderson, 1984). For every word a student learns, there are between one and three related words that should be understandable to the student because of semantic transparency of words—whether the meaning of the base word is apparent in a longer word that contains that base word (e.g., *red* and *redness* have relative semantic transparency, whereas *apply* and *appliance* do not)—that reduces the number of distinct words that need to be learned (Nagy & Anderson, 1984). About 60% of the unfamiliar words encountered by students in the middle school years and beyond are sufficiently semantically transparent that a reader might be able to infer the mean-

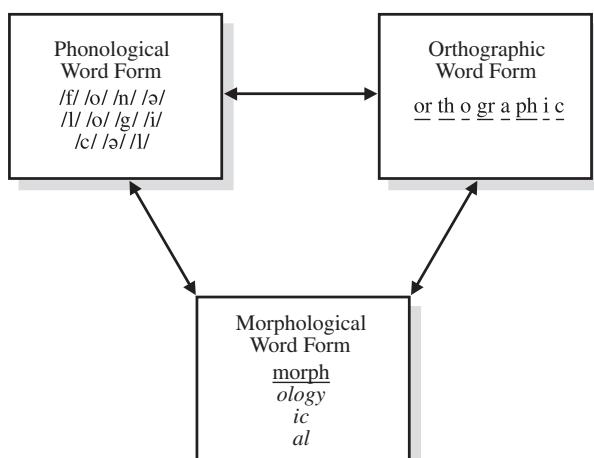

Figure 11.2 Schema of three word forms and their parts that are interrelated in decoding in working memory and creating precise orthographic word forms in long-term memory. *Sources:* From "Processes Underlying Timing and Fluency of Reading: Efficiency, Automaticity, Coordination, and Morphological Awareness" (Extraordinary Brain Series, pp. 383–414) by V. Berninger, R. Abbott, F. Billingsley, and W. Nagy, 2001, in *Dyslexia, Fluency, and the Brain*, M. Wolf (Ed.), Baltimore: York Press; and *Brain Literacy for Educators and Psychologists*, by V. Berninger and T. Richards, 2002, San Diego: Academic Press.

ing of the word from context (Nagy et al., 1989). Thus, students with reading and writing disability also need explicit instruction in the word formation processes and inferring word meaning from context.

Triple Word Form Theory

Studies that integrated treatment and brain imaging provided support for the theory depicted in Figure 11.2. Both unique neural signatures for the three word forms (Richards et al., 2005, 2006) and cross-over effects (Richards, Aylward, Raskind, et al., in press) were observed: Individuals who received *morphological treatment* showed significant changes in *phoneme mapping* during brain scans, whereas individuals who received *phonological treatment* showed significant changes in *morpheme mapping* during brain scans. Richards et al. (2002) showed that morphological awareness training improved efficiency (rate) of phonological decoding and led to greater metabolic efficiency in neural processing during phonological judgment while the brain was scanned than did training in only phonological awareness. In addition, structural equation modeling of subphenotypes in the family genetics study showed that a second-order factor modeled on indicators of each word form factor predicts reading and spelling outcomes better than the first-order factors for each word form (Berninger, Abbott, Thomson, Wijsman, & Raskind, in press). The benefits of Wolf et al.'s (2003) RAVO, an intervention that trains rapid automatic retrieval of spoken names (phonology), vocabulary, and orthography, for the reading disabled may be related to the way it integrates phonological, orthographic, and morphological word forms.

Speech and Language Pathology and Child Language

Linguistics is a basic discipline. A professional specialization for applying basic knowledge of child language is speech and language pathology. All public schools at the beginning of the twenty-first century, in large part because of the federal special education laws, now have access to practitioners with professional training in speech and language pathology. Although they primarily work with children who qualify for services under the category of Communication Disorders, many of whom have more severe problems in receptive aural language, speech, or expressive oral language than those with specific learning disabilities, they are typically the professionals in the schools with the most training in language.

Thus, they are a valuable resource for other educational professionals because children with reading and writing disabilities often have associated aural/oral language processing deficits. Developmental studies by speech and language specialists have shown that speech and language problems during the preschool years are associated with a variety of developmental outcomes during the school-age years, including (a) mental retardation, (b) specific aural/oral language impairment, (c) specific reading disabilities, (d) specific writing disabilities, and (e) normal reading function (e.g., Aram, Ekelman, & Nation, 1984; Bishop & Adams, 1990; Catts, Fey, Zhang, & Tomblin, 1999, 2001).

Clinical Psychology and School Psychology

Clinical psychology and school psychology are applied disciplines that have contributed scientific research knowledge about learning disabilities and train the practitioners who serve individuals with specific learning disabilities in the private and public school sectors. They are typically trained in cognitive, academic, social, and emotional assessment that yields relevant information for diagnosing and treating specific learning disabilities. Historically, they have relied on education to translate the assessment results into instructional practice. However, recently, there is growing interest in the treatment validity of linking psychological assessment with research-supported instructional practices (see Berninger, Dunn, & Alper, 2004). Because the federal special education law stipulates that all students with educationally handicapping conditions have the right to evaluation, whether or not they attend public schools, psychologists who work in school settings assess students attending public schools, students referred from private schools, and students who are home-schooled. However, there is a large and growing market for clinical psychologists, especially those with neuropsychological training, because many parents seek independent evaluations outside the public school. This trend is likely to increase because student achievement standards continue to increase in this era of educational accountability and are linked to high school graduation in some states.

Developmental Pediatrics

The child's pediatrician or family physician is the professional who often has the best knowledge of an individual child across development. Levine, who has been a

leader in developmental pediatrics, has (a) increased awareness of the normal variation among learners (Levine, 1993, 1998, 2002), (b) demystified learning problems for affected individuals (Levine, 1990), (c) documented that many learning disabled have developmental output failure (writing problems; Levine, Overklaid, & Meltzer, 1981), and (d) emphasized that students who do not complete written work satisfactorily are more likely to have undiagnosed processing problems than to be lazy (Levine, 2003). Most students want to succeed—if only a caring, competent teacher could teach them in a way they can learn (Berninger & Hidi, in press). Because of my earlier clinical and research experience in the Ambulatory Pediatrics Department at Boston's Children's Hospital, headed by Levine, I began a programmatic line of research on normal variation as a reference point for understanding learning disabilities and focused on writing as well as reading.

CONTRIBUTIONS OF DEVELOPMENTAL PSYCHOLOGY

In this section, we highlight a few of the representative contributions of the discipline of developmental psychology to the field of learning disabilities.

Rule-Learning Deficit and Computational Mechanisms

Manis and Morrison (1985) and Manis et al. (1987) questioned whether the problems of the reading disabled in learning alphabetic principle (correspondences between letters and phonemes) reflects a more general underlying difficulty in inducing and applying rules. To test this hypothesis, Manis et al. paired words with visual symbols (arrows, squares, triangles plus dots or asterisks) so that rules were consistent across some situations but not others (as is the case in language, which tends to have predictable but flexible regularities). Their findings supported their hypothesis and are also consistent with recent brain imaging research showing activation in the fusiform gyrus (a brain region associated with pattern recognition and abstracting rules or regularities and pattern) in normal readers (e.g., Booth et al., 2003; Booth, Perfetti, & MacWhinney, 1999) and dyslexics (e.g., Richards et al., 2005). If the reading disabled have difficulty inducing the rule-governed patterns of regularities and/or flexibly adapting these as

necessary across contexts, then they are likely to benefit from explicit instruction that assists them in abstracting those regularities and applying them strategically.

Connectionist models, which simulate computational processes in the brain during written word learning (e.g., Seidenberg & McClelland, 1989), demonstrated that overt, verbally articulated rules are not necessary to learn to read written words, and that one computational mechanism may underlie regular and irregular word reading. Manis and Seidenberg (e.g., Manis, Seidenberg, Doi, McBride-Chang, & Petersen, 1996), who collaborated in longitudinal studies of how children learn rule-governed phonological decoding and irregular word reading, identified subtypes of children with deficits in decoding or irregular word reading, but the subtypes were not completely stable across reading development. Over time, regular and irregular reading may converge because phonological decoding (often assessed by regular word reading) contributes to automatic word recognition (Ehri, 1992; Uhry & Shephard, 1997), which may be assessed with real words that are regular and irregular because exception words are at least partially decodable (Berninger, 1998; Berninger, Vaughan, et al., 2002). The contribution of the connectionist models was showing that procedural knowledge (unconscious computations without overt verbalizations of declarative knowledge of phonics rules) may guide reading development. Our instructional studies apply this principle in teaching connections between letters and sounds explicitly (both out of word context and in word context) but without overtly articulating any rules (e.g., Berninger et al., 1999; Berninger, Abbott, et al., 2000).

The research on the rule-deficit and computational modeling suggests that there is a *continuum of rule-learning in reading*, ranging from (a) highly implicit to (b) moderately implicit to (c) moderately explicit to (d) highly explicit:

1. Computational procedures out of conscious awareness induce connections between spoken and written words that support reading of unknown and familiar words.
2. Through repeated practice in word reading (applying procedural knowledge based on those connections between spoken and written words), *an autonomous lexicon is created* that can be accessed automatically for specific words.
3. Explicit instruction engages children in active manipulations of spoken and written words and their parts and in the process creates conscious linguistic aware-

ness of phonemes, spellings, and morphemes (see Figure 11.2).

4. Explicit instruction in deductive application of the verbalized phonics, morphology, or spelling rules (patterns within and between written and spoken words) creates strategic readers who consciously apply this knowledge to unknown words.

For individuals without the genetic influences associated with learning disabilities (discussed later in the chapter), 1 and 2 alone may be sufficient. For many children, with or without learning disabilities, 3 and 4 may be necessary for learning to read. There are individual differences in how much explicit instruction and what kind of explicit instruction students of the same age and grade level need. One of the greatest challenges in teaching reading is to provide differentiated instruction in the general education program during early and middle childhood so that children receive the appropriate degree of explicit instruction they require for mapping spoken words they already know onto written words they are learning, and recognizing new written words that may not be in their spoken vocabulary. Preservice teachers should be prepared to assess how much explicit instruction individual children require and to provide appropriate instruction along the continuum of explicit rule learning.

Is Phonology the Only Language Deficit?

Phonological skills appear to be impaired across development in reading disability (e.g., Berninger, Abbott, Thomson, et al., 2001, in press; Bruck, 1992, 1993; Pennington & Lefly, 2001; Scarborough, 1984). At the same time, there is evidence that other aspects of language (e.g., vocabulary or syntax) may contribute to reading development and its disorders, and which is the most important may change across development (Scarborough, 1984, 1989, 1990, 1991, 2001; Scarborough, Ehri, Olson, & Fowler, 1998). However, phonological processing is complex and may refer to at least three separable skills: phonological awareness of sound segments in spoken words, phonological working memory (storing and manipulating sound units in temporary working memory), and phonological decoding (translating orthographic units in written words into spoken words; Wagner & Torgesen, 1987).

Each of these phonological processes may be related to multiple levels of aural/oral or written language. For

example, aural nonword repetition (see Bishop & Snowling, 2004) may be related to vocabulary (Gathercole & Baddeley, 1989), sentence processing (Willis & Gathercole, 2001), comprehension (Montgomery, 2003; Nation, Clarke, Marshall, & Durand, 2004), and executive functions (Baddeley & Della Sala, 1996). Thus, in the complex brain systems supporting reading (Berninger, 2004a) and writing (Berninger & Winn, in press), there are *systems within systems*, and it can be misleading to attribute any complex skill to a single underlying process. Nevertheless, there are identifiable language skills that can be assessed and taught explicitly for specific reading or writing skills at specific phases in reading and writing development. If professionals are not aware that language is a multilayered, complex system (Berninger & Richards, 2002) and use this knowledge in their assessment and treatment practices, some children will be *assessment casualties*, their problems going undetected, or *curriculum casualties*, children who can learn to read but have not been taught in a developmentally appropriate way. Teaching preservice teachers about the complexities of language may prevent learning disabilities.

Rapid Automatic Naming, Fluency, Efficiency, and Timing

One of the most reliable predictors that a prereading child will have a reading disability is inability to name objects or colors (assuming the child is not color blind; Manis, Seidenberg, & Doi, 1999; Wagner et al., 1994; Wolf, Morris, & Bally, 1986). By first grade and thereafter, the time required for naming multiple rows of continuous letters is one of the most frequent concurrent deficits in individuals with reading disabilities (e.g., Wolf & Bowers, 1999) and writing disabilities (e.g., Berninger, Abbott, Thomson, et al., 2001, in press). Students who have a double deficit in rapid naming of letters and phonological awareness are more impaired than those who are impaired in only one of those skills (Wolf & Bowers, 1999). Number of deficits in phonological, orthographic, and rapid naming skills predicts severity of reading disability (Berninger, Abbott, Thomson, et al., 2001).

Rapid automatic naming (RAN) is a deceptively simple task that reflects complex processing (see Wolf & Bowers, 1999): attention to visual stimuli (colors, pictures, or alphanumeric stimuli), rapid automatic access to familiar phonological codes in long-term memory,

and coordinating codes on different time scales (one visual/orthographic code and one oral linguistic code, for lexical or word-level representations) in real time (Breznitz, 2002).

Not all timing problems in reading disability involve rapid retrieval of single lexical items. Some appear to involve fluency (quick, smooth, coordinated processing of serial items), which is influenced by the efficiency of each of the language processes involved (e.g., Perfetti, 1985). A precise timing mechanism for coordinating reading processes may be impaired in reading disability (Wolf, 1999). Treatment that accelerates rate of processing appears to increase efficiency of the multiple processes involved and thus fluency (Breznitz, 1987, 1997a, 1997b).

Dyslexia (a specific kind of reading disability) may cause undue difficulty in *sustaining mental effort over time*. On the first row of the Wolf et al. (1986) RAN tasks (10 items), the child dyslexics do not differ significantly from grade norms, but on the remaining four rows of 10 items each they do (Berninger & Hidi, in press). Dyslexics appear to have an invisible difficulty in sustaining time-sensitive, goal-directed activity carried out in working memory. Many teachers have no empathy for students who cannot complete written assignments in a timely manner. They cannot directly observe this hidden disability in sustained effortful word retrieval, which is apparent on the clinically administered RAN task. In contrast, oral reading dysfluency is a publicly visible disability.

Comorbidities

Reading disability may occur with or without other learning or behavior problems. Some gifted children have disabilities in low-level writing skills that interfere with their high-level composing skills (Yates, Berninger, & Abbott, 1994) or low-level reading skills that interfere with high-level comprehension skills (e.g., untreated child dyslexics in our family genetics study). Many children with behavioral disabilities have undiagnosed and untreated learning disabilities in academic content domains and in aural/oral language (Berninger & Stage, 1996). Reading or writing disabilities may also occur along with developmental psychopathology, including ADHD (especially the Inattentive subtype) and/or Conduct Disorder (see Pennington, 2002, for further discussion of the issue of comorbidity that complicates both research and treatment and for a review of research on this topic).

Normal Variation in Reading and Writing

In contrast to comorbidities based on categorical variables, normal variation is based on quantitative traits modeled as continuous variables. *Normal variation (interindividual and intraindividual differences)* occurred in the processing skills related to reading and writing in a large, representative sample of typically developing primary grade students (Berninger & Hart, 1992). Intermediate grade students in another large, representative sample exhibited *intraindividual variation* in their profiles of word reading and text-level reading skills (Berninger, 1994) and their profiles of word choice, sentence construction, and discourse organization in composing (Whitaker, Berninger, Johnston, & Swanson, 1994). We observed *normal variation in response to the same instruction*. Berninger and Abbott (1992) documented normal variation among individual children in response to the same reading instruction across first grade. Traweek and Berninger (1997) and Abbott, Reed, Abbott, and Berninger (1997) documented normal variation in response to the same instruction during second grade. Among children who do not have ADHD, normal variation in their ability to self-regulate attentional focus and goal-directed attention uniquely predicts their ability to process the orthographic word form (see Figure 11.2; Thomson et al., 2005).

Taken together, these various studies show that variation among learners is *normal*; the typical classroom will have students exhibiting many individual differences in processes and skills related to literacy learning. Thus, one of the pressing needs in an era of increasing expectations for high levels of academic performance is to prepare teachers to deal effectively with the normal diversity in cognitive processes among the students in their classrooms. This diversity requires a continuum of explicit instruction to create awareness of language processes. Another pressing need is to understand learning disabilities in reference to the normal variation in reading and writing acquisition (Berninger, 1994) and typical reading (e.g., Chall, 1983, 1996) and writing (e.g., Templeton & Baer, 1992; Treiman, 1993).

Gender Differences

Gender differences in reading disabilities appear to be related to referral biases (Shaywitz et al., 1990). However, gender differences do occur in writing. Typically developing boys are more impaired in handwriting auto-

maticity and its related orthographic (not motor) skills (Berninger & Fuller, 1992; Berninger, Fuller, & Whitaker, 1996). Boys with dyslexia are impaired on a wide variety of writing skills (handwriting, spelling, written composition, and related neuropsychological processes in our family genetics phenotyping battery; Berninger, Nielsen, Abbott, Wijsman, & Raskind, 2005; Nielsen, Berninger, & Raskind, 2005).

Nature and Nurture

Although some think of the biological and experiential influences on learning and its disorders as mutually exclusive, independent factors, it is more likely that they are interacting variables. In this section, we consider studies of environmental influences, genetic influences, and then of combined brain imaging and instructional interventions to study nature-nurture interactions in individuals with learning disabilities.

Role of Education and Experience

Although developmental research historically emphasized the biologically constrained maturational processes in development, during the past 15 years there has been a more balanced approach that acknowledges the role of experience. Morrison, Smith, and Dow-Ehrensberger (1995) conducted groundbreaking school cutoff studies showing that children who just made the cutoff and entered kindergarten outperformed, during the current and subsequent years, their age-equivalent peers who just missed the cutoff. Vellutino and Scanlon's (e.g., Vellutino et al., 1996) longitudinal instructional study showed that explicit instruction could eliminate many (but not all) reading problems; these findings, based on direct manipulation of experience, added to those based on indirect measures of experience (self-reported print exposure; Cunningham & Stanovich, 1998) to make the case that instruction and reading experience matter (Morrison et al., 1995). A number of longitudinal treatment studies pointed to the same conclusion: Reading problems could be prevented or the severity of their expression reduced to a large extent with appropriate early intervention, even if children came from low-literacy homes (Foorman, Francis, Fletcher, Schatschneider, & Mehta, 1998; Foorman et al., 1996; Torgesen, Wagner, & Rashotte, 1997; Torgesen et al., 1999). Yet, close scrutiny of data showed that not all children were treatment responders

in early intervention (Torgesen, 2000) or over the course of schooling (Shaywitz et al., 2003). That is, even though most reading problems can be prevented with appropriate instruction, some will not be totally eliminated because there is a genetic (Olson, 2004) and neurological (Hynd, Semrud-Clikeman, Lorys, Novey, & Eliopoulos, 1990; Shaywitz et al., 2003) basis for reading disability, which may persist throughout schooling in some form in some individuals.

Genetic Influences in Reading and Writing

Heritability studies with twins (e.g., Byrne et al., 2002; Olson, Datta, Gayan, & DeFries, 1999; Olson, Forsberg, Wise, & Rack, 1994) and family genetics studies (e.g., Chapman et al., 2003, 2004; Raskind, 2001, Raskind et al., 2005) have documented genetic influences on reading disability. Genetic influences on phonological processes and verbal working memory emerge in the preschool years (Byrne et al., 2002). These are the same two areas of functioning that we observed showed the greatest genetic influences during the school-age and adult years (Berninger, Abbott, Thomson et al., 2005; Berninger & O'Donnell, 2004). Considering these genetic influences on processes that affect ease of learning written language, students would probably benefit from learning environments that are optimally designed for their genetically influenced, reading-related processing characteristics (cf. Plomin, 1994) that include anomalies in phonological processing and working memory (Swanson & Siegel, 2001).

Brain Constraints in Infancy versus Plasticity of the Brain during Childhood and Adult Years

Electrophysiological recording in newborns identified event-related potential (ERP) components for speech discrimination of stop consonants in consonant-vowel patterns that predicted language development at age 3 and 5 and reading (including diagnosis of dyslexia) at age 8 (D. Molfese et al., 2002). Newborn ERP recordings were more isolated within brain regions, and adults showed more interactions between brain regions (D. Molfese et al., 2002). Not only brain variables but also social and other environmental variables influenced reading development at the brain and behavioral levels (V. Molfese & Molfese, 2002). Event-related potential waveforms change as a result of training in infants and adults (D. Molfese et al., 2002).

Plasticity of Brain in Middle Childhood and Adult Years

At least nine studies, using a range of imaging methodologies, including functional magnetic resonance imaging (fMRI), functional magnetic spectroscopic imaging, magnetic source imaging, and electrophysiological recordings of ERPs, now show that the brains of beginning readers (Shaywitz et al., 2004; Simos et al., 2002), developing readers (Aylward et al., 2003; Richards et al., 2000, 2002; Temple et al., 2000, 2003), and adults (Eden et al., 2004; D. Molfese et al., 2002) change in processing related to reading in normal and disabled readers.

The University of Washington brain imaging studies have shown that the brain responds to reading and spelling instruction. The treatment that contained all the instructional components recommended by the National Reading Panel (Berninger, Nagy, et al., 2003) resulted in significant lactate reduction (increased efficiency during neural metabolism) in left frontal regions during phonological judgment (Richards et al., 2002) and increased fMRI Blood Oxygen-Dependent Level (BOLD) activation in frontal and parietal regions (Aylward et al., 2003). In both cases, pretreatment differences between dyslexics and controls disappeared after treatment. Evidence of *treatment-specific brain responding* (e.g., Richards et al., 2005) have also been observed, for example, robust changes during scanning on a spelling task following orthographic treatment but not morphological treatment in dyslexics in grades 4, 5, and 6. Richards et al. (2005) proposed a paradigm for analyzing the results of combined brain imaging and treatment studies that takes into account (a) reliability of responding in controls from time 1 to time 2, (b) significant pretreatment differences between dyslexics and controls in regions that are reliably activated in controls, and (c) significant change following treatment in those regions in the direction of normalization (activating regions that controls had activated or deactivating regions that controls had not activated).

Prevention and Treatment Validity

We conclude this section on contributions of developmental psychology to learning disabilities with an example of a programmatic line of research at the University of Washington that is grounded in theory of reading and writing development and instructional interventions for preventing and treating reading and writing disabilities. Berninger, Stage, Smith, and Hildebrand (2001) pro-

posed a three-tier model to redirect psychologists' attention from diagnosis of chronic failure in reading and writing to early intervention and prevention. The first tier focuses on screening for early intervention, similar to approaches taken to prevent developmental psychopathology and social-emotional problems (see Cicchetti & Toth, Chapter 13, and Selman & Dray, Chapter 10, this *Handbook*, this volume). The second tier focuses on ongoing progress monitoring and supplementary intervention throughout schooling. The third tier focuses on differential diagnosis and specialized treatment for those with persisting, biologically based specific learning disabilities. At each tier, randomized controlled instructional experiments have been conducted, and the assessment measures that were validated in the studies of intraindividual and interindividual differences are used as predictors of response to intervention and/or outcome measures. In contrast to many instructional studies that use convenience samples or school-identified samples, our samples are ascertained on the basis of well-defined subject inclusion criteria for individuals who are at risk or disabled in specific reading or writing skills.

Randomized, Controlled, Longitudinal Experimental Studies

A brief overview of findings is provided that is based on large-scale studies in the schools for tiers 1 and 2 and on smaller-scale studies at the University of Washington Multidisciplinary Center for Learning Disabilities (UWLDC) for tier 3. A summary of instructional design principles implemented in all three tiers follows the research review.

Effective Tier 1 and Tier 2 Reading Instruction

At-risk first graders improved more in word reading when their attention was drawn explicitly to letters in words corresponding to phonemes than to the whole word (all letters and the word name; Berninger et al., 1999). At-risk first graders learned taught words and transfer words better when taught the alphabetic principle in isolation, in word context, and in story context than when only phonological awareness of spoken words was taught (Berninger, Abbott, et al., 2000). Explicit instruction for 20 minutes twice a week for 24 lessons over a 4-month period resulted in half the at-risk readers reaching grade level by the end of the year and maintaining gains at the beginning and end of second grade; the other half reached average levels after a second dose

of 24 additional, explicit lessons at the beginning of second grade and maintained the gains at the end of second grade (Berninger, Abbott et al., 2002).

Combined explicit instruction in reading comprehension and decoding led to greater improvement in word decoding than decoding instruction alone for at-risk second-grade readers (Berninger, Vermeulen, et al., 2003). Integrated reading instruction aimed at linguistic awareness, word decoding, automatic word reading, oral reading fluency, and reading comprehension resulted in greater improvement in word decoding and fluency than did the regular, balanced reading program for at-risk second-grade readers (Berninger, Abbott, Vermeulen, & Fulton, in press).

Effective Tier 1 and Tier 2 Writing Instruction

First graders at risk in handwriting improved more in handwriting legibility and automaticity than did children in the contact control group or four alternative handwriting treatments when given a treatment combining (a) studying numbered arrow cues in model letters, and (b) holding the letter forms in memory for increasing duration. All children practiced composing from teacher prompts, but only the treatment combining numbered arrow cues and writing letter forms from memory generalized to both improved handwriting and better compositional fluency (Berninger et al., 1997). At-risk second-grade spellers given instruction in multiple correspondences between units of written words and spoken words did better in dictated spelling and spelling during composition than did the control group given phonological awareness training (Berninger, Vaughan, et al., 1998). Training phonological awareness of six syllable types in English had some added value to training alphabetic principle for spelling polysyllabic words (Berninger, Vaughan, et al., 2000). Explicit instruction in alphabetic principle facilitated learning to spell structure words that were not as phonologically predictable as content words, and explicit instruction in planning, translating, and revising/reviewing led to improved composing (Berninger, Vaughan, et al., 2002).

Effective Tier 3 Treatment in the Multidisciplinary Center for Learning Disabilities

Teaching struggling readers multiple correspondences between units of written and units of spoken words resulted in greater improvement in reading than teaching a single correspondence (Hart, Berninger, & Abbott,

1997). At-risk spellers learned to spell equally well with pencil or keyboard (Berninger, Abbott, et al., 1998). At-risk writers taught integrated handwriting, spelling, and composing skills improved more in each of these skills than the controls at posttest and 6-month follow-up (Berninger, Abbott, Whitaker, Sylvester, & Nolen, 1995). Children taught content reading skills improved more than those in the wait-list control group (Berninger, Abbott, Abbott, Graham, & Richards, 2001). Morphological awareness treatment improved rate of phonological decoding more than phonological awareness treatment did (Berninger, Nagy, et al., 2003), suggesting that dyslexics in upper elementary grades need to learn to coordinate phonological, morphological, and orthographic processes to develop efficient phonological decoding (see Figure 11.2). Morphological awareness training benefited the spelling of pseudowords, and orthographic awareness training benefited the spelling of real words (Berninger & Hidi, in press).

It is never too late to remediate: Upper elementary and middle school students responded positively to instructional interventions that emphasized linguistic awareness and executive functions (Abbott & Berninger, 1999). See Hooper, Swartz, Wakely, deKruif, & Montgomery, 2002, for the importance of executive functions in writing.

Effective Tier 3 Treatment in Schools

Second graders meeting research criteria for dyslexia who used rate criteria in phonological decoding training and progress monitoring improved more in real word reading than those who used accuracy criteria (Berninger, Abbott, Billingsley, Nagy, 2001). For dyslexics in grades 4, 5, and 6, prior attention training did not transfer directly to improved written composition but did lead to greater improvement in written composition, compared to the control group, once written composition instruction was introduced for both groups (Chenault, Thomson, Abbott, & Berninger, in press). Prior attention training also improved oral verbal fluency significantly more in the treatment group that had received reading fluency training.

Instructional Design Principles for Educational Treatment for Biological Problems

All UWLDC treatment research is grounded in a *nature-nurture perspective*. Dr. Raskind, the principal investigator of the Family Genetics Study, emphasizes that the value of genetics research lies in identifying the

subphenotypes that have a genetic basis so that instruction is uniquely designed to help dyslexics overcome these genetic influences. For example, based on the aggregation (Raskind, Hsu, Thomson, Berninger, & Wijsman, 2000), segregation (Wijsman et al., 2000), linkage and brain imaging results (Richards, Berninger, et al., submitted) for aural nonword repetition, all our *phonological training starts with spoken words before we introduce the same written words*. Students clap the number of syllables and count with color tokens the number of phonemes in each word to develop precise phonological word forms before they are ever shown the written form of the word.

Also, based on the finding of a unique genetic pathway for rate of phonological decoding (Chapman, Raskind, Thomson, Berninger, & Wijsman, 2003), we use *rate criteria for training alphabetic principle in "Jibberwacky" words* (our modification of Lewis Carroll's Jabberwocky) to teach children to apply alphabetic principle when meaning cues are not available; we use both accuracy and rate criteria in progress monitoring (Berninger, Nagy, et al., 2003). Children with persisting reading problems are typically assessed with pseudowords and often have aversive reactions to them. We use them in instruction in playful ways to reduce the negative affect associated with them. Another instructional design principle is *teaching to all levels of language close in time and to low-level and high-level skills close in time so that the working memory architecture works efficiently* (Berninger & Abbott, 2003).

A final instructional design principle is *externalizing cognition for purposes of overcoming limitations in working memory and learning strategies for self-regulation that do not require overt verbalization of rules*. Instructional approaches that externalize cognition render students' ideas visible to themselves and to others so that they can be objectively viewed and manipulated. Once cognition is externalized, students can experiment with their ideas in ways that are difficult to do internally (possibly because of overloading working memory). We *externalize cognition through cue cards that are designed to cue orthographic and phonological awareness of units in the alphabetic principle during teacher-directed instructional activities and for self-regulation during independent reading and writing activities*. (For further information, see the chapter on instructional design principles in Berninger & Abbott, 2003.)

Treatment Validity

A new approach to assessment examines the validity of assessment-intervention links. Results of the UWLDC

programmatic research are relevant to treatment validity and have been presented in a way practitioners can use in practice with time-efficient branching diagnosis, validated instructional based assessment, and multilevel profile assessment (Berninger, Dunn, & Alper, 2004). Berninger and Abbott (2003) have developed lesson plans based on the tier 1, tier 2, and tier 3 interventions.

Social and Cognitive Development

Although learning disabilities involving written language are academic problems, they have important implications for both social and cognitive development. Using the gold-standard treatment research paradigm (evaluate whether a new treatment has added value over and beyond that usual treatment), Weiss, Catron, Harris, and Phung (1999) showed that traditional psychotherapy was no more effective than academic instruction in changing mental health status. This finding implies that fostering academic learning may have positive effects on social and emotional development. Moreover, chronic cognitive learning problems can cause social problems, even though social or emotional problems are not the initial cause of the learning problems. Effective treatment may require both cognitive and social/affective components. Many research-supported approaches for fostering social/affective development in the general education program are now available (e.g., Frey et al., in press; Frey, Nolen, Van Schoiack-Edstrom, & Hirschstein, 2005; Van Schoiack-Edstrom, Frey, & Beland, 2002). Emotional coaching implemented in whole classrooms consistently throughout the school year may enhance learning by improving social relationships in the classroom (Lovitt, 2005). Likewise, interventions designed to improve social relationships between teachers and students are proving fruitful in enhancing school learning (Pianta, 1999; see Vaughn, Sinaguh, & Kim, 2004, for a review of social competence and social skills of students with learning disabilities).

ALTERNATIVE APPROACHES TO DEFINING LEARNING DISABILITIES

In this section controversies regarding how to define learning disabilities for purposes of research and of service delivery in the schools are discussed, along with recent developments that take into account response to

early intervention in identifying students with learning disabilities.

Defining Reading Disabilities for Research Purposes

There is a continuing lack of consensus around the world about how to define dyslexia (one kind of specific reading disability; Chapman et al., 2003, 2004; Igo et al., 2005; Raskind et al., 2005), which may confound interpretation of results across research groups. We adopted the definition proposed by the International Dyslexia Association (Lyon, Shaywitz, & Shaywitz, 2003) in the UWLD Family Genetics Study: unexpectedly low word reading, decoding, spelling, and oral reading fluency of neurobiological origin.

The Verbal Comprehension Factor (based on pro-rated Verbal IQ without arithmetic or digit span subtests) is used rather than Full-Scale IQ in determining relative criteria for two reasons. First, evidence from studies funded by the National Institutes of Health (NIH) and available at the time this family genetics study began showed that Verbal IQ (VIQ) is a better predictor than Performance IQ of reading disability in referred samples (Greenblatt, Mattis, Trad, 1990) and unreferrals samples (Vellutino, Scanlon, & Tanzman, 1991). Second, since then, the publishers of the Wechsler scales recommend using factor scores rather than Full-Scale IQ in identifying students with learning disabilities (e.g., Prifitera, Weiss, & Saklofske, 1998). Also, site visit reviewers in 1995 recommended setting an IQ cutoff at the 25th percentile (standard score of 90 for a scale with a mean of 100 and standard deviation of 15) because it is well documented that prevalence of developmental disorders of genetic origin is significantly higher in children whose IQs fall in the bottom quartile of the population, and these genetic disorders may cause development to fall outside the normal range in specific developmental domains, including cognitive, language, motor, attention/executive, and/or social-emotional function, and could confound a study seeking the genetic mechanisms for a specific learning disorder that affects only written language in children whose development is otherwise normal. In addition, the NIH-funded research of Olson et al. (1999) showed that reading disabilities identified on the basis of relative criteria (low reading relative to IQ) are more

likely to have a genetic basis than those identified only on the basis of low achievement.

The size of VIQ-achievement discrepancy that we required (at least 1 standard deviation) is much less than that required by the special education law in the state where this research was conducted and that is used by other research groups, particularly in England. So that the discrepancy could not be attributed to normal intraindividual variation, we required that the achievement be below the population mean as well as discrepant from IQ on the inclusion measures for reading and spelling. This approach, using simple differences relative to VIQ and low achievement relative to the population mean, has been fruitful in genetic linkage studies that replicated others' work (Chapman et al., 2004) and identified novel chromosome sites for fluency-related subphenotypes for dyslexia (Igo et al., in press; Raskind et al., 2005).

Definitions Related to Providing Services in Schools

Berninger, Hart, Abbott, and Karovsky (1992) adopted a systems approach (of multiple component processes in the reading and writing systems) and applied the Mahalanobis statistic to determine how many students might be at risk for specific kinds of learning disabilities. Mahalanobis D^2 measures the distance a set of scores is from the centroid formed by the means of the joint distribution of the scores, taking the correlations among the measures into account. For two scores, Mahalanobis measures the distance that the value of X is from the mean of X and the distance that the value of Y is from the mean of Y, taking the XY correlation into account. In regression, only the distance of the predicted Y from the actual Y is considered. Results showed that different children were identified depending on whether only low achievement was considered or whether that and discrepancy from VIQ were both considered. We therefore took the position that flexible definitions, based on both absolute (low achievement) and relative (IQ-achievement discrepancy) criteria, were needed to meet the needs of all students in educational settings. In our early intervention, we studied any child whose VIQ appeared to be at least in the low-average range (standard score of 6 on the Wechsler Intelligence Scale for Children, third edition [WISC-III] Vocabulary subtest) and whose word reading and/or decoding accuracy was at least 1 standard deviation below the mean. However, in our family genetics

research, we took a different approach based on existing research literature at the time and feedback from the site visitors, as previously explained.

We recognize that there is widespread dissatisfaction with the rigid approach to IQ-achievement discrepancy for qualifying students for special education services (e.g., Bradley et al., 2002; Lyon et al., 2001; Siegel, 1989; Steubing et al., 2002; Vellutino, Scanlon, & Lyon, 2000). Others (e.g., Fletcher et al., 1994) used other data analysis approaches to support the claim that the same children are identified for special education services whether IQ is or is not used. However, those analyses were conducted in a state that uses different criteria for identifying students with learning disabilities for special education and for dyslexia in general education. The results of the Mahalanobis analyses and procedures in place in our state lead to a different conclusion, and we are concerned that all students with learning differences are served appropriately: those with low IQs, those with high IQs, and all those in between (Berninger, 1998).

Thus, the flexibility in the recently revised federal special education law (IQ-achievement discrepancy shall not be the sole criterion for identifying learning disabilities) will allow school professionals in many states to serve students whose learning disabilities express themselves in ways that are difficult to capture in a single diagnostic algorithm and also to focus more on early intervention than in the past. The concept of response to intervention, discussed next, is relevant to the new approach to identifying children needing special help in reading and writing.

Response to Instruction

This emerging approach for defining learning disability—failure to respond to intervention—is relevant in early childhood. Rice (1913) conducted the first large-scale application of the scientific method to evaluate effective educational methods based on student response to instruction. She studied spelling instruction in classrooms throughout the United States and found that children who received 15 minutes of spelling instruction a week achieved significantly higher spelling test scores than those who were drilled for an hour or more a week. This result suggests that explicitness of instruction may be more important than intensity. Chall (1967/1996) showed that primary grade children responded better to

explicit phonics instruction than to the basals in use at that time. Brown and Felton (1990) reported evidence that explicit phonics instruction was associated with better student learning outcomes. Despite this research knowledge regarding the importance of explicit phonics instruction, many teachers in the last 3 decades of the twentieth century favored whole-language methods over explicit reading instruction. Left untreated, early reading problems persist (Juel, 1988). Thus, it was not always clear whether reading disabilities resulted from a biological basis or lack of explicit instruction.

In 1993, NIH sponsored a working conference for researchers in the field of learning disabilities at which these issues were discussed; it resulted in *New Frames of Measurement* (Lyon, 1994). Analyzing change by modeling individual growth (Francis, Fletcher, Stuebing, Davidson, & Thompson, 1991) was a theme in the NIH conference on new frames of measurement. Berninger and Abbott (1994) proposed response to intervention as a research tool to control for effects due to lack of opportunity to learn. We subsequently carried out our proposed research on early intervention in reading and writing outlined in our chapter for the conference. Results were analyzed for individual growth curves, treatment effects, classes of responses (faster and slower responses to instruction), and process measures that predicted individual response to treatment (the earlier discussed tier 1 and tier 2 interventions).

Following that conference, Slavin, Madden, Dolan, and Wasik (1996) showed that the effects of poverty and low literacy could be overcome by changing educational practice at the system level. Vellutino and colleagues (1996) showed that longitudinal early intervention in reading could eliminate most (but not all) reading disabilities. Compton (2000a, 2000b, 2002, 2003a, 2003b) documented that (a) there are individual differences prior to the beginning of instruction, (b) dynamic change occurs in response to instruction for children in general, and (c) processes such as phonological awareness, knowledge of letter-sound correspondence, and rapid automatic naming predict the slopes of individual growth curves.

From its inception (Deno, Marston, & Mirkin, 1982; Fuchs, 1986; Fuchs, Deno, & Mirkin, 1984), curriculum-based measurement (CBM) has been a progress-monitoring, response to intervention model. Unfortunately, with the widespread use of literature-

based texts in the whole-language movement, it was often not possible to link the assessment to actual instruction, and CBM made increasing use of standard passages unrelated to those used during classroom instruction. Nevertheless, at a time when prevailing practices were to assess only accuracy and not rate, even though children may have either accuracy and rate reading disabilities or only rate disabilities (Lovett, 1987), CBM provided a useful fluency metric. Another contribution of CBM was that it encouraged teachers to assess student progress on a more regular basis than typically happens in the general education classroom or than is required by federal special education law (every 3 years). A new form of CBM, *instructionally based assessment*, which is more closely yoked to teacher's instructional goals and cognitive processes for adapting instruction, has been introduced (Peverley & Kitzen, 1998; Wong, 2000) and is used in the UWLDC reading and writing lessons (Berninger & Abbott, 2003). One view is that norm-referenced tests are not sensitive to change in response to instruction, but we have not found that to be the case for the explicit instructional treatments we evaluated in randomized, controlled designs. Thus, we use a mix of standardized tests and instructionally based assessments in evaluating response to instruction.

Processes That Mediate Written Language Learning

Some believe that all that needs to be done to prevent reading and writing disabilities is to teach children. Others value the importance of assessment of mediating processes and designing instruction that improves these processes in the context of comprehensive reading and writing instruction. A large body of research points to processes that are concurrent and longitudinal predictors of written language acquisition: *phonological* (e.g., Bishop & Snowling, 2004; Catts et al., 2001; Catts, Fey, Tomblin, & Zhang, 2002; Manis et al., 1999; Mattingly, 1972; Scarborough, 1998; Snowling, 1980; Stanovich, 1986; Torgesen et al., 1997; Vellutino & Scanlon, 1987; Wagner et al., 1994); *letter naming* (Catts et al., 2001), *rapid letter naming* (Compton, 2003a, 2003b; Manis et al., 1999; Meyer, Wood, Hart, & Felton, 1998; Wolf et al., 1986), *rapid switching between letter and number naming* (Wolf, 1986) or *rate* (Wolf, 1999); *orthographic* (e.g., Berninger, Abbott, Thomson, et al., 2001, in press;

Olson, Forsberg, & Wise, 1994; Schlagal, 1992); *morphological* (Carlisle, 2000; Carlisle & Stone, 2004; Carlisle et al., 2001; Nagy & Anderson, 1984; Nagy, Anderson, Shommer, Scott, & Stallman, 1989; Nagy, Berninger, Abbott, Vaughan, & Vermeulen, 2003; Singson, Mahony, & Mann, 2000; White et al., 1989); *syntactic* (e.g., Scarborough, 1990); and *attention* (Berninger et al., 1999; Thomson et al., 2005; Torgesen et al., 1999). Individual differences in *both vocabulary and phonological skills* predict whether children require teacher-directed, explicit instruction to respond optimally to instruction (Connor, Morrison, & Katch, 2004). Just as medical professionals now screen newborns for markers of medical disorders that can be prevented (e.g., mental retardation or other handicaps due to phenylketonuria, thyroid deficiency, RH factor incompatibility), so should educational professionals now screen children during early or middle childhood for marker processes associated with specific reading or writing disabilities and, when necessary, provide supplementary or specialized instruction with frequent progress monitoring (assessment of student response to instruction) and instructional adaptation as needed.

Developmental Expression of Dyslexia Subphenotype(s)

Which of the processes that impair written language learning in early or middle childhood are impaired throughout development? In a dyslexia phenotyping study based on families who were enrolled after a major revision in the test battery, we sought the developmentally stable, impaired processes. Based on relative criteria (for VIQ) and absolute criteria (for population mean), on average, child probands ($n = 122$; affected children who qualified the family) had a mean of 6.0 ($SD = 2.8$) deficits on the nine reading measures used for inclusion and a mean of 4.1 deficits on the six writing measures used for inclusion. Their affected parents had on average a mean of 1.9 ($SD = 1.7$) deficits on the same reading measures and 1.8 ($SD = 1.6$) deficits on the same writing measures.

Table 11.1 summarizes which subphenotypes met both absolute (low achievement at or below 1 SD) and relative (at least 15 standard score points difference between VIQ and measure based on transformation to make scales comparable if necessary) criteria at each developmental level. Six met both criteria at both

Table 11.1 Impaired Phenotypes Based on Absolute and Relative Criteria in Children Only and Children and Adults with Dyslexia

Child and adult	CTOPP nonword repetition, TOWRE pseudoword reading efficiency, Wolf RAN letter naming, UW alphabet letter writing, Wolf RAS letter and number, and Wolf RAS color, letter, and number. <i>Note:</i> D-KEF color word inhibition and verbal fluency repetitions met only the relative criteria in both child and adult dyslexics.
Child only	WRMT-R Word Identification and Word Attack, TOWRE sight word efficiency, GORT3 accuracy and rate, UW morphological decoding and accuracy, WRAT 3 and WIAT II spelling, WIAT II written expression, PAL receptive and expressive orthographic coding, CTOPP phoneme reversal, Wolf RAN color, Wolf RAN number, D-KEF color word inhibition. <i>Note:</i> Only in child dyslexics did inhibition on the Stroop meet both absolute and relative criteria.
Adult only	None.

Notes: CTOPP = Comprehensive Test of Phonological Processing; D-KEF = Delis Kaplan Executive Functions; PAL = Process Assessment of the Learner; RAN = Rapid Automatic Naming; RAS = Rapid Automatic Switching; TOWRE = Test of Word Reading Efficiency; WIAT II = Wechsler Individual Achievement Test, second edition; WRAT3 = Wide Range Achievement Test, third edition; WRMT-R = Woodcock Reading Mastery Test Revised.

Source: From “Modeling Developmental Phonological Core Deficits within a Working-Memory Architecture in Children and Adults with Developmental Dyslexia,” by V. Berninger, R. Abbott, J. Thomson, et al., in *Scientific Studies in Reading*, in press; and “Research-Supported Differential Diagnosis of Specific Learning Disabilities” (pp. 189–233), by V. Berninger and L. O’Donnell, in *WISC-IV Clinical Use and Interpretation: Scientist-Practitioner Perspectives*, A. Prifitera, D. Saklofske, L. Weiss, & E. Rolphus (Eds.), 2004, San Diego: Academic Press.

developmental levels and are stable hallmark features across development. Many subphenotype measures met both criteria in children but not adults and thus are more likely to show compensation (normalization) over development. No impairments met both criteria only in the adults, but the adults met both the absolute and relative criteria for impaired real word reading efficiency but not for real word reading accuracy (Berninger & O’Donnell, 2004); and real word reading accuracy and rate appear to have different genetic mechanisms based on chromosome linkage (Igo et al., in press).

The stable impaired skills represent the three components of working memory: phonological storage (aural

nonword repetition), phonological loop (rapid letter naming and writing), and executive functions (switching attention and inhibition; e.g., Baddeley, 2002; Baddeley & Della Sala, 1996). The stable phonological deficits (cf. Morris et al., 1998) may explain the word decoding problems, and the set of all three deficits may explain the persistent fluency problems of dyslexics due to inefficient working memory (Berninger, Abbott, Thomson, et al., in press; Berninger & O’Donnell, 2004).

The findings raised new questions we are still investigating. The phonological loop has a role in learning new written words by coordinating linguistic codes (e.g., Baddeley, Gathercole, & Papagano, 1998) and in accessing familiar words rapidly and efficiently in long-term memory. Does the RAN deficit reflect the impaired time-sensitive phonological loop? Did the Vicar of Nibbleswicke, whom Roald Dahl introduced us to, have a recurrence of childhood dyslexia moments with written text in his adult years when he faced his first adult job as a pastor delivering sermons where he transposed the sounds in spoken words (e.g., God and dog; Dahl, 1990)? If inefficiency in the executive functions for phonologically coded working memory is the underlying problem, it may make it more difficult to learn to read (coordinate spoken and written words) in childhood but also to express oneself later in life when working memory is being taxed as in learning a new job and may affect oral expression as well as reading or written expression. More than phonological decoding may be impaired in dyslexia.

Research-Supported Inclusionary Criteria

Resolving issues of definition for research purposes is also important for educational practice if both assessment and instruction are ever to be grounded in scientific research. It is no wonder that educators are confused about what dyslexia is and whether it exists if neither federal legislation nor professionals can define it on the basis of *inclusionary criteria*. Toward the goal of developing inclusionary criteria, we carefully examined cases of children who did and did not have discrepancies between VIQ and reading and spelling achievement. Based on Snow (1994) and Snow, Cancino, Gonzales, and Shriberg (1989), Nagy, who is on the UWLDC research team, proposed that defining words is really a metalinguistic awareness index of a child’s ability to use words in a decontextualized manner, distinct from contextual-

ized use of language in conversation (see Berninger, Abbott, Vermeulen, et al., *in press*). It follows that VIQ, which is highly correlated with expressive vocabulary, may be a general metalinguistic awareness index.

Further group analyses showed that dyslexics appeared to be primarily impaired in phonological and orthographic processing, rapid automatic naming, and executive functions (such as supervisory switching attention and inhibition) but to have intact oral language skills for morphology and syntax, that is, good metalinguistic awareness at those levels of language. However, the language learning disabled (Butler & Silliman, 2002; Wallach & Butler, 1994) children appeared to be impaired in those oral language skills as well as in phonological skills and also to be more impaired in reading comprehension than the dyslexics. Their impaired metalinguistic awareness of morphology and syntax may account for their lower VIQs.

Differential diagnosis for dyslexia versus language learning disability has implications for research and treatment. Dyslexics and language learning disabled individuals are probably included in many studies of reading disability, and results may or may not generalize across studies depending on the relative proportion of these individuals in a particular study. For dyslexics, all that may be needed is explicit instruction in orthographic and phonological awareness and decoding, but for those with language learning disability affecting all aspects of metalinguistic awareness, effective treatment may require explicit instruction in phonological, morphological, and syntactic awareness.

Drawing on Chall's (1983) observation that students first learn to read and then use reading to learn, we have observed that the language learning disabled have *significant problems in using language to learn*. School learning requires using language to understand teachers' instructional language, using language to self-regulate the internal mental processes in learning across the academic curriculum, and using language to self-regulate emotions and behavior. Thus, the language learning disabled need special instruction in using language to learn. The Appendix describes assessment procedures for the differential diagnoses among dyslexia, language learning disability, and dysgraphia (also see Berninger & O'Donnell, 2004). In addition, some individuals have specific comprehension disability without any language disability (e.g., Oakhill & Yull, 1996) or combinations of dyslexia, dysgraphia, and/or language learning disability.

Differential Diagnosis for Teaching versus Labels

Many parents and teachers reject terms such as learning disabilities as labels that stigmatize and do not make a difference in instruction. In contrast, we use the terms *dyslexia*, *dysgraphia*, and *language learning disability* because they identify both the nature of the problem and the need for specialized instruction in the affected academic skills:

Dyslexia: Impaired word reading and spelling (see Berninger, 2001)

Dysgraphia: Impaired handwriting and/or spelling (forming the letters of the language by hand; see Berninger, 2004b)

Language learning disability: Impairments in both aural/oral and written language (see Berninger & O'Donnell, 2004)

These terms can be used in the general education program, without the legal and paperwork constraints of special education, as well as in special education.

Effective Instruction for Dyslexia and Dysgraphia

Although there is a long-standing clinical research literature on treating dyslexia and specific reading disabilities, studies employing randomized, controlled designs have increased in recent years. Three programmatic lines of research on effective treatment of children with dyslexia include the groundbreaking studies of Wise and Olson at the University of Colorado Learning Disabilities Center with Talking Computers (e.g., Wise, Ring, & Olson, 1999), Lovett and colleagues at Toronto Children's Hospital (e.g., Lovett et al., 1994, 2000), and Torgesen and colleagues (e.g., Torgesen et al., 1999, 2001). More recently, a large randomized controlled study across three sites was conducted by Morris, Wolf, and Lovett (Wolf et al., 2003).

There has been a recent explosion of knowledge in evidence-based, effective reading instruction (e.g., McCardle & Chhabra, 2004; National Reading Panel, 2000; Snow, Burns, & Griffin, 1998); although there is not as much knowledge available for writing instruction, there is some (e.g., Berninger & Richards, 2002, chap. 9; Hooper et al., 1993; Swanson, Harris, & Graham, 2003, chaps. 16, 20, 21). High-stakes tests in

many states require writing skills for assessing all domains, not just reading (Jenkins, Johnson, & Hileman, 2004). Also, many of the reviews of research-supported instruction are focused on early reading—and in the general education classroom. There is need for continuing research on instructional interventions that are effective across development and that are validated for specific kinds of learning and development problems, including but not restricted to dyslexia and dysgraphia.

Effective Instruction for Language Learning Disability

Little is known about effective reading or writing treatment for students with reading disabilities and additional oral language disabilities, which increasingly are referred to as language learning disabilities (e.g., Butler & Silliman, 2002; Wallach & Butler, 1994). In our experience, these children show mild to moderate indicators of difficulty in learning aural/oral language during the pre-school years; although these oral language problems resolve in terms of production during the school-age years, lingering problems in metalinguistic awareness remain that may affect oral as well as written language. They may also have written expression problems (Fey, Catts, Proctor-Williams, Tomblin, & Zhang, 2004). Effective treatment is needed to help them improve in using decontextualized language to learn (to self-regulate internal learning processes for reading and writing and across the content subjects in the curriculum). They may learn more easily nonverbally (the twenty-first-century curriculum is very verbally oriented), but more research is needed on this issue.

Summary Position on Definitional Issues

We believe the trends toward more flexible criteria for qualifying children for services in the schools and the addition of a response to intervention component are steps in the right direction to prevent severe learning disabilities. Response to intervention will establish dynamic assessment as standard psychological practice (see Grigorenko & Sternberg, 1998; Lidz & Elliott, 2000). At the same time, it is important to retain comprehensive assessment and introduce scientifically supported differential diagnosis that has treatment validity for those who fail to respond to early intervention and have biologically based learning disabilities. Differential diagnosis relies on cognitive tests and associated phenotypic markers of specific learning disabilities.

CONTINUING CHALLENGES

Validity of Special Education Categorical versus Research-Supported Practices

The special education categories for qualifying children for services are not the same as research-supported diagnoses (Berninger, 1998). The shortcomings of the categories for qualifying children for special education services go beyond problems in IQ-achievement discrepancy the way it has been implemented. Often, cluster scores that are composites of more than one subtest are used to qualify students for special education services. This practice is problematic because when subtests are combined; a relative strength on one subtest may mask impairment on another subtest that contributes to the cluster. For example, beginning at-risk readers show *intraindividual differences in the growth curves for real word reading and pseudoword reading* (Berninger, Abbott, et al., 2002). Children who show significant growth in both of these single-word reading skills have the best outcomes; those who show significant growth in only one of these have significantly lower outcomes in reading. Combining these two subtests may miss a significant deficit in either pseudoword reading or real word reading that has important implications for diagnosis and treatment (see Berninger & O'Donnell, 2004).

Likewise, in computing IQ-writing achievement discrepancy, only accuracy measures of writing achievement—cluster scores on the Woodcock-Johnson, third edition (WJ-III) or Wechsler Individual Achievement Test, second edition (WIAT-II) that confound quality of writing samples and writing fluency—are often used. In addition, impaired spelling, handwriting, or compositional fluency are often not recognized as learning disabilities, but 15 years of our National Institute of Child Health and Human Development (NICHD) supported research indicates they are. For example, higher scores on WJ-III Writing Samples (an untimed test that does not require sustained writing and that is scored for content and ideas but not the mechanics of written expression with which students with learning disabilities have difficulty) may mask problems in writing fluency (speed of composing). However, when WJ-III Writing Samples is compared to writing fluency or writing fluency is compared to VIQ, the disparity is evident (significantly lower writing fluency) and typically is confirmed through examination of daily written work.

Thus, children with persisting reading or spelling problems may not qualify for any specialized instruction if they are significantly impaired in (a) accuracy of word decoding (reading pseudowords) but not word reading (real words) or of real word but not pseudoword reading; (b) rate of single word or pseudoword reading or rate of oral reading of passages; (c) spelling; and/or (d) handwriting. It does not matter if it is obvious that the child cannot read classroom materials with accuracy and fluency, spell at a grade-appropriate level in daily written work, and/or has illegible or painfully slow handwriting. There also is no procedure in place to identify or serve students with language learning disability, which may account for more cases of specific learning disability than classic dyslexia or dysgraphia.

The Problem Is Lack of Knowledge, Not Lack of Money

Given the sociopolitical context in which we conduct our research (11 local schools have sued the state superintendent of education, director of special education, and governor because they do not think they have enough money to teach students who qualify for special education), we frequently remind educators that *there is nothing in the special education law that says it is illegal or unethical or unprofessional to help students with learning disabilities in the general education program by implementing research-supported assessment and teaching practices*. Although qualifying students for special education is sometimes an appropriate goal, some parents want appropriate diagnosis and services in general education. Unfortunately, schools are reluctant to accept the research-based definitions of learning disability (many of which have been shown to have a genetic or neurological basis) because they fear the state auditors will penalize them by decreasing their funding if they do not use the current legally mandated procedures even if they are not supported by research and children who have obvious reading or writing problems do not qualify under one of the existing legal definitions. Even though the federal regulations now require that science-based reading instruction be used in schools accepting No Child Left Behind funding, there are no regulations that support use of scientifically supported diagnostic categories for diagnosing or treating reading, writing, or math disabilities.

Although students with tier 3 problems benefit from specialized instruction, it is not cost-effective to provide *all* of their reading, writing, and math instruction in

pull-out programs. Therefore, students with these specific learning disabilities in reading, writing, math, or language learning should be given the option of a special section within general education taught by a qualified teacher who provides *explicit, language-based, intellectually engaging instruction*. Although affected individuals can learn to decode and read real words if given appropriate, explicit instruction, the underlying genetic basis for the disorder appears to exert its effects in different ways as affected individuals advance in schooling and the curriculum requirements change. Persisting spelling and written expression problems and silent reading fluency problems are typically observed in older students unless new kinds of instructional interventions are put in place. Unfortunately, many schools offer older students only accommodations rather than continuing explicit instruction aimed at fluent reading, spelling, and written expression and executive functions. Schools might benefit from a return to the flexible model of building-based, well-trained academic learning specialists who provide direct services and also collaborate with teachers to plan and implement differentiated instruction. Such an approach would necessitate more comprehensive teacher training in explicit instruction strategies (e.g., Cunningham, 1990) and domain knowledge relevant to literacy (e.g., Cunningham, Perry, Stanovich, & Stanovich, 2004; McCutchen & Berninger, 1999).

High-Stakes Tests

Based on the experiences of students in our research studies, we wonder whether the high-stakes tests, which are aimed at high-level thinking skills, are adequately assessing low-level decoding, word reading, fluency, handwriting, and spelling skills that can compromise performance on daily school assignments, whether or not students pass the high-stakes tests. (See Figure 11.1, which is a recent writing sample from an eighth grader who passed the high-stakes test in writing.)

Another issue is that high-stakes tests often require writing across all academic domains (reading, math, and writing; Jenkins et al., 2004). Many students who have writing rather than reading problems may perform poorly on these tests because, although they have the domain-specific knowledge, they lack adequate writing skills to express what they know. As one adolescent suicide survivor told me, "I am good at math [and individually administered psychometric tests support this

self-perception] and I can explain my math thinking by talking, but I cannot explain my math thinking in writing. I thought my life was over because I can do math but not write about it." Although federal initiatives emphasize the importance of research-supported reading instruction and now annual reading and math assessment, they have not yet included writing in that mandate for scientifically supported instruction and annual assessment. Many students who are failing in course work or achieving far below grade-appropriate levels are mistakenly thought to be not motivated; yet, when they are given tests of writing-related processes validated in research, they are typically shown to have undiagnosed and untreated writing disabilities (Berninger & Hidi, in press). Introducing research-supported writing interventions so that they can become successful in writing often transforms a reluctant writer into an able and willing writer.

Increasingly, students with learning disabilities are brought to our attention because they have not passed the high-stakes test or teachers fear they will not pass it. One of the worst cases we have encountered was the school who refused to listen to parents' concerns that their child was not learning to read during the early grades. Later, a teacher asked the parents to agree to a special education placement for learning disabilities so that the child's scores on the high-stakes test would not bring down her class average. According to the UWLDC assessment results, the child was a nonreader. Had tier 1 research-supported screening and early intervention been in place in this school, this child would probably not have had years of chronic failure and likely would have been a reader and writer. There are many more such stories that constantly remind us that there is still an enormous job yet to be done in educating educators about learning disabilities and effectively teaching students with learning disabilities.

PROFESSIONALS WHO PRACTICE THE THREE Cs: CARE, CONNECT, AND COMMUNICATE

Instructional Research Is Necessary but Not Sufficient

Basic laboratory research may not generalize to real-world settings. Therefore, when applying research results, the effectiveness of the implementation should also be evaluated on the basis of evidence. Achieving desired results in practice may well require both art as well as science. The art involves clinical skills for direct services

and consulting with other professionals (Rosenfield, 1987; Rosenfield & Gravois, 1996). Over the years, we have encountered many dedicated, competent professionals who work hard and effectively to help students with learning disabilities. At the same time, we have encountered many cases in which the students were not being served well and the schools were resistant to outside professional assistance in helping the students with learning disabilities.

Professional Approach

In our professional preparation program for psychologists, I emphasize the three Cs for effective clinical practice: *caring* about the individuals affected with learning disabilities, *connecting* with them and their families, and *communicating* effectively with parents and teachers regarding ways to help children with learning disabilities. This kind of professional practice, reflecting the spirit of federal legislation that guarantees the civil rights of children with educationally handicapping conditions, cannot be legislated. It involves opening one's heart to others (see "Open Hearts," the March 2 reflection in *Native Wisdom for White Minds*, Schaeff, 1995). Well-trained professionals, knowledgeable about scientifically supported assessment and instruction, able to open their hearts to care about the plight of children who learn differently because of biological influences (which make it harder but not impossible to learn) are as necessary as laws to optimize academic success during childhood and workplace success during adulthood of individuals with specific learning disabilities. Professionals who practice the three Cs develop collaborative rather than adversarial relationships with parents. Because the parents know that the educators care, there is no need to turn to lawyers who are not professional educators to resolve disputes. This emphasis on caring about others is consistent with progressive pedagogy that underscores the need to meet student strengths and needs (Barth, 2002; Bruner, 1966; Dewey, 1963) through caring (Noddings, 1992).

VISION OF APPROPRIATE EDUCATION FOR STUDENTS WITH LEARNING DISABILITIES

This chapter ends with a vision of what could be so that students like Susan, Sean, Sam, and Sharon do not come to a standstill, flounder, or agonize over why no one can teach them, or waste precious years of their lives be-

cause they learn in a different way. This vision does not require more money, but rather more creative and intelligent use of the limited resources available to schools so that they are not needlessly drained by expensive legal proceedings. What follows is implemented fully within general education, with building-level flexibility, and without special education auditors, paperwork, and legal procedures. Special education still exists to provide an appropriate education for students with more severe handicapping conditions, but those with dyslexia, dysgraphia, and language learning disability are appropriately diagnosed and served within the general education program in a manner that provides the specialized instruction they require.

To begin with, schools make greater use of the *language arts block*, during which all teachers at the same grade level or across grade levels teach language arts at the same time. In keeping with the continuum of explicit instruction discussed earlier in the chapter, each school designates at least one class or section at the elementary and middle school level for offering explicit, intellectually engaging reading and writing instruction for those who require, depending on grade level, highly explicit instruction for phonological, orthographic, and morphological awareness (see Figure 11.2, p. 426), alphabetic principle, word families, structure words, decoding, automatic word recognition, oral and silent reading fluency, reading comprehension, handwriting automaticity, spelling, compositional fluency, or genre-specific composing, including report writing, note taking, study skills, and test taking. Not all children require highly explicit instruction, but those with dyslexia, dysgraphia, and language learning disability and others need this option in the general education curriculum. (See Berninger, 1998, and Berninger & Richards, 2002, for the inspiring story of a special education teacher who organized such a language arts block in the general education program and showed that the children with learning disabilities who start out behind can reach the same literacy outcomes as their peers without learning disabilities if provided explicit, intellectually engaging instruction.)

The *role of the school psychologist* changes from giving a battery of tests for the sole purpose of deciding whether children qualify for costly pull-out, special education services, to that of assessment specialist (funded by general education) who serves two important roles in meeting the needs of students with learning disabilities. First, the school psychologist organizes a schoolwide screening and progress monitoring program. The purpose of the tier 1 screening is to identify those students who

are at risk for dyslexia, dysgraphia, language learning disability, or other developmental or learning problems. When children show indications of being at risk, the school psychologist shares this information with the general educator (and parents, to create collaborative rather than adversarial relationships) and uses problem-solving consultation skills (Rosenfield, 1987; Rosenfield & Gravois, 1996) to help the general educator provide differentiated instruction to meet individual students' instructional needs within a group setting. The school psychologist also assists with progress monitoring so that teachers, parents, and the children themselves know if they are making reasonable progress in specific reading and writing skills. Second, when a child is not making adequate progress in response to the initial intervention and possibly tier 2 additional intervention, the school psychologist then conducts tier 3 assessment and administers standardized tests, obtains a developmental history from parents, collects work samples, and observes the child in the classroom to determine if any of the differential diagnoses in the Appendix or others apply. The goal of diagnosis is to (a) understand why a child has struggled, (b) identify an educationally handicapping condition that qualifies the child for both explicit instruction and accommodation in the regular program, and (c) plan differentiated instruction for this student within the language arts section that is explicit, intellectually engaging, and appropriate for the diagnosis.

Had this kind of approach been in place, Susan would have been identified in the kindergarten and first-grade screening and given tier 1 supplementary reading and writing instruction in the general education program. By third grade, she would not have been at a standstill, but would probably have been flagged again in fourth grade for reading and writing rate and spelling problems and then again given supplementary instruction for those skills. Likewise, the teachers and psychologists would have realized that just because Sean has learned to decode and read with accuracy does not mean that his dyslexia no longer has implications for his instructional needs. Sean would have continued to receive explicit instruction in silent reading fluency, spelling, and written composition during the upper elementary grades until those skills were well developed. Sam (see Figure 11.1, p. 423) would not be begging for someone to teach him to read and write better. What is unfortunate in his case is that with appropriate intervention at school (supplemented with university assistance), Sam was reading and writing on grade level up through the end of elementary school. He lost relative ground when all explicit instruction in reading and

writing was eliminated in middle school, highlighting the necessity for *sustained explicit instruction across schooling for students with dyslexia and dysgraphia (and also language learning disability)*. Finally, Sharon's mother's pleas to have her assessed during the school years would not have been dismissed with the misguided assumption that she cannot possibly have a learning disability because she is bright. Her dyslexia would have been diagnosed and treated and she may even have fared better in learning a second language with specialized instruction; she would have graduated from college at the same time as her peers and found employment commensurate with a college education.

Translating this vision of research into practice requires keeping abreast of the rapidly expanding body of research on learning disabilities. It also requires common sense, caring, and commitment to educating all students, even those who pose more challenges because they do not learn as easily despite being intelligent. There is no teacher-proof curriculum that will bring about this vision. Achieving this vision will require developing more informed and collaborative relationships between educators and state legislators to pass legislation that affirms the professionalism of educators entrusted with bringing about this vision and delegates to them the responsibility of doing so.

APPENDIX WITH HALLMARK FEATURES FOR DIFFERENTIAL DIAGNOSIS

Inclusionary Hallmark Criteria for Dyslexia Constellation

- Verbal IQ (or Verbal Comprehension Factor) at least 90.
- Meets at least one of the following criteria (most will probably meet several):
 - Decoding or real word reading accuracy or rate is below the population mean and at least 1 *SD* (15 standard score points) below VIQ.
 - Oral reading accuracy or rate is below the population mean and at least 1 *SD* (15 standard score points) below VIQ.
 - Spelling is below the population mean and at least 1 *SD* (15 standard score points) below VIQ.
- Does not meet any exclusionary criteria related to other neurodevelopmental disorder, brain injury or disease, or psychiatric disorder, and is not an English-language learner.

Comorbidity Issues

Oral language milestones are normal during the pre-school years except in phonology. Rarely do the children who meet this criterion meet the criteria for ADHD specified in the *Diagnostic and Statistical Manual for Mental Disorders (DSM-IV)*, but they do show individual variation along a continuum of inattention (based on parental ratings).

Inclusionary Hallmark Criteria for Language Learning Disability Constellation

- Preschool history of some indicator of slower language milestones (first words, first sentences, early intervention in speech or expressive language).
- Performance IQ or Perceptual Organization Factor at least 90 (to reduce probability of confounding developmental neurogenetic disorders); WISC-III or WISC-IV VIQ may be below 90 (or Vocabulary sub-test below 8).
- Meets at least one of the following criteria (most will probably meet several):
 - Decoding or real word reading accuracy or rate at least 1 *SD* below the mean.
 - Oral reading accuracy or rate at least 1 *SD* below the mean.
 - Spelling at least 1 *SD* below the mean.
 - Oral or reading vocabulary at least 1 *SD* below the mean.
 - Reading comprehension at least 1 *SD* below the mean.
- Does not meet any exclusionary criteria related to other neurodevelopmental disorder, brain injury or disease, or psychiatric disorder, and is not an English-language learner.

Comorbidity Issues

The following indicators are typical: (a) slower preschool language milestones, (b) preschool motor milestones are possibly slower, (c) some oral language skills (morphological and syntactic awareness and sentence formulation) during the school-age years are outside the normal range, and (d) comorbid diagnosis of ADHD (especially Inattention), although the attention problems may be the result of language-processing problems.

Inclusionary Hallmark Criteria for Dysgraphia Constellation

- No preschool history of slower language milestones (first words, first sentences, early intervention in speech or expressive language) but may have preschool indicators of motor delays or dyspraxias or attentional difficulties.
- VIQ at least 90.
- Meets at least one of the following criteria (most will probably meet several):
 - Does not meet the criteria for dyslexia for word decoding, real word reading, or oral reading of passages.
 - Does meet one or more of the following criteria:
 - Handwriting is below the population mean and either at least 15 standard score points below VIQ or at least 1 SD below population mean.
 - Spelling is below the population mean and at least 15 standard score points below VIQ.
 - Does not meet any exclusionary criteria related to other neurodevelopmental disorder, brain injury or disease, or psychiatric disorder, and is not an English-language learner.

Comorbidity Issues

Does not tend to have slower language milestones during the preschool years or oral language skills during the school-age years that are outside the normal range. Some of these children meet *DSM-IV* criteria for ADHD and are more likely to have Hyperactivity symptoms (particularly impulsivity) than the other subtypes but also show signs of Inattention.

Note well: Some children meet the inclusionary criteria for more than one specific learning disability and may have combinations of dyslexia, dysgraphia, and/or language learning disability.

For developmental psychologists, mental retardation is a topic that is both old and new. On one hand, developmental research in mental retardation predates studies of most other applied topics. In the 1940s, Inhelder and Piaget (Inhelder, 1943/1968; Piaget & Inhelder, 1947) examined children with mental retardation to determine whether Piagetian sequences were traversed in universal, invariant order. At about the same time, Werner (1938, 1941) examined children with mental retardation to help develop his orthogenetic principle ("development proceeds from a state of relative globality . . . to a state of differentiation, articulation, and hierarchic integration"; 1957, p. 126). Even earlier, during the 1920s and 1930s, Vygotsky's "defectology"

studies used children with mental retardation to explore the developmental interplay between children and their surrounding cultural environments (Rieber & Carton, 1993; van der Veer & Valsiner, 1991).

Granted, mental retardation would probably not be considered central to the work of Piaget, Werner, or Vygotsky. Each theorist tackled many developmental phenomena; their studies of children with mental retardation generally occurred at the beginning of each theorist's career and were not sustained over time (Hodapp, 1998). Still, to varying extents, Piaget, Werner, and Vygotsky all realized that children with mental retardation could be used to apply, extend, and test out their theories.

Yet, despite these early explorations, in other ways mental retardation is a new topic for developmental psychology. Bluntly stated, many developmentally oriented researchers and practitioners feel that children with mental retardation are somehow less theoretically important or interesting, and that these children simply require instruction that presents less material at a slower pace. Partly reflecting this view, few training programs in developmental psychology or applied developmental psychology offer specializations in mental retardation or developmental disabilities. In journals such as *Child Development* and *Developmental Psychology*—even in the *Journal of Applied Developmental Psychology* and *Applied Developmental Science*—only a few articles feature children with mental retardation and their families. Mental retardation remains less prominent in both child development and applied child development.

To be fair, mental retardation's second-class status is not limited to developmental psychology. Mental retardation is also a part of—but not prominent in—many other disciplines. Mental retardation is the first disorder addressed in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (American Psychiatric Association, 1994, pp. 39–46), but holds only a minor place in psychiatry, child psychiatry, or clinical psychology (King, State, Shah, Davanzo, & Dykens, 1997; Routh, 2003). Similarly, special education exists but is not prominent in education. One could make similar observations about nursing, social work, genetics and clinical genetics, pediatrics, speech-language pathology, and a host of other disciplines. In each field, mental retardation exists as a subfield, but its place is not prominent.

And yet, this situation may be changing, for two reasons. First, increasing numbers of studies have moved from examining children with mental retardation to examining children with different types of mental retardation (Dykens & Hodapp, 2001). In contrast to prior years, we now have many more studies of children with Down syndrome, fragile X syndrome, Williams syndrome, Prader-Willi syndrome, and other of the 1,000+ genetic mental retardation disorders (Hodapp & Dykens, 2004).

These studies, in turn, are producing many new findings about these disorders. For example, certain genetic syndromes show particular, etiology-related cognitive or linguistic strengths or weaknesses. Others show etiology-related trajectories (or rates) of development in different areas, and still others have much higher rates

of particular maladaptive behaviors or co-occurring psychiatric conditions. Although we later detail these intriguing findings, suffice it to note here that different genetic mental retardation disorders show different, etiology-related behaviors.

Developmentally oriented researchers are among those intrigued by such findings. If, for example, individuals with a specific genetic disorder show particular strengths in one area (e.g., language) and weaknesses in another area (e.g., visual-spatial skills), what does this say about the “modularity” of intelligence? How do such profiles develop over time? Which environmental factors enter in, which neurological factors, when, in what ways, to what effect(s)? Just as, in prior decades, Piaget, Werner, and Vygotsky were intrigued by development in children with mental retardation, so are modern-day developmentalists interested in children with different types of mental retardation. Modern-day developmentalists are reaching out to such children to test, extend, and apply what we think we know about how development operates.

In addition to their importance to our theoretical understandings of human development, etiology-related behaviors also have implications for interventions. For this reason, parents, special and general educators, speech-language pathologists, and clinical psychologists and psychiatrists have all become increasingly excited about how etiology-related behavioral profiles might be used for intervention efforts. Consider the idea that children with certain genetic syndromes show etiology-related strengths in one area and weaknesses in another. If so, it may be possible to play to the child's strengths in terms of how or what information is presented. Although the application of research into practice has, until now, rarely been attempted, recent advances provide hope for more targeted, etiology-oriented types of special education services (Hodapp & Fidler, 1999).

A second reason for interest in mental retardation concerns the meaning of “development” to developmentally oriented professionals. Like the larger field of child development, developmentally oriented researchers in mental retardation increasingly examine the environments in which children with mental retardation develop. As they examine these environments, researchers and practitioners realize that environments can have both good and bad effects on children with mental retardation. Indeed, from an earlier perspective on parental and familial pathology, the field has recently noted that a range of child, parent, and family characteristics may

help or hinder the functioning of both the child with mental retardation and his or her family.

In a related way, developmentally oriented professionals are realizing just how little we currently know about the larger ecology of children with mental retardation. As in any child's development, the child with mental retardation interacts with many, outside-of-family systems, including the child's school, peers, and other environments. In mental retardation, these outside systems have changed drastically over the past few decades; indeed, one could almost argue that parents and families rearing children with mental retardation in 2005 face an entirely different social service world—with entirely different advantages and challenges—than did parents and families in 1980 or 1970 (Glidden, 2002).

From the perspective of both the child and the ecology, then, mental retardation constitutes an important area of applied developmental psychology. But as a topic that may be less known to many readers, we begin this chapter by briefly defining mental retardation, as well as describing issues of classification within the population itself. We then discuss findings arising from an approach that classifies children with mental retardation by genetic etiology. From such child-centered discussions, we proceed to developmental issues relating to parents, families, and larger ecologies. After discussing several research issues, we end this chapter with examples of preliminary interventions and remaining issues that such interventions entail.

DIAGNOSIS AND CLASSIFICATION

Before summarizing new findings, it is first necessary to define the term mental retardation and to present different ways of classifying these children. As noted in the discussion that follows, controversies arise in both the definition and classification of mental retardation. Such definitional and classificatory controversies are mainly examined as background for later, more expanded discussions of developmental findings and their applications.

Diagnosis

From the early 1960s on, definitions of mental retardation have included three basic factors. First, the person (child or adult) must display impaired intellectual functioning. Second, that person must show concomitant im-

pairments in adaptive behavior. Third, such intellectual and adaptive impairments should begin during the childhood years; thus, cognitive-adaptive impairments involving adult-onset diseases or accidents are not considered to involve mental retardation. These three basic principles are generally referred to as the three-factor definition of mental retardation.

Unfortunately, the specifics of all except the final criterion have been the subject of long-standing, often heated debate. Consider the first criterion, impaired intellectual functioning. In definitions from the 1960s (Heber, 1961), the IQ cutoff was placed at 85; that is, all persons with IQs below 85 were considered to have mental retardation. More recently, most definitional manuals have placed the IQ cutoff 2 standard deviations below the mean of 100 (i.e., IQ 70 or below). Even now, however, some influential systems (e.g., American Association on Mental Retardation [AAMR], 1992) have noted that the IQ cutoff should be placed at IQ 70 or 75 and below, which may have the unintended effect of vastly increasing the number of persons eligible for the diagnosis of mental retardation (e.g., MacMillan, Gresham, & Siperstein, 1993). In addition, all other controversies with intelligence tests apply, including whether IQ tests really measure intelligence and whether one can achieve a “culturally fair” IQ test.

Similarly, controversy also surrounds the second criteria. The idea is simple: Children or adults should be considered to have mental retardation only when, in addition to cognitive-intellectual deficits, these individuals also show impairments in their everyday, adaptive functioning. Directly following from the first tests of adaptive behavior during the 1950s (Doll, 1953), adaptive impairments have constituted an explicit diagnostic criterion in diagnostic-classificatory manuals from the early 1970s on (e.g., Grossman, 1973).

Again, the devil is in the details. What are the “correct” dimensions or factors of adaptive behavior? No one really knows. In one major test of adaptive behavior, the Vineland Adaptive Behavior Scales, Sparrow, Balla, and Cicchetti (1984) identify three domains: communication, daily living skills, and socialization. In the 1992 version of the AAMR's (1992) manual, 10 different domains are proposed: communication, self-care, home living, social skills, community use, self-direction, health and safety, functional academics, leisure, and work. In that same organization's more recent manual, three domains are proposed (conceptual, social, and practical adaptive skills; AAMR, 2002).

Factor analytic studies provide some help, but these findings are also not definitive. In general, studies reveal from two to seven factors of adaptive behavior, with a single primary factor accounting for most of the variance (Harrison, 1987; McGrew & Bruininks, 1989). Most researchers and practitioners therefore agree that mental retardation involves impaired intellectual and adaptive functioning. But problems arise when one specifies the nature of the construct, how it is to be measured, and what cutoff scores will bring about the diagnosis of mental retardation.

For our purposes, mental retardation should be diagnosed when a child or adult has an IQ below 70 and has impairments in adaptive behavior (as tested by the Vineland or other standardized instrument), and when onset occurs during the childhood years. Interested readers should refer to more detailed explanations and discussions (e.g., Switzky & Greenspan, 2003).

Classification: Three Approaches

Most people would agree that children and adults with mental retardation differ one from another. As before, the problem is exactly which classifications are most meaningful for research, intervention, or policy. In general, three approaches characterize attempts to classify individuals with mental retardation.

Degree-of-Impairment Approach

Over the years, most researchers and clinicians have employed a system that classifies persons with mental retardation by their degree of intellectual impairment. This classification system designates persons with mental retardation as mildly, moderately, severely, or profoundly retarded.

Although Table 12.1 describes each level, a few points should be made. First, the degree-of-impairment system has predominated in both research and practice over many years. Granted, names have changed over the years, and different fields use slightly different terms. Still, most professionals are familiar with categorizing mental retardation by the child's degree of impairment.

Second, although adaptive behavior is a part of mental retardation's three-factor definition, most professionals classify individuals by levels of intellectual, not adaptive, impairment. As noted in Table 12.1, individuals at identical IQ levels vary in their adaptive functioning. This variability in adaptive behavior is particularly common for individuals with mild (IQ 55 to 69) and

moderate (IQ 40 to 54) mental retardation; individuals with severe or profound mental retardation usually show closer ties of adaptive and intellectual impairments.

Third, the degree-of-impairment system says nothing about the causes of the person's mental retardation. Individuals with moderate mental retardation might have Down syndrome, Williams syndrome, another genetic disorder, fetal alcohol syndrome (FAS), anoxia at birth, or no clear cause for their mental retardation. The relevant issue pertains to the person's degree of intellectual

TABLE 12.1 Degree-of-Impairment Classification System

Mild mental retardation (IQ 55–70): This group constitutes as many as 90% of all persons with mental retardation (American Psychiatric Association, 1994). These individuals appear similar to typical individuals, and often blend into the nonretarded population in the years before and after formal schooling. As adults, some of these individuals hold jobs, marry, and raise families and are indistinguishable from nonretarded people. More persons with mild mental retardation come from minority and low socioeconomic (SES) backgrounds than would be expected from their numbers in the general population (Hodapp, 1994; Stromme & Magnus, 2000).

Moderate mental retardation (IQ 40–54): The second most prevalent group are those individuals who are more impaired intellectually and adaptively. More of these individuals are diagnosed as having mental retardation during the preschool years. Many individuals with moderate mental retardation show one or more clear organic causes for their mental retardation (e.g., Down syndrome, fragile X syndrome). Although some persons with moderate mental retardation require few supportive services, most continue to require some help throughout life. In one study, 20% of persons with IQs from 40 to 49 lived independently, 60% were considered dependent, and 20% were totally dependent on others (Ross, Begab, Dondis, Giampiccolo, & Meyers, 1985). In a similar way, some of these individuals hold jobs in the outside workforce as unskilled laborers, and others work in supervised workshop programs.

Severe mental retardation (IQ 25–39): This category refers to persons with more severe impairments. The majority of these individuals suffer from one or more organic causes of mental retardation. Many persons with severe mental retardation show concurrent physical or ambulatory problems; others have respiratory, heart, or other co-occurring conditions. Most persons with severe mental retardation require some special assistance throughout their lives. Many live in supervised group homes or small regional facilities, and most work in either workshop or "pre-workshop" settings.

Profound mental retardation (IQ below 25 or 20): In this group are persons with the most severe levels of intellectual and adaptive impairments. These persons generally learn only the rudiments of communicative skills, and intensive training is required to teach basic eating, grooming, toileting, and dressing behaviors. Persons with profound mental retardation require lifelong care and assistance. Most show organic causes for their mental retardation, and many have severe co-occurring conditions that sometimes lead to death during childhood or early adulthood. Some persons with profound mental retardation can perform preworkshop tasks, and most live in supervised group homes or small, specialized facilities.

impairment, not any causes or etiologies of the mental retardation per se.

Finally, controversy exists in that the 1992 edition of the AAMR's diagnostic and classificatory manual proposes to do away with this degree-of-impairment classificatory system. The AAMR asserts that the degree-of-impairment system does not give enough weight to the interplay between the individual and the environmental supports needed by that individual. Therefore, in that 1992 version (and again in the 2002 version), the AAMR instead categorizes individuals by the amount and length of the supportive services that they need. Instead of the mild-moderate-severe-profound distinction, the AAMR 1992 manual classifies individuals by their need for intermittent, limited, extensive, or pervasive environmental supports. Because these support levels somewhat relate (albeit imperfectly) to the person's degree of impairment, we ignore this modification, as do almost all researchers; the system appears in fewer than 2% of recently published behavioral research articles in the main mental retardation journals (Polloway, Smith, Chamberlain, Denning, & Smith, 1999).

Two-Group Approach

A second approach categorizes by the cause of mental retardation. An early form of this process is called the "two-group approach" to mental retardation. Formalized by Edward Zigler (1967, 1969) in the late 1960s, variants of this approach have existed from the early twentieth century (Burack, 1990). By the mid-1960s, researchers had long discussed two groups of persons with mental retardation.

Proponents of the two-group approach hold that the first group consists of persons who show no identifiable cause for their mental retardation. Such individuals are generally more mildly impaired and tend to blend in with other, nonretarded persons. Causes probably range from polygenic inheritance to environmental deprivation (or overstimulation); different persons may have different polygenic or environmental causes, or there may be an interplay between the two (Hodapp, 1994). This type of mental retardation has been referred to as familial, cultural-familial, or sociocultural-familial; nonorganic, nonspecific, or undifferentiated; and mental retardation due to environmental deprivation. Even this listing highlights the discrepant beliefs about the causes of mental retardation in these individuals.

In contrast to those with cultural-familial mental retardation, other individuals show one or more organic

causes for their mental retardation. Such causes include hundreds of separate organic insults. These insults can occur prenatally, perinatally, or postnatally. Prenatal causes include all of the 1,000+ genetic mental retardation disorders, FAS, fetal alcohol exposure (FAE), and rubella, as well as all accidents in utero. Perinatal causes include prematurity, anoxia at birth, and other birth-related complications. Postnatal causes range from sicknesses (meningitis) to head trauma. In addition, those with organic mental retardation are more likely to show greater degrees of intellectual impairments; in most surveys, as IQ levels decrease, increasingly higher percentages of persons show an identifiable organic cause (Stromme & Hagberg, 2000).

Etiological Approach

In many ways, classifying by specific etiology of the child's mental retardation updates the earlier two-group approach. Instead of examining a single organic group, one now begins to examine behavioral development in many different groups (Burack, Hodapp, & Zigler, 1988).

This more detailed etiological approach also reflects recent biomedical advances. In contrast to earlier years, when little was known about mental retardation's causes, more than 1,000 different genetic anomalies have now been linked to mental retardation (King, Hodapp, & Dykens, 2005). For most such disorders, we can go back and forth between the beginning point, the genetic anomaly itself, and the endpoint, the behavior that seems predisposed by having that specific genetic anomaly (as well as the many different medical and physical sequelae). Over the past few decades, we have come to realize that persons with different genetic disorders are prone to different behavioral characteristics. We now turn to genetic disorders' effects on behavior.

BEHAVIORAL PHENOTYPES: EXAMPLES, CONCEPTUAL ISSUES, AND DEVELOPMENTAL IMPLICATIONS

To provide a flavor of how genetic disorders affect behavior—the subfield of "behavioral phenotypes"—we first briefly describe Down syndrome, Prader-Willi syndrome, and Williams syndrome. From there we step back a bit, explaining what we mean by the term

behavioral phenotypes and highlighting that definition's most important features.

Down, Prader-Willi, and Williams Syndromes

Although one could choose as examples any of the 1,000+ genetic mental retardation syndromes, we here pick three: Down syndrome, Prader-Willi syndrome, and Williams syndrome. These three disorders are reasonably well-known and feature recent studies that have produced some interesting behavioral findings.

Down Syndrome

Caused in most cases by the occurrence of three (instead of two) chromosome 21s, Down syndrome is the best-known and the most prevalent genetic (i.e., chromosomal) abnormality, occurring once in every 800 to 1,000 live births. First described in 1866 by J. Langdon Down (see Dunn, 1991), Down syndrome has for many years been the focus of genetic and behavioral research.

Children with Down syndrome usually have characteristic physical features, including an epicanthic fold above the eyes (leading to the syndrome's original label, "mongolism"), a protruding tongue, short stature, and, during infancy, hypotonia (weak muscle tone). Down syndrome often occurs together with such medical conditions as heart defects, leukemia, and gut atresia (Leshin, 2002). Although in the past, persons with Down syndrome were often institutionalized and had a short life span, most individuals now live at home and medical treatments for all ages have increased the life span (Cohen, 2002). Down syndrome may be detected during pregnancy through chorionic villus sampling or amniocentesis; such procedures are usually recommended in women above age 35, who bear a substantially higher risk (Pueschel, 1990).

Three behavioral characteristics appear in most individuals with Down syndrome. The first involves a specific set of cognitive-linguistic strengths and weaknesses. In various studies, persons with Down syndrome appear particularly impaired in language. Such impairments, which are more pronounced than overall levels of mental age, occur in linguistic grammar (Chapman & Hesketh, 2000), in expressive (as opposed to receptive) language (Miller, 1999), and in articulation (Kumin, 1994). Conversely, persons with Down syndrome often show relatively higher performance on tasks of visual short-term memory, and the "visual-over-auditory" pattern of short-term memory seems to become more pro-

nounced beginning in the late teen years (Hodapp & Ricci, 2002).

A second behavioral issue involves the rate of development, with children with Down syndrome developing at slower rates as they get older. Most studies show that children with Down syndrome have their highest IQ scores in the earlier years, with gradually decreasing IQ as time goes on. These children continue developing, but at slower and slower rates as they get older (Hodapp, Evans, & Gray, 1999). Such slowings of development may relate to age-related changes or to difficulties these children have in achieving certain cognitive tasks (e.g., language; Hodapp & Zigler, 1995).

A third, possibly related change concerns Alzheimer's disease. It is now known that neuropathological signs of Alzheimer's disease appear to be universal in individuals with Down syndrome by age 35 (Wisniewski, Wisniewski, & Wen, 1985). Geneticists continue to explore the connection of Down syndrome with Alzheimer's and to learn more about pathological segments of chromosome 21 involved in overlapping conditions.

Case Example of a Young Adult Woman with Down Syndrome

Julie, a 21-year-old with Down syndrome, sits in the clinic with her mother. "It's just us," offers mother, "and we have our routines, but I am worried that she doesn't get out enough, like she used to in school." Julie did well in school, her reading and math skills were between the fourth- and sixth-grade levels, and Julie also had very well-developed daily living skills, especially in performing personal grooming and household chores. Julie chimes in, "Overland High School, I graduate," and with increased animation, starts to list the names of her former classmates. Her mother smiles and nods and adds that Julie was well-liked by her high school friends and was greeted warmly by students and teachers alike. Julie was always quick with a smile or an enthusiastic high-five, and much to her delight, received a standing ovation from her classmates at graduation!

But since then, things had not gone as well. The vocational training program that Julie was slated to attend after graduation had a long waiting list, and in the interim, Julie attended a social program three mornings a week. Her mother was concerned that this was not enough for Julie, that the program did not encourage Julie to practice or learn new academic skills, nor to interact with new friends. With her mother working full time,

most of Julie's days were spent watching TV alone at home and helping to take care of a neighbor's cat. Julie has lost some of her "sparkle," complained her mother, and she was also becoming a bit more "into herself" and passive, not to mention overweight.

Ultimately, the clinic staff, Julie, and her mother agreed on a plan of action. The social worker would check on the status of the vocational program, and should the wait be excessive, identify alternative training programs that met for at least 5 hours a day. The idea of an advocate was raised, although Julie's mother declined the need for one. Julie offered that she wanted to take care of more cats, and she and her mother agreed to explore the possibility of volunteering at a local animal shelter. Julie and her mother agreed to try to take walks after dinner, and Julie, once an avid swimmer, was encouraged to reenroll in the Special Olympics swimming program.

Julie's story demonstrates several concerns for persons with Down syndrome and other young adults:

- The difficulties families face when services are no longer provided at school
- The need for families to advocate for quality adult services
- The propensity for adults with Down syndrome to become more sedentary and withdrawn
- The need for innovative programs that foster lifelong learning in adults with mental retardation (adapted from Hodapp & Dykens, 2003)

Prader-Willi Syndrome

Prader-Willi syndrome is caused by missing genetic material from the chromosome 15 derived from the father—either a deletion on the paternally derived 15 or two chromosome 15s from the mother (maternal uniparental disomy). Most individuals with Prader-Willi syndrome are short in stature (about 5' in adulthood) and show extreme hyperphagia (overeating). Such hyperphagia (and resultant obesity) have long been considered the hallmarks of Prader-Willi syndrome, and most cases of early death in the syndrome relate to obesity and its related heart and circulatory problems (Butler et al., 2002; Whittington et al., 2001).

In addition to hyperphagia, many individuals show high levels of many different maladaptive behaviors. Along with hyperphagia, many persons with Prader-Willi syndrome also show temper tantrums and other acting-out

behaviors. Dykens, Leckman, and Cassidy (1996) also showed the very high presence of obsessions and compulsions in this group. In both children and adults with Prader-Willi syndrome, non-food-related obsessions and compulsions occurred at similar levels among nonretarded children and adults who had been clinically diagnosed with obsessive-compulsive disorder.

Intellectually, most children with Prader-Willi syndrome show relative weaknesses on tasks involving consecutive, step-by-step order in problem solving, or sequential processing. In contrast, these children perform well on tasks requiring integration and synthesis of stimuli as a unified whole, or simultaneous processing (Dykens, Hodapp, Walsh, & Nash, 1992). Dykens (2002) has recently found that many individuals with Prader-Willi syndrome demonstrate particularly high-level abilities in jigsaw puzzles. Such high levels in jigsaw puzzles are, on average, even above those shown by typical children of comparable chronological ages. Why such spared areas of functioning occur remains unknown, nor are we currently clear about whether these children's skills in jigsaw puzzles are specific to this single task or instead reflect a more general visual-spatial ability.

Case Example of a Boy with Prader-Willi Syndrome

"We have reached the point where we need to lock." Jake, age 11 years, was busy at the table, working at a puzzle, while his mother brought the clinic team up to date on Jake's diet. Jake was diagnosed with Prader-Willi syndrome shortly after birth and has since demonstrated the classic features of the syndrome: hypotonia in infancy, delayed milestones, and a marked interest in eating and food that began at about age 5. From preschool on, Jake had a "stubborn" streak that evolved into a more pervasive insistence that certain things be "just so," such as his collection of airplane books and book bag. Jake was also now having troubles at school because he insisted on erasing and reworking his letters to the point where he wore holes through the paper and couldn't move on to the next activity.

Further, adds his mother, his food seeking is much worse. Although the clinic staff had previously discussed with the family the possibility of locking the cabinets and refrigerator, the family had not yet felt the need to do so; they could manage Jake's food seeking with a watchful eye from parents and older sister. Now,

though, Jake's weight was creeping up, as were instances of food snitching at home and school.

"Now that we are locking," notes Jake's mother, "he asks about food less and less, and it relieves his older sister, who is 15, from being the 'food police.' If he knows that he can't get into it, he is more apt to get involved with other things, like his puzzles." Indeed, Jake, who has just completed a 50-piece puzzle with remarkable speed, looks up with a grin. "This one was easy," he boasts. "I thought you said you had hard puzzles!"

As suggested by this brief case, many youngsters with Prader-Willi syndrome show a host of behavioral concerns, especially hyperphagia and compulsions. For children like Jake, the management of diet and behavior needs to be carefully coordinated between school and home, and later between work and home (or group home). As families struggle to maintain a low-calorie diet, managing their offspring's compulsive behaviors and tantrums are often more stressful for them. As Jake demonstrates, however, many persons with Prader-Willi syndrome have relatively well-developed expressive vocabulary and visual-spatial strengths, especially in solving jigsaw puzzles. In Jake's case, the school teacher and staff used special "puzzle time" at school as an incentive for letting go of his rewriting and erasing and to make easier transitions.

Williams Syndrome

Occurring in about 1 per 20,000 births, Williams syndrome is caused by a microdeletion on one of the chromosome 7s that includes the gene for elastin, a protein that provides strength and elasticity to tissues of the heart, skin, blood vessels, and lungs (Ewart et al., 1993). Children with this syndrome generally show a characteristic, "elfin-like" facial appearance, along with heart and other health problems (Dykens, Hodapp, & Finucane, 2000). As many as 95% of these children suffer from hyperacusis, or a hypersensitivity to sound.

Williams syndrome is best known for its cognitive-linguistic profile. Specifically, children with Williams syndrome appear strikingly good at many linguistic tasks. Indeed, earlier studies even hinted that these children might be able to perform linguistically at or nearly at levels shown by nonretarded age-mates (Bellugi, Marks, Bahrle, & Sabo, 1988). Recent studies dispute this finding, showing that only about 5% of children with Williams syndrome seem spared in language abilities (Bishop, 1999; Mervis, Morris, Bertrand, & Robinson, 1999). Still, language skills are relatively strong

(compared to overall mental age) in children with Williams syndrome.

In contrast, many children with Williams syndrome perform poorly on visual-spatial measures (Udwin & Yule, 1991; Udwin, Yule, & Martin, 1987), including such tasks as putting together a jigsaw puzzle and drawing (Bellugi, Wang, & Jernigan, 1994; Dykens, Rosner, & Ly, 2001). These children seem to have difficulties in "constructive visuo-spatial skills": visuospatial activities requiring one to mentally put together an object's various pieces or parts. In addition, the discrepancies between the higher-level language skills and the lower-level language abilities appear to become increasingly pronounced as children get older (Jarrold, Baddeley, Hewes, & Phillips, 2001).

In contrast to work on cognitive-linguistic profiles, studies have yet to fully examine the personality or psychiatric features of people with Williams syndrome. Early descriptions hinted at a "classic" Williams syndrome personality, described as pleasant, unusually friendly, affectionate, loquacious, engaging, and interpersonally sensitive and charming (e.g., Dilts, Morris, & Leonard, 1990). Such qualities may change over the course of development, with adults being more withdrawn and less overly friendly than children (Gosch & Pankau, 1997).

Recent findings expand these observations. Using the Reiss Personality Profiles (Reiss & Havercamp, 1998), Dykens and Rosner (1999) found that, relative to controls, adolescents and adults with Williams syndrome are more likely to initiate interactions with others (87% of sample), to enjoy social activities (83%), to be kind-spirited (100%) and caring (94%), and to empathize with others' positive feelings (75%) or when others are in pain (87%). At the same time, however, these subjects had difficulties making or keeping friends and were often dangerously indiscriminate in their relating to others.

Recently, attention has also begun to focus on anxieties and fears in this population. Generalized anxiety, worry, and perseverative thinking are commonly seen in Williams syndrome (e.g., Einfeld, Tonge, & Florio, 1997), and people with the syndrome appear to show unusually high levels of fears and phobias. Relative to suitably matched controls, fears in persons with Williams syndrome are more frequent, wide-ranging, and severe and are also associated with impaired social-adaptive adjustment. In one study, Dykens (2003) compared fears in 120 people with Williams syndrome (ages 6 to 48

years) to those with mental retardation of mixed etiologies. Only two fears, getting a shot and going to the dentist, were mentioned by over 50% of the group with mixed causes of mental retardation. In contrast, 50 different fears were mentioned by over 60% of subjects with Williams syndrome. Such fears ran the gamut. Some involved interpersonal issues such as being teased, getting punished, or getting into arguments with others; others involved such physical issues as injections, being in a fire or getting burned, or getting stung by a bee; still others related to these children's hyperacusis or clumsiness (loud noises/sirens, falling from high places, thunderstorms). Though not every person with Williams syndrome shows one or all of these fears, the vast majority seem overly fearful compared to most others with intellectual disabilities.

Case Example of a Teenage Girl with Williams Syndrome

Susie, a highly energetic 14-year-old with Williams syndrome, declared with great enthusiasm, "Why, everyone is my friend!" Indeed, so it seemed to her parents, who were both tickled and worried by their daughter's quest to interact with everyone they met. On the one hand, they loved her sociable nature; on the other, they worried about her poor social judgment and vulnerability as she entered adolescence.

Diagnosed with Williams syndrome at 10 months of age, Susie had come through corrective heart surgery and an infancy marked by fussiness and feeding difficulties. At around age 3, however, Susie "came around," and her language and interest in the world took off. She stared intently at the faces of teachers and therapists, an endearing quality that adults loved. After a period of language delay, she quickly caught up, and on formal testing as a first-grader, Susie's vocabulary skills exceeded her overall cognitive abilities. Although her educational testing also showed that Susie had poorly developed visual-spatial abilities, this had always been less a source of worry for her parents than her increasing anxiety and social disinhibition.

Increasingly, Susie frets and worries about things—what will happen next, or what if the car breaks down or her piano teacher has a heart attack. Her father affectionately calls her his "worrywart." Even so, her anxiety can get out of hand at times, but never to the point that it stops her from getting in the car or taking her piano lesson. Along with her growing anxiety, Susie has a grow-

ing interest in music. She is persistent at the keyboard, yet not necessarily "gifted" in the way that some persons with Williams syndrome seem to be. She simply loves music and often hums tunes to herself as she plunks at the piano, what she herself calls "my creative me in motion." Her father observes that this activity seems to calm her down and helps her to settle for the night. Recently, Susie has asked to try another instrument so that she can play in the school band, or to join the glee club, so that she can sing with others.

Susie thus demonstrates many of the key behavioral features of Williams syndrome:

- Well-developed expressive language
- A strong social orientation coupled with poor social judgment and disinhibition
- A worried, fretful stance
- An interest in music that may or may not reflect remarkable "talent" but that is emotionally compelling and gratifying

Concepts and Issues

Although these descriptions provide a quick sense of etiology-related behavioral characteristics in three syndromes, we have left until now several conceptual issues concerning the nature and study of behavioral phenotypes.

The first issue is one of basic definition. While interest in behavioral phenotypes has increased enormously over the past 2 decades, the very term itself has been debated widely. What is a behavioral phenotype? To us, a behavioral phenotype involves "the heightened probability or likelihood that people with a given syndrome will exhibit certain behavioral and developmental sequelae relative to those without the syndrome" (Dykens, 1995, p. 523). In contrast to other definitions, such a definition focuses on probabilities, the idea that genetic disorders predispose those who have them to a greater chance or likelihood of showing a particular behavior or set of behaviors. Compared to groups with mental retardation in general (arising from any number of other causes), groups with a particular genetic cause will show certain behaviors to a greater extent or in a higher percentage of individuals. Such behaviors might be a particular pattern of cognitive-linguistic strengths and weaknesses, or a particular age at which development slows, or a particular type of maladaptive behavior.

This more probabilistic definition highlights three basic facts, which we discuss next.

Many, but Not All, Individuals Show the Syndrome's "Characteristic" Behaviors

A more probabilistic definition acknowledges the large amount of variance within specific etiologies. Rarely are etiology-related behaviors found in every person with a particular syndrome. Consider the case of Down syndrome. Even compared to their overall mental age, children and adults with Down syndrome generally show deficits in linguistic grammar (Fowler, 1990) and often show receptive language abilities in advance of expressive abilities (Miller, 1999). In addition, approximately 95% of mothers of children with Down syndrome report that others have difficulty understanding their child's articulation of words and phrases (Kumin, 1994).

Yet, despite such commonly observed deficits, not every person with Down syndrome shows particular difficulties with grammar, articulation, or expressive language. Rondal (1995) reported on the case of Françoise, a 32-year-old woman whose IQ is 64. Although Françoise has trisomy 21, she nevertheless utters long and complex sentences. Rondal reports her saying (translated), "And that does not surprise me because dogs are always too warm when they go outside" ("Et ça m'étonne pas parce que les chiens ont toujours trop chaud quand ils vont à la port"; p. 117). Although grammatical, articulatory, and expressive language problems may be common in Down syndrome, not every person with the syndrome shows such behavioral characteristics.

Some Etiology-Related Behaviors Are Unique to a Single Syndrome, Others Are Common to Two or More Syndromes

A more probabilistic definition's second corollary involves the Uniqueness Question (Pennington, O'Connor, & Sudhalter, 1991): To what extent is any etiology-related behavior or pattern of behaviors unique to a single syndrome, as opposed to being shared by a few genetic disorders?

At this point, both unique and partially shared behavioral phenotypes occur, although partially shared phenotypes are probably more common (Hodapp, 1997). Considering unique or totally specific behavioral outcomes first, the following behaviors seem unique to a single syndrome:

- Extreme hyperphagia (Dykens, 1999) in Prader-Willi syndrome
- The "cat cry" (Gersh et al., 1995) in 5p- syndrome (formerly called cri-du-chat—or cry of the cat—syndrome)
- Extreme self-mutilation (L. T. Anderson & Ernst, 1994) in Lesch-Nyhan syndrome
- Stereotypic hand washing or hand wringing (Van Acker, 1991) in Rett syndrome
- Body self-hugging (Finucane, Konar, Haas-Givler, Kurtz, & Scott, 1994) and putting objects into bodily orifices (Greenberg et al., 1996) in Smith-Magenis syndrome

In contrast to what seems likely to remain a fairly short list, many more instances will probably be discovered in which partial specificity is at work. To give but a few examples, a particular advantage in simultaneous (i.e., holistic, Gestalt-like) processing compared to sequential (step-by-step) processing has now been found in children with Prader-Willi syndrome (Dykens et al., 1992) and in boys with fragile X syndrome (Dykens, Hodapp, & Leckman, 1987; Kemper, Hagerman, & Altshul-Stark, 1988). Similarly, compared to groups with intellectual disabilities in general, hyperactivity is more frequently found in children with 5p- syndrome (Dykens & Clarke, 1997) and in boys with fragile X syndrome (Baumgardner, Reiss, Freund, & Abrams, 1995). In both instances, a pattern of strengths and weaknesses or a particular type of maladaptive behavior-psychopathology is found in a few genetic disorders to much greater degrees (or in higher percentages of individuals) than is commonly noted among others with mental retardation.

Finally, partially specific behavioral effects seem more in line with many areas of genetics, child psychiatry, and psychiatry. Across these different disciplines, researchers are now discussing the many pathways, both genetic and environmental, by which one comes to have one or another psychiatric disorder. The clinical geneticist John Opitz (1985, p. 9) put it well when he noted, "The causes are many, but the common developmental pathways are few."

Etiology-Related Behaviors Occur across Many Behavioral Domains

When considering behavioral phenotypes, most researchers probably think of salient maladaptive behaviors. We therefore see a keen interest in hyperphagia, obsessive-compulsive disorder, and tantrums in Prader-

Willi syndrome; autism or autism-like behavior in fragile X and Rett syndromes; and extreme self-mutilation in Lesch-Nyhan syndrome. To many professionals, the term “behavioral phenotypes” connotes the different, etiology-related maladaptive behavior-psychopathology seen in several syndromes.

Without discounting the excitement brought about by the study of etiology-related maladaptive behavior and psychopathology, behavioral phenotypes also involve many other domains of functioning. Thus, etiology-related strengths and weaknesses occur in language, cognition, and social and adaptive behaviors and within specific subdomains. Etiology-related profiles of strengths and weaknesses also exist across these various domains and show distinct patterns of development. One could also examine sequences across various developmental domains to determine whether early language, social, emotional, or cognitive development (or developments within subareas of each; e.g., theory of mind) show the “usual” or normative orderings. Rates of development are also open to etiology-related analyses. In short, we envision the purview of behavioral phenotypes as very large indeed, and sample from this large purview in the next section.

DEVELOPMENTAL IMPLICATIONS

Although one could discuss many different developmental issues, we here examine sequences, cross-domain relations, and how those cross-domain relations might change with increasing chronological age.

Sequences

From Piaget on, developmentalists have been interested in identifying universal, invariant sequences of development. Similarly, from the 1960s on, usual or normative developmental sequences have been linked to children with mental retardation. In Zigler’s (1967, 1969) original developmental approach to mental retardation, he described what came to be known as the “similar sequence hypothesis.” This hypothesis held that children with mental retardation, like children who are typically developing, will traverse Piagetian, early language, or other universal developmental sequences in the same, invariant order.

But even in Zigler’s earliest formulations, the similar-sequence prediction was also tied to the child’s

type of mental retardation. In contrasting cultural-familial from organic forms of mental retardation, Zigler (1969) held that only children with cultural-familial mental retardation would necessarily show sequences in their development similar to that of nonretarded children. In contrast, he was unclear as to whether normative developmental processes applied to children with organic forms of mental retardation. To quote Zigler:

If the etiology of the phenotypic intelligence (as measured by an IQ) of two groups differs, *it is far from logical* to assert that the course of development is the same, or that even similar contents in their behaviors are mediated by exactly the same cognitive processes. (p. 533, emphasis added)

To date, however, the findings generally support the similar sequence hypothesis for most children with mental retardation (of either cultural-familial or organic forms). Several reviews indicate that most children, on most developmental tasks, do seem to progress in the usual, invariant order (Hodapp, 1990; Weisz, Yeates, & Zigler, 1982). Possible exceptions involve children with severe seizure disorders, but here difficulties arise in relation to what constitutes a valid test of these children’s abilities. Children with mental retardation may also become less systematic or differently sequential when tasks are more social—or occur later in development—as opposed to these children’s more usual, invariant sequential development on earlier and less social tasks (Hodapp, 1990).

Until recently, such findings have generally characterized the similar sequence hypothesis. But over the past few years, it has become apparent that not all developments occur in the usual, invariant order in every genetic etiology. Specifically, consider the finding that young, typically developing children usually show pointing before labeling in their earliest communications. Most 10- to 12-month-olds will gesturally point to or show an object in order to get adults to attend (what Bates, Camaioni, & Volterra, 1975, call “proto-declaratives”), achieving the appropriate verbal labels only sometime during their 2nd year of life. But Mervis, Robinson, Rowe, Becerra, and Klein-Tasman (2003) have recently reported that this sequence of pointing before speaking was not found in 9 of 10 children with Williams syndrome. On average, these 9 children with Williams syndrome produced referential object labels (“ball”) 6 months before beginning to comprehend or produce referential pointing gestures. As we note later,

this finding makes sense given the relatively strong linguistic skills and relatively weak visuospatial skills shown by most children with William syndrome. Still, such findings are interesting and have many theoretical and practical implications.

Cross-Domain Relations

Cross-domain relations in children with mental retardation also feature a long history. In addition to his similar sequence hypothesis, Zigler (1969) also proposed what came to be called the “similar structure hypothesis.” This hypothesis implicitly drew on developmental theories of the 1960s that asserted that children’s development was “all of a piece,” that a child’s level of development in one area (e.g., language) was roughly equal to that same child’s development in all other areas (e.g., cognitive, social). And again, Zigler explicitly applied this similar structure hypothesis only to children with cultural-familial mental retardation.

This time, the findings seem clearer. The similar structure hypothesis holds up reasonably well for children with cultural-familial mental retardation, although even here children display performance that is below overall mental age levels on some attentional and information-processing tasks (Weiss, Weisz, & Bromfield, 1986). Less clear is why such lower than expected functioning occurs. Some researchers have postulated that children with cultural-familial mental retardation really do have a deficit in their information-processing abilities (Mundy & Kasari, 1990); conversely, any seeming deficit may be due more to the boring, repetitive nature of many information-processing tasks (Weisz, 1990).

In contrast, all would agree that children with organic mental retardation show performance on several cognitive-linguistic tasks that falls below their overall mental age. As noted earlier, the specifics of such deficits vary widely. Summarizing from our earlier discussions, the following characterize the cognitive-linguistic profiles of children with Down syndrome, Prader-Willi syndrome, and Williams syndrome:

- *Down syndrome:* Children with Down syndrome show relative strengths in visual versus auditory short-term memory (Hodapp et al., 1999; Pueschel, Gallagher, Zartler, & Pezzullo, 1986), as well as weaknesses in expressive language and in grammar (Chapman & Hesketh, 2000; Miller, 1999).
- *Prader-Willi syndrome:* In addition to showing abilities in simultaneous, or holistic (Gestalt), processing rela-

tive to sequential, step-by-step processing (Dykens et al., 1992), children with Prader-Willi syndrome solve jigsaw puzzles at levels well above both mental age-matched children with mental retardation and chronological age-matched, typically developing children (Dykens, 2002).

- *Williams syndrome:* Children with Williams syndrome show extreme weaknesses in many visuospatial tasks, even as they show relative strengths in several areas of language (Bellugi, Mills, Jernigan, Hickok, & Galaburda, 1999; Mervis et al., 1999).

Such findings obviously lead to many new questions. Given that each syndrome has a different pattern of strengths and weaknesses, how does one divide up cognitive functioning? Examining only Down syndrome, one might conclude that intelligence is divided into visual versus auditory short-term memory, or into linguistic versus nonlinguistic functioning. If one were instead to examine the other two syndromes, then simultaneous versus sequential processing (in Prader-Willi syndrome) or linguistic versus visuospatial functioning (Williams syndrome) might seem the preferred way of cutting up the intellectual pie. At this point, no one can say for certain, but findings from genetic syndromes definitely must be included when considering the possible connections and disconnections among diverse areas of human functioning.

A second issue concerns connections among various domains. Particularly in earlier studies, language functioning was thought to be modular in Williams syndrome. Modularity, in Fodor’s (1983) sense, refers to an encapsulated system that develops with little or no contact with other of the child’s developments (see also Gardner’s, 1983, multiple intelligences). But unlike what might be predicted from a modular perspective, Mervis et al. (1999) found strong correlations (from .47 to .64) between various measures of short-term memory and grammatical levels. Although language is relatively strong—and visuospatial skills weak—in Williams syndrome, the language of these children is also not totally modular. In line with typically developing children, language in children with Williams syndrome connects to other areas of these children’s cognition.

Cross-Domain Relations over Age

Although etiology-related strengths and weaknesses do not appear fully formed at birth, how such strengths and weaknesses appear has only begun to be examined. Dur-

ing the past few years, several researchers have examined cognitive-linguistic profiles over time in children with several different etiologies of mental retardation. Most such studies have been cross-sectional, although a few recent studies have examined evolving profiles as the child develops.

Across several etiological groups, with increasing chronological age the children's strengths develop more quickly than do their weaknesses. In Down syndrome, the pattern of visual over auditory short-term memory becomes more pronounced during the late teen years (Hodapp & Ricci, 2002), and, among boys with fragile X syndrome, the advantage of simultaneous over sequential processing also becomes more pronounced as these children get older (Hodapp, Dykens, Ort, Zelinsky, & Leckman, 1991). In the sole longitudinal study, Jarrold et al. (2001) examined children with Williams syndrome to determine the development in vocabulary (a relative strength in this syndrome) versus visuospatial skills (a relative weakness). Examining 15 children/adolescents on six occasions over a 4-year period, Jarrold et al. found that vocabulary levels developed much more quickly over time than did visuospatial skills. Figure 12.1 illustrates developmental trajectories by plotting age-equivalent (mental age-like) scores for both vocabulary and visuospatial abilities, averaged over all children and

all testings. Such divergent trajectories allow already existing relative strengths to become gradually stronger and relative weaknesses gradually weaker as these children get older.

Although no good explanations exist as to why strengths become stronger and weaknesses weaker over time, one possibility involves an interplay between the child's etiology-related propensities and subsequent experiences. One measure of experience involves the child's everyday, leisure-time activities, that is, those behaviors that children (or their parents) choose to perform every day. In one study, Rosner, Hodapp, Fidler, Sagun, and Dykens (2004) examined the everyday leisure activities of three groups of children: those with Williams syndrome, those with Prader-Willi syndrome, and those with Down syndrome. Using parent reports of leisure-time behavior from Achenbach's (1991) Child Behavior Checklist, behaviors were grouped into those involving music, reading, visual-motor activities, athletics, pretend play, and focused interests.

Our findings mostly reflect etiology-related strengths and weaknesses. In line with their excellent skills in jigsaw puzzles, a full 50% of children with Prader-Willi syndrome played with jigsaw puzzles, whereas only 9% and 2%, respectively, of persons with Down syndrome and Williams syndrome engaged in this activity. Conversely, in line with their visuospatial weaknesses, children with Williams syndrome did not engage in visuospatial activities. In the overall category of visual-motor activities, only 31% of the sample with Williams syndrome participated in any visual-motor activities, compared to 76% and 60% of persons with Prader-Willi and Down syndromes, respectively. Specific behaviors such as arts-and-crafts activities were listed in 35% of the group with Down syndrome and in 30% of individuals with Prader-Willi syndrome, but in only 7% of those with Williams syndrome. Persons with Williams syndrome (or their parents) seem to be avoiding activities that these children may find difficult to perform.

Our suspicion is that genetic etiologies predispose children to particular cognitive-linguistic profiles, but that these profiles then become more pronounced due to the child's ongoing experiences. For most syndromes, the degree of difference between levels of "strong" versus "weak" areas is probably relatively small during the early years. As children more often perform activities in strong areas and avoid activities in weaker areas, however, increasing discrepancies arise. A snowball effect may thus result from the interplay of the child's

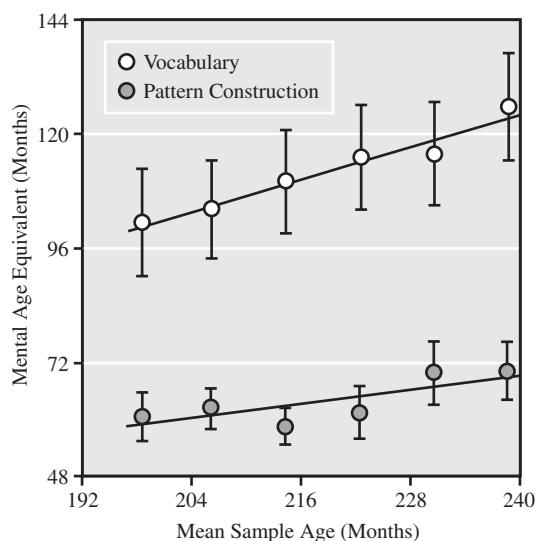

Figure 12.1 Average vocabulary and pattern construction ages at 6 time points (average best fit lines). *Source:* From "A Longitudinal Assessment of Diverging Verbal and Non-Verbal Abilities in the Williams Syndrome Phenotype," by C. Jarrold, A. D. Baddeley, A. K. Hewes, and C. Phillips, 2001, *Cortex*, 37, pp. 423–431.

etiology-related propensities and the child's ongoing transactions with the environment. Such views also seem consonant with the late-appearing gestures (as opposed to verbal labels) in the early communication of children with Williams syndrome (Mervis et al., 2003). For now, how etiology-related profiles evolve is relatively unknown, and much more work is needed.

Summary

Beginning with several tricky definitional and classificatory issues, this section explored the many interesting issues and findings relating to children with mental retardation. The most provocative findings relate not to development in children with mental retardation per se—or even to children with cultural-familial versus organic forms—but instead to children with different genetic syndromes of mental retardation.

As we examine these syndromes in more fine-grained studies, the old, familiar senses of development are giving way to more intricate, nuanced understandings. Although the usual or normative developmental sequences appear for most children with mental retardation in most domains, such is not always the case. With their relative weakness in visuospatial abilities, children with Williams syndrome violate the usual ordering by not engaging in communicative gestures (i.e., pointing and showing) in their earliest communications, behaviors that are simple and early occurring for typically developing children.

In the same way, cross-domain relations become complicated when one considers children with different types of mental retardation. Many children, both typical and with mental retardation, show areas of stronger and weaker development, but here we see specific, etiology-related profiles. As a group, children with Williams syndrome show relative strengths in many linguistic tasks, while they simultaneously demonstrate relative weaknesses in many visual-spatial tasks. Children with Down syndrome show linguistic (particularly grammatical and expressive) weaknesses, as well as etiology-related strengths in visual (as opposed to auditory) short-term memory. In several syndromes, already existing patterns of strengths and weaknesses then become more pronounced, and environmental, genetic, or other factors all seem implicated.

In short, children with Prader-Willi, Down, Williams, and other genetic syndromes are telling us much about how development operates. Partly for this

reason, the amount of behavioral research on these disorders has exploded during the past few years (Hodapp & Dykens, 2004), and a wide array of developmental psycholinguists, cognitive developmentalists, and others have been drawn to children with these intriguing syndromes. Just as children who have been adopted, are twins, have experienced maternal deprivation, or are otherwise “natural experiments” all tell us much about typical developmental processes (Rutter, Pickles, Murray, & Eaves, 2001), so, too, do we learn from the behavioral development of children with different genetic forms of mental retardation. We are gradually learning more specifically how atypical development informs typical development (Cicchetti, 1984), an approach first advocated (in more primitive forms) by Piaget, Werner, and Vygotsky.

CONTEXTUALIST VIEWS OF DEVELOPMENT: INTERACTIONS, TRANSACTIONS, ECOLOGIES

In our discussions so far, we have considered development only in its organismic, child-related sense. But as developmentalists have increasingly realized over the past 40 years, development also involves children's larger environments and ecologies. From the late 1960s on, a major strand in developmental psychology has highlighted the child's ongoing interactions and transactions with others. Bell (1968), Sameroff and Chandler (1975), Bronfenbrenner (1979), and others may each focus on slightly different aspects of the child's interactions and transactions with the world, but each highlights ways in which child-environment interactions are important and worthy of study.

Such changes in the intellectual landscape have also influenced developmentally oriented studies of children with mental retardation. Although Zigler's original developmental approach to mental retardation focused mainly on child-related aspects of development, developmentally oriented research from the 1980s on has included parents, families, siblings, and other outside-of-the-child influences. Granted, such studies are newer and less advanced than is similar work in developmental or applied developmental psychology. Still, mother-child interaction, families, and ecologies definitely persist as ongoing, important areas of developmentally oriented mental retardation research (Hodapp & Zigler, 1995).

Before discussing such work, we provide a brief theoretical background. In contrast to more child-centered discussions, we here need to adapt several well-known, contextualist developmental perspectives in light of issues specific to children with mental retardation and their families.

Issues Specific to Mental Retardation

When thinking about the interactions and transactions with various environments over time of children with mental retardation, we need to consider issues of socialization and interaction, parental reactions, history of the mental retardation field itself, and the changing ecology of mental retardation.

Socialization-Interaction

From the late 1960s until today, those interested in parent-child relations have generally adopted one of two perspectives. In the first, or socialization, perspective, parents influence children. Parents directly instruct, model, reward, punish, and encourage or discourage their children at certain times and in certain ways, and children undoubtedly are affected as a result. The most well-known example of socialization probably involves Baumrind's (1973, 1989) studies of the effects of parent socialization styles on children's later adjustment. Parents can also be thought of as indirectly engineering their children's environments by living in certain neighborhoods, choosing certain schools, making friends with certain families, and exposing their children to some, but not other, environments and experiences. In each instance, the direction of causality goes from the parent to the child.

Conversely, others have emphasized the ways children affect parents. Best exemplified by Bell's (1968, 1979) concept of interactionism, this perspective holds that children and parents mutually affect one another. Thus, just as parents socialize children into gradually becoming adults, so, too, do the child's level of functioning, temperament, personality, maladaptive behaviors, and interests all change parental behavior. Other, more "status" characteristics—such as whether the child is a boy or a girl, or considered attractive or unattractive—might also influence parental behaviors.

When dealing with children with mental retardation, both behavioral and status characteristics differ from those of most typically developing children. By definition, children with mental retardation develop at slower

rates, and such rates may be differentially slowed in stronger versus weaker areas in certain syndromes. Children with several genetic syndromes are also predisposed to have particular personalities and amounts and types of maladaptive behavior and psychopathology. Most children with Down syndrome do appear to others as sociable and upbeat in personality (Hodapp, Ricci, Ly, & Fidler, 2003; Wishart & Johnston, 1980); children with Prader-Willi syndrome are prone to hyperphagia, obsessions-compulsions, temper tantrums, and other maladaptive behaviors (Dykens & Cassidy, 1999). Etiology-related health problems and physical or facial features might also influence parental behaviors.

We have recently become intrigued by these special twists of Bell's (1968) interactionism (Hodapp, 1997, 1999). Briefly, if children with particular genetic syndromes are predisposed to show one or more etiology-related behaviors, might not others be more likely to react to these children in specific, predictable ways? If so, then genetic disorders have "indirect effects" on others: Genetic disorders predispose children to show particular behaviors (i.e., direct effects), which in turn elicit specific behaviors and reactions from others in their surrounding environments (indirect effects).

Parental Reactions

Unlike parents of typical children, parents of children with mental retardation often experience strong negative reactions on the birth or diagnosis of their child with mental retardation. Earlier studies even talked of how parents thought of themselves as failures for having produced children with mental retardation. At the very least, parental perceptions of their children's development and needs may differ from the usual reactions and perceptions of parents of children with mental retardation (Hodapp, 2002).

Over 40 years ago, Solnit and Stark (1961) exemplified this perspective by hypothesizing that mothers experienced a mourning reaction in response to the birth of a child with mental retardation. Following Freud's (1917/1957) article on "Mourning and Melancholia," these psychoanalytically oriented researchers hypothesized that maternal reactions to the birth of a child with mental retardation were akin to reactions to a death or, more generally, to any experience of loss in which a person feels disappointed, hurt, or slighted. Partly in response to the maternal mourning idea, various stage theories were developed to conceptualize how mothers react emotionally to these children over time. Although

differing in specifics, most such models predicted that parents first feel shock or denial, then depression or anger, and finally emotional acceptance. Although such stage theories have been criticized (Blacher, 1984), they do highlight ways in which the emotions and perceptions of parents of children with mental retardation may differ from the emotions and perceptions of parents of typically developing children.

History of the Mental Retardation Field

Apart from Bell, Sameroff, and Bronfenbrenner, mental retardation's small field of behavioral researchers has itself long been interested in the environments of children with mental retardation. Blacher and Baker (2002) have recently compiled 100 years of articles on families of children with mental retardation that have appeared in the *American Journal on Mental Retardation* (and its earlier, differently named forerunner journals). In addition to predating most studies by developmental or applied developmental psychologists on these issues, recent family and ecological research in mental retardation has not been so tightly tied to similar research on typically developing children.

One example illustrates this separate history within the mental retardation field. Until the early 1980s, most studies on families of children with mental retardation were negatively tinged, emphasizing how different family members were negatively affected by raising the child with mental retardation. Over many studies during the 1960s and 1970s, researchers concluded that (compared to parents and families of same-age, typically developing children):

- Mothers of children with mental retardation were more often depressed (W. L. Friedrich & Friedrich, 1981) and preoccupied with their children and had more difficulty handling anger at their children (Cummings, Bayley, & Rie, 1966).
- Fathers experienced "role constriction" (Cummings, 1976) and more depression and neuroticism (Erickson, 1969).
- Couples showed lower levels of marital satisfaction (W. L. Friedrich & Friedrich, 1981).
- Families were considered to be "economically immobile" (Farber, 1970) and "stuck" in earlier stages of family development (Farber, 1959).

Beginning in the early 1980s, this focus on negative effects began to change. Crnic, Friedrich, and Green-

berg (1983) noted that children with mental retardation were better thought of as stressors on the family system. Like illness, moving, loss of a job, or natural disasters, a child with mental retardation could either negatively or positively affect parents and families as a whole. The child with mental retardation did not necessarily negatively impact the family. Although some researchers question the degree to which perspectives have changed over the past 2 decades (Dunst, Humphries, & Trivette, 2002; Helff & Glidden, 1998), most would agree that studies of parents, families, and siblings of children with mental retardation have become less negative. We thus see a historical change in research orientation that is specific to mental retardation family research.

Changing Ecology of Mental Retardation

In addition to shifting research perspectives, major changes have occurred in children's ecologies. Consider even the living status of children with mental retardation. Forty years ago, many more persons, including children, resided in large, often impersonal institutions. In 1967, almost 200,000 Americans lived in institutions, including 91,000 children. By 1997, that number had fallen to 56,161, including fewer than 3,000 children (L. L. Anderson, Lakin, Mangan, & Prouty, 1998; Lakin, Prouty, Braddock, & Anderson, 1997). Children with mental retardation now live in their own family home; adults are living either in their family home or in group homes, apartments, or other community-based settings.

As these children increasingly live in their family home, community-based services have increased many times over. Again, comparisons to the 1960s and early 1970s are instructive. Until the mid-1970s, children with mental retardation were not guaranteed access to public schooling during the school-age years. Access to formal education therefore varied widely, depending mainly on the generosity of the family's particular town or state. Only in 1975, with the passage of the federal Education for All Handicapped Children Act (PL 94-142), were states and towns in the United States required to provide a "free, appropriate public education" to all students, including those with disabilities (Hallahan & Kauffman, 2002).

Over the past 3 decades, other services have also been instituted that cover the preschool and the after-school years. In addition to school services from age 3 through 21 years, states now provide early intervention services during the 0- to 3-year period. Under federal law PL 99-457, educational and support services have

been expanded to the 0- to 3-year-old group, allowing a bridging of services from birth into the school years. A major component of PL 99-457 is its provision of an Individualized Family Service Plan, thereby recognizing that the family, as opposed to the child alone, needs services during these early years (Krauss & Hauser-Cram, 1992). And later, after the school-age years, so-called transitional services help persons with disabilities to make the transition from the school years to lives in which young adults work and live as independently as possible (for helpful programs, services, and agencies, see Morris, 2002). Services for individuals and their families are thus lifelong, and one must consider the interplay between children-parents-families and the service-delivery system from a life-span perspective.

Finally, one must appreciate changes in how all services are being conceptualized. No longer are children, parents, siblings, and families conceptualized as patients who need to be cured; instead, they are seen as persons—or consumers of services—who require long- or short-term support to enable them to cope more effectively. The goal, then, is to provide individualized supports to address the needs of each family. One family may require more information about a range of state-supported services, another respite care (i.e., short-term out-of-family care) so that the family can get a break from the full-time care of the offspring with disabilities. Still other parents may need to be put in touch with parents of children with similar problems, or who have dealt with the same school district, or who can otherwise help in their particular situation. This “support revolution” has changed the nature of services and how such services are understood by families and professionals (Hallahan & Kauffman, 2002).

Children, parents, the mental retardation field, and society at large, then, must all be considered when discussing larger ecological issues for children with mental retardation. We now discuss parent-child interactions, parental perceptions, parent-family reactions, and larger environments.

Parent-Child Interactions

Influenced by interactionism and the work on maternal input language begun in the early 1970s (Snow, 1972), developmentally oriented researchers began to examine interactions between parents and their children with mental retardation. These findings yielded inconsistent results. Sometimes parents of children with mental re-

tardation acted the same as parents of typically developing children, sometimes they differed markedly.

These inconsistent findings, however, were not random. Instead, two dimensions seemed important. The first concerned whether one compared parents of children with mental retardation to typical children who were of the same chronological age or the same level of functioning (such as the child’s mental age or language age). When chronological age comparisons were employed, parents of children with mental retardation showed different behaviors. Buium, Rynders, and Turnure (1974) and Marshall, Hegrenes, and Goldstein (1973) both found that mothers of children with Down syndrome provided less complex verbal input and were more controlling in their interactive styles than were mothers of same-age nonretarded children. In both of these early studies, however, children with mental retardation were compared to typically developing children of the same chronological age. With Rondal’s (1977) work in the late 1970s, researchers began to appreciate that parental behaviors might best be compared using typically developing groups of the same mental or language age, as opposed to the same chronological age.

But a second dimension was also at play. Specifically, one needed to distinguish the structure versus the style of parental behaviors. Structure, in this sense, includes the grammatical sophistication (the mean length of utterance, or MLU) or the degree of information (type-token ratio) of sentences uttered by the parent to the child. In contrast, style refers to the degree to which the parent teaches the child, leads or follows the child in the interaction, and is generally didactic and intrusive.

Once one makes this second, structure-style distinction, findings have been fairly consistent. Rondal (1977, p. 242) noted that, when children with Down syndrome and nonretarded children were matched on the child’s MLU, “None of the comparisons of mothers’ speech to normal and to Down Syndrome children led to differences that were significant or close to significant” between the two groups. Additionally, both groups of mothers adjusted their language upward (i.e., longer MLUs, type-token ratios) as the children’s language levels increased. Rondal concluded that “the maternal linguistic environment of DS children between MLU 1 and 3 is an appropriate one” (p. 242).

In contrast, mothers of children with mental retardation are different when one focuses on their styles of interaction. Even when children with versus without mental retardation are equated on overall mental or

linguistic age, mothers of children with mental retardation are generally more didactic, directive, and intrusive compared to mothers of nonretarded children (Marfo, 1990). Tannock (1988) found that, compared to mothers of nonretarded children, mothers of children with Down syndrome took interactive turns that were longer and more frequent; in addition, these mothers more often "clashed," or spoke at the same time as, their children (see also Vietze, Abernathy, Ashe, & Faulstich, 1978). Mothers of children with Down syndrome also switched the topic of conversation more often, and less often silently responded to the child's utterance. The result was a greater percentage of more asymmetrical conversations, conversations in which mothers controlled the topic, the child's response, and the nature of the back-and-forth conversation.

Why this difference between the structure and the style of parent-child interactions vis-à-vis typically developing children? The most common explanation is that mothers of children with mental retardation inject their parenting concerns into the interactive session. Compared to mothers of typically developing children, more of the mothers of children with mental retardation consider interactions as "teaching sessions," as moments not to be squandered in the nonstop effort to intervene effectively. As one mother said about interacting with her child with Down syndrome, "It's sit him on your knee and talk to him, that's the main object. Play with him, speak to the child, teach him something" (quoted in Jones, 1980, p. 221). Other parents also spoke of their desires to intervene with their children, even in situations in which mothers of nonretarded children feel fine with playing or becoming emotionally close to their offspring (Cardoso-Martins & Mervis, 1984).

Further complicating matters are behavioral characteristics of the children themselves. Here we again note differences relating to children with specific types of mental retardation. Specifically, young children with Down syndrome are often more lethargic and more hypotonic than are infants and young children with mental retardation in general. As a result, young children with Down syndrome may provide fewer and less clear interactive cues, at least in the months directly prior to intentional communication (Hyche, Bakeman, & Adamson, 1992). These infants may be less "readable" to the mother (Goldberg, 1977; Walden, 1996), even as mothers gradually learn to interpret their child's vague or slight communicative behaviors (Sorce & Emde, 1982; Yoder, 1986).

Similarly, one might speculate about the effects on others of the facial appearance of children with Down syndrome. In general, children (and adults) with Down syndrome possess a face that appears more infantile and "babylke," rounder and with smaller facial features. As Zebrowitz (1997) has shown, adults perceive more baby-faced individuals as friendlier, more social, and more compliant. Such attributions also occur when rating the faces of children with Down syndrome compared to typically developing children or to children with another (more adult-looking) genetic mental retardation syndrome (Fidler & Hodapp, 1999). Compared to mothers of children with other forms of mental retardation, mothers of children with Down syndrome give vocalizations that are at a higher register and that show greater pitch variance (i.e., sing-songy; Fidler, 2003). Such vocalizations are congruent with the intonations of "motherese" that have been universally found by Fernald (1989) and others.

Two additional issues deserve mention. First, several studies have now examined variation in maternal behaviors *within* samples with mental retardation (usually with Down syndrome). In the first direct examination of this issue, Crawley and Spiker (1983) rated maternal sensitivity and directiveness of mothers in their interactions with their 2-year-old children with Down syndrome. They found wide individual differences from one mother to another. Some mothers were highly directive, whereas others followed the child's lead; similarly, mothers varied widely in their rated degrees of sensitivity to their children. Because the two dimensions of sensitivity and directiveness were somewhat orthogonal, mothers could be high or low on either sensitivity or directiveness. All four combinations were demonstrated in this study. Just as mothers of nonretarded children vary widely on both directiveness and sensitivity, so, too, do mothers of children with Down syndrome.

A second issue concerns the effects of different maternal behaviors on children's development. In the sole study of this issue, Harris, Kasari, and Sigman (1996) examined the effects of maternal interactive behaviors on the expressive and receptive language behaviors of children with Down syndrome. Examining children when they were 2 and again at 3 years of age, Harris et al. found that the mean length of time in which mothers and children were engaged in joint attention (i.e., focusing on the same object) was correlated to the child's degree of receptive language gain over the 1-year interval. In addition, the child's receptive language gains

were also correlated with the amount of time that mothers maintained the child's attention to child-selected toys, and (negatively) to instances of redirecting the child's focus of attention and of engaging in greater numbers of separate joint-attention episodes. Such findings parallel those found for interactions between mothers and typically developing infants, where increased maternal sensitivity (Baumwell, Tamis-LeMonda, & Bornstein, 1997) and more joint-attention episodes (Tomasello & Farrar, 1986) also promote young children's early language abilities. For both typically developing children and children with Down syndrome, then, mothers facilitate children's processing of maternal input language when they attempt to prolong episodes of mother-child joint attention by following their child's lead and responding to the child's interests and behaviors (Paparella & Kasari, 2004). The child's receptive language abilities increase accordingly.

Parent-child interactions are, then, the same in structure and different in style when the child has mental retardation. Although maternal emotions and perceptions may account for style differences, differences may also reside in the children themselves. As we examine children's behaviors and maternal emotions and perceptions, we come to understand what is happening, why, and how such interactions may be most useful for intervention efforts.

Perceptions

Although most would acknowledge that parental perceptions probably differ when raising a child with versus without mental retardation, how such perceptions differ is less well understood, nor do we know how any differences in parental perceptions might relate to differing behaviors or to different child outcomes. It is important, too, to acknowledge just how widespread parental perceptions truly are, ranging all the way from parental emotions to parental attributions of their children's needs and abilities.

Considered in these ways, the finding of differing parental interactive behaviors is most likely due to differences in parental perceptions. More didactic and controlling parental behaviors may indeed reflect parents' perceptions that they need to teach, stimulate, and push their children. Such differences in style seem common among parents of children with mental retardation and with other forms of disability as well (e.g., children with motor impairments, blindness, deafness, autism).

It is also possible to consider parental perceptions in light of the child's cause of mental retardation. Moreover, the very fact that there is a clear, identifiable cause may be helpful to parents. In one study, Goldberg, Marcovitch, MacGregor, and Lojkasek (1986) found that mothers of children with mental retardation from unknown causes suffered greater amounts of stress compared to mothers of children with either Down syndrome or mental retardation caused from specific neurological impairments. Being able to identify a clear cause may itself help parents of children with mental retardation.

Recently, we have begun to explore the idea of using attribution theory to help explain parental behaviors in response to children with different genetic mental retardation syndromes (with their specific, etiology-related strengths and weaknesses). In prior work with typically developing children, Graham (1991) found that, in accordance with attribution theory (Weiner, 1985), teachers showed different patterns of attributions when their students were perceived to have high versus low levels of skills in particular activities. When children were judged to be skilled at a particular task, teachers and parents attributed these children's success to their children's high levels of skill, whereas failure was attributed to the child's not trying (i.e., lack of effort). In contrast, children perceived to have low levels of skill were perceived to succeed at a task only by effort (if children failed, it was due to their low level of ability). Such perceptions then linked to subsequent adult behaviors, such that adults gave greater amounts of help and reward to lower- than to higher-skill children when each succeeded (the idea being that higher-skill children do not need as much help/reward to successfully complete the task).

Given such clear predictions from attribution theory—and such clearly divergent levels of ability in specific etiological groups—Ly and Hodapp (2005) recently examined maternal helping and reinforcement behaviors in children with two genetic syndromes. Recall that, as a group, children with Prader-Willi syndrome perform especially well on jigsaw puzzles (Dykens, 2002); in contrast, children with Williams syndrome show deficits (beyond their overall mental age) in most tasks of visuospatial functioning (Mervis et al., 1999). Capitalizing on this contrasting strength-weakness across these two syndromes, Ly and Hodapp had mothers and their children with either Prader-Willi or Williams syndromes interact around a novel jigsaw puzzle.

As might be expected from an attributional perspective (Graham, 1991), mothers of children with Williams

syndrome gave over twice as many reinforcers (praises, clapping) and helping behaviors to their children as did parents of children with Prader-Willi syndrome. Looking further, such etiology-group differences appeared due both to the child's ability level in puzzles (measured separately from the mother, in another room) and to the child's etiology (Prader-Willi syndrome versus Williams syndrome). Parents respond not only to the child's actual level of ability, but also to ability profiles that generally characterize each of these two syndromes.

Attribution theory has also been used to help explain the perceptions of parents of children with Down syndrome. Ly and Hodapp (2002) gave parents of children with Down syndrome versus parents of children with other, non-Down syndrome forms of mental retardation hypothetical vignettes. These vignettes involved the child's noncompliance to parental commands: one command to clean up his or her room, another to turn down the television set when the mother received a phone call. In addition to rating various reasons for why their child would not comply in these two instances, mothers also were asked to rate their child's personality and maladaptive behaviors.

Again, parents reacted to the child's more sociable, upbeat personality, but also to the child's specific etiological label. Specifically, parents of children with Down syndrome more often attributed the child's noncompliant behaviors to normative concerns ("My child is acting like other children his or her age"). But such connections between child personality and normalizing behaviors were found only within the Down syndrome group. Among parents of children with Down syndrome, those who saw their child as more sociable also more highly rated normalizing as the reason for their child's noncompliance ($r = .43, p < .01$). But among parents of children with mixed forms of mental retardation, no such connections existed between child personality and parental ratings of normalizing attributions ($r = .05, ns$).

Although intriguing, these studies merely scratch the surface in our understandings of parental perceptions. We continue to know little about these parents' perceptions, or how such perceptions might relate to the child's etiology, overall abilities, or specific abilities on individual tasks. We know little as well about any changes in attributions, perceptions, and expectations by different adults (mothers, fathers, teachers), in different contexts (schools, homes, communities), and when the child is faced with different tasks (academic, leisure, specific tasks reflecting etiology-related skills). Finally, we have

no idea how parents develop these perceptions, how parental perceptions link to behaviors, and how parental perceptions (and subsequent behaviors) link in turn to the child's own behaviors or perceptions.

Parent and Family Reactions

As noted earlier, the conceptualization of parental and familial reactions has changed markedly over the years, as have the nature and philosophy of service delivery. Partly as a result of such changes, changes have also occurred in how studies are performed. In effect, moving from a pathology to a stress-and-coping perspective emphasizes those risks and protective factors that foster better parental and familial coping. From the earlier view that all parents and families of children with mental retardation are prone to depression, conflict, and other negative consequences, we can now better appreciate characteristics—in the children themselves, in parents, and in families—that might predict more successful reactions. We now turn to findings showing different child, parent, and family factors predisposing to better or worse outcomes.

Child Factors

Certain aspects of children seem to be associated with better parent and family functioning, whereas others are not. In most studies, the child's overall degree of impairment (i.e., IQ), level of functioning (mental age), and gender are unassociated with better or worse parent and family reactions. In contrast, the child's degree and amount of maladaptive behavior and psychopathology seem to adversely influence parent and family functioning, whereas the child's sociability and interest in people seem helpful to parents.

The influences of maladaptive behavior can be seen in groups with mixed forms of mental retardation and in children with specific etiologies. Minnes (1988) and Margalit, Shulman, and Stuchiner (1989) have found that more child maladaptive behavior is associated with greater amounts of parental stress. Similarly, higher levels of child maladaptive behavior is associated with higher parental stress levels in children with Prader-Willi syndrome (Hodapp, Dykens, & Masino, 1997) and comparing parents of children with Prader-Willi, Down, and Smith-Magenis syndromes (Fidler, Hodapp, & Dykens, 2000).

From the opposite perspective, parents and families of children with Down syndrome may cope better com-

pared to parents of children with other disability conditions. Such an advantage arises in studies that compare parents of children with Down syndrome to children with autism (Holroyd & MacArthur, 1976; Kasari & Sigman, 1997), with mixed forms of mental retardation (Hodapp et al., 2003), with other disabilities (Hanson & Hanline, 1990), and with emotional problems (but without mental retardation; Thomas & Olsen, 1993). Granted, a few studies do not find this advantage for parents of children with Down syndrome (Cahill & Glidden, 1996). Overall, however, most studies do find that parents of children with Down syndrome experience less parental stress than do parents of children with other disabilities.

Three further issues deserve mention. First, the so-called Down syndrome advantage probably occurs only in comparison to parents of children with other disabilities. In most studies, parents of typically developing children report less stress than do parents of children with Down syndrome (Roach, Orsmond, & Barratt, 1999; Scott, Atkinson, Minton, & Bowman, 1997; although see also Sanders & Morgan, 1997; Wolf, Noh, Fisman, & Speechley, 1989).

Second, certain aspects of parental reactions might show more of a Down syndrome advantage. Across several studies, parents of children with Down syndrome rate their children as more rewarding and as more acceptable than do parents of children with other disabilities. Hoppes and Harris (1990) found that, relative to parents of children with autism, parents of children with Down syndrome regarded their children as more rewarding. Noh, Dumas, Wolf, and Fisman (1989) also found the same pattern when contrasting parents of children with Down syndrome to parents of children with autism or with conduct disorder. Likewise, Hodapp et al. (2003) found that, relative to parents of children with heterogeneous causes of mental retardation, mothers of children with Down syndrome considered their child more acceptable and more rewarding. Some studies even find that parental reinforcement and acceptability are equal in parents of children with Down syndrome versus same-age typically developing children (e.g., Roache et al., 1999). In a few studies, parents of children with Down syndrome even exceed parents of typically developing children on these two specific measures. Thus, Noh et al. conclude that, although parents of children with Down syndrome rated their children as less attractive, socially appropriate, and intelligent, they regarded "their children as happier and as a greater source of pos-

itive reinforcement than the parents of normal children" (p. 460).

Third, one must consider the age of the child with Down syndrome. In a large cross-sectional study, Dykens, Shah, Sagun, Beck, and King (2002) noted that adolescents with Down syndrome, in addition to showing lesser amounts of stubbornness and other externalizing problems, may become more "inward" during the adolescent years (see also Meyers & Pueschel, 1991; Tonge & Einfeld, 2003). Using a personality questionnaire, Hodapp et al. (2003) found a similar, subtle withdrawal, and parents of these older teens and young adults reported that their children were less rewarding and acceptable (see also Cunningham, 1996). Though there may be a Down syndrome advantage for parents and families of children with Down syndrome, this advantage may be affected by the inwardness gradually occurring in many adolescents and young adults with this disorder.

Finally, although we view the child with Down syndrome as eliciting reactions from parents and families, we acknowledge that children with Down syndrome may differ in other ways from children with other disabilities. Down syndrome is a common disorder, is diagnosed at birth, is widely known to both professionals and the lay public alike, and has several active parent and advocacy groups. As such, some of the Down syndrome advantage may come about through characteristics that are separate from the child's behavior. The question boils down to whether any Down syndrome advantage arises from behaviors of the children themselves, or from parental or societal characteristics that are associated with Down syndrome. We suspect that child and associated characteristics may both be operating, but more studies are needed.

Parent and Family Factors

In addition to various child factors, one must also realize the importance of parent and family factors on parent and family coping. A first important issue concerns the outlook and general problem-solving style of parents (usually mothers) themselves. Following Folkman, Schaefer, and Lazarus (1979), mothers can be identified as predominantly using either "problem-focused" or "emotion-focused" coping strategies (for a review, see Turnbull et al., 1993). In the first, mothers essentially address their child's mental retardation as a practical, concrete problem to be dealt with. These mothers make plans to address everyday problems, work hard to

alleviate those problems, and feel that they have learned from their experiences. In contrast, another group of mothers either totally deny their feelings about their child and the disability, or instead become overly concerned, almost obsessed, with their own feelings of depression and grief.

Across a range of studies, such differences seem intricately involved with the mother's emotional outcomes. Those mothers who are active, problem-focused copers do better. Several studies have now documented that those parents who engage in active, problem-based styles of coping experience less depression than those who either deny their emotional feelings or who engage in what has been called "emotion-based coping" (e.g., Essex, Seltzer, & Krauss, 1999).

A final set of characteristics concerns family demographics. To list briefly, the following have been shown in various studies:

- Families who are more affluent cope better with rearing a child with disabilities than do those making less money (Farber, 1970).
- Two-parent families cope better than one-parent families (Beckman, 1983).
- Women in better marriages cope better than those in troubled marriages (Beckman, 1983; W. N. Friedrich, 1979).

Although none of these findings is surprising, each nevertheless highlights the ways family or couple demographics or dynamics affect the coping of both parents and families.

Schools, Neighborhoods, and Larger Ecologies

In contrast to the work on parent-child interactions, parental perceptions, and parent and family factors, much less research has been done on the larger ecologies of children with mental retardation. Unlike, for example, Bryant's (1985) neighborhood walk with typically developing children to determine these children's support network, few studies examine the neighborhoods or larger ecologies of children with mental retardation. Although schooling has been of interest within the special education field, most studies do not look at schools in what might be considered ecological ways; instead, dominant issues include parental satisfaction with different types of placements for their children, or school-

parent connections, or the effects of the child's specific school placement (fully integrated or mainstreamed only some of the day) on these children's academic and social achievements (Freeman & Alkin, 2000).

Such inattention to ecological matters is surprising given the many societal changes in the lives of children with disabilities and their families. As noted earlier, changes have occurred in where children with mental retardation live, in the increased amount of community-based services, and in the changes from pathological to supportive philosophies underlying those services. Such changes make more complicated the lives of children with mental retardation and their families. Consider the experience of giving birth and raising a child with mental retardation, as seen from the perspective of parents. With only a few exceptions (e.g., parents who adopt children with Down syndrome; Flaherty & Glidden, 2002), most parents are unprepared for the birth of a child with disabilities. If the child has Down syndrome or another easily diagnosed disorder, parents learn at birth about their child's diagnosis. Physicians and other health personnel are also feeling guilty and upset, and stories abound about parents who were told about their child's diagnosis in uncaring, unprofessional ways, or were given wildly pessimistic outcomes about their child's ultimate capabilities and life outcome (Turnbull & Turnbull, 1997). For parents who do not learn of their children's diagnosis at birth, nagging suspicions often persist that somehow their child is not right, even as pediatricians and others often tell them that the child will grow out of it.

Apart from diagnosis itself, these parents are generally unprepared to navigate the entire gamut of existing services. When parents give birth to a child with a disability, they must negotiate the service-delivery system. In every state, parents thus begin dealing with such agencies as the Department of Developmental Disabilities (differently named from state to state), and with that department's various agencies or centers, who actually administer the funds and programs. Later, during the school years, parents work most closely with their child's school district, school administrators, and teachers. After the school years, transition and adult services enter in. These departments and services are generally unknown to most people in the general public.

As these interactions proceed, parents are faced with a wide array of rights and responsibilities. Consider schools, the main service provider from the time the child is 3 to the time he or she is 21 years old (Hallahan

& Kauffman, 2002). Federal laws such as the Individuals with Disabilities Education Act (passed in 1990; amended in 1997 and 2004) now provide as a right a free, appropriate public school education for all children with disabilities. But parents need to be aware of an entire gamut of hearings, appeals, and procedures (Council for Exceptional Children, 1998).

Such hearings and procedures then culminate in the child's actual placement within a specific educational setting. Ideally, all children should be educated in the "least restrictive environment" (LRE), with "least restrictive" generally referring to environments that are most like the typical, general education classroom. Depending on the child's individual needs, LRE allows for full-time integration with nondisabled children, part-time integration with a resource room or specialist, special classes within a public school, and even special classes or special residential schools when necessary to meet the child's educational needs.

In whatever setting education takes place, the child's teachers, administrators, and parents must agree on the various goals, services, and practices that will be put in place to educate the student with disabilities. Such goals and practices are codified in the child's individualized educational plan (IEP; Bateman & Linden, 1998), which has been developed out of the series of legal hearings and appeals mentioned earlier.

Although we often think of disabilities as pertaining mostly to children, children with disabilities eventually grow up to become adults. In this regard, one of the most widespread adaptations has involved transition services. To simplify slightly, transition services focus on skills needed for independent living and working. The goal is that, upon graduation, young adults with disabilities will be able to live either on their own or in a community group home, and to be competitively employed in the community (Rusch & Chadsey, 1998). To live independently, students are taught to shop for clothes and food within a budget, to use the post office, to understand schedules and take public buses or trains, and to visit a doctor or dentist. To be able to be competitively employed by community businesses, students are trained in a variety of vocational skills. Such training addresses more general issues such as being punctual, courteous, and on task, as well as providing actual practice in working in unskilled or semiskilled jobs in the community.

Clearly, the amount and complexity of such information are staggering to most parents, who generally have little knowledge or experience of child development, spe-

cial education, social service systems, law, or other relevant areas. In addition, parents must simultaneously deal with all of the usual transitions that arise when they embark on parenting any child (Bornstein, 2002; Heinicke, 2002). For these reasons, parenting children with mental retardation has often been likened to entering a foreign country, a country in which the language, customs, and expectations are all different from expected.

Fortunately, some guideposts are available to help parents and families in navigating this new, foreign world. In each state, a lead agency has been designated to be in charge of early intervention services, and all states have some version of a Department of Mental Retardation or Department of Developmental Disabilities. In every state, the federal government has set up one (or a few) University Centers for Excellence in Developmental Disabilities (UCEDD; formerly called University Affiliated Programs). These centers provide family resource centers, support groups for parents and siblings, conferences, and advocacy services to deal with schools or regional centers. Local and state educational organizations can also help parents, as can local hospitals and social service agencies.

On the national level, many informational services exist to help parents of children with disabilities. Some organizations, such as the Arc of the United States (originally, the Association for Retarded Citizens), can help parents find resources in their area, and the Council for Exceptional Children can help parents locate educational resources. Others involve parent-professional groups (e.g., National Organization of Rare Disorders) or federally sponsored Web sites (National Institutes of Health). Compared to only a few decades ago, families can access an almost bewildering amount of supportive services, contacts, and educational and medical information. This exponential increase in potential knowledge and support is an important change in the "culture" of disabilities. More knowledge and supportive services are created every day, and parents are both helped and challenged by these vast information and service systems. See Table 12.2 for a listing of helpful resources.

Summary

By definition, children with mental retardation are different from typically developing children, and any studies of parent-child interactions, parental perceptions, families, or even neighborhoods and schools all need to consider these differences. One must acknowledge the

many reactions that parents have to rearing a child with mental retardation, the parallel history of parent and family studies in the mental retardation field, and the many historical changes in how society has treated and conceptualized children with mental retardation and their families.

Given these important background issues, we note the ways interactions are the same but different when considering parents and their children with mental retardation. When compared to typically developing children of the same levels of functioning on structural aspects of maternal input language, such interactions seem similar. In contrast, differences emerge in parent-child interactions when children in the typical versus retarded groups are matched on chronological age (not on mental or language age) and when one examines maternal style. Stylistically, mothers of children with mental retardation (versus mothers of typically developing children matched for mental or language age) seem much more didactic and controlling.

Such stylistic differences lead one to consider the perceptions of parents of children with mental retardation. Although a general consensus holds that these parents differ from parents of typically developing children in their strong desires to teach their children, other aspects of parental perceptions seem much less well examined. In addition, only a few studies have yet used attribution theory in relation to children with mental retardation, or to children whose genetic etiologies lead to relatively strong versus weak performances on particular tasks.

So, too, is more work needed on many issues relating to families of children with mental retardation. Family work has changed dramatically in its orientation over the past 30 years, as researchers now adopt perspectives focusing on the child as a stressor on the family system. Conceptualized as a stressor, children with mental retardation might contribute to better, worse, or unchanged family functioning. To date, a few risk and protective factors have been identified using this stress-and-coping perspective, but many areas of family functioning remain open for research.

Finally, the reaction of the wider society has changed markedly in regard to children with mental retardation and their families. Even compared to 20 or 30 years ago, the amount and type of services have increased enormously, as have the ways that professionals and families think about such services. Such changes have mostly been helpful, as children with mental retardation and their families can now benefit from a lifelong array of

services. Nevertheless, such services raise new challenges for parents, who must increasingly learn their child's disability, available services, and how and when parents can access such services. We know little about how parents come to know about or use such services, how they overcome barriers to knowledge or access, or what the effects of such services are on children themselves or on family members.

RESEARCH ISSUES

In summarizing findings of the child's and environment's development, we have often mentioned gaps in our understanding. But in addition to gaps related to content knowledge, other gaps also exist concerning how best to perform developmentally oriented behavioral research. Such research issues include but go beyond similar issues in child or applied child development. Four such issues are discussed next.

The Nature of Research Groups

The first unresolved issue in mental retardation research concerns the nature of the group itself. As noted earlier, researchers differ in how they classify persons with mental retardation, with some choosing to examine groups based on level of impairment (mild, moderate, severe, or profound mental retardation), others on mental retardation's two groups (cultural-familial versus organic), still others on the individual's etiology.

Although historically the degree-of-impairment approach has predominated, newer mental retardation behavioral research is more often taking etiology into account. Consider Figure 12.2, a graph of articles published in the *American Journal on Mental Retardation* (*AJMR*), the most prominent journal devoted to behavioral studies in the mental retardation field (Hodapp, 2004a). The large majority of behavioral research articles in *AJMR* published during the 1970s and 1980s classified their research subjects by level of impairment; similar conclusions arise when considering other mental retardation journals (Hodapp & Dykens, 1994) and when surveying articles on persons with both mental retardation and emotional-behavioral problems (Dykens, 1996). But as the figure illustrates, such a state of affairs may be changing; at present, almost one-third of behavioral research articles in *AJMR* now separate their groups by etiology.

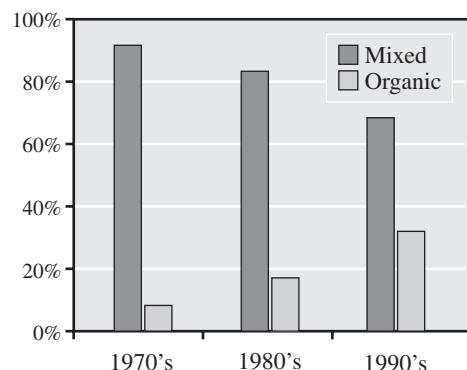

Figure 12.2 Percentage of articles, by type, in the *American Journal on Mental Retardation*, 1975–1980, 1985–1990, and 1995–2000. *Source:* From “Behavioral Phenotypes: Going beyond the Two-Group Approach,” by R. M. Hodapp, 2004a, *International Review of Research in Mental Retardation*, 29, pp. 1–30. Reprinted with permission from Elsevier.

This recent rise in etiology-based behavioral articles can be illustrated in other ways as well. Consider the numbers of behavioral research articles on such disorders as Down syndrome, Prader-Willi syndrome, Williams syndrome, and fragile X syndrome. Comparing these numbers during the 1980s (1980 to 1989) versus the 1990s (1990 to 1999), one finds that empirical journal articles on the behavior of individuals with Williams syndrome increased from 10 to 81; on Prader-Willi syndrome, from 24 to 86; on fragile X syndrome, from 60 to 149. Even for Down syndrome, the single genetic syndrome with a long-term, well-established history of behavioral research, the numbers of behavioral studies almost doubled from the 1980s to the 1990s (607 to 1,140; Hodapp & Dykens, 2004). With intriguing findings occurring in many of these syndromes, the numbers of articles should continue rising in the decades to come.

But such steep rises tell only a part of the story. At least 1,000 genetic syndromes are now thought to be associated with mental retardation. Many such syndromes are fairly rare, making it difficult to attain large enough subject groups. Still, not a single study exclusively devoted to behavior or behavioral development exists for the large majority of these syndromes. Although our knowledge of individuals with different etiologies of mental retardation has increased tremendously, we still have a long way to go.

Control-Contrast Groups to Examine Children’s Own Behavioral Functioning

Once one settles on the nature of the subject group, the next problem concerns control or comparison groups. To

whom, exactly, should one compare one’s group with mental retardation? We begin with a historical sense of this issue, then discuss the ways the control-contrast group issue has played out when considering etiology-based behavioral research.

Historical Issues

Over the years, a long-standing controversy has related to two types of comparisons to typically developing children (Hodapp & Zigler, 1995). One group, referred to by the term “defect theorists,” has asserted that etiology does not matter, that all children with mental retardation suffer from organic defects. These researchers have generally compared their children with mental retardation to typically developing children of the same chronological age. An entire research tradition has shown that, relative to typically developing children, numerous aspects of cognition and language are deficient in children with mental retardation (e.g., Ellis & Cavalier, 1982).

In contrast, developmentally oriented researchers have generally favored comparisons to typically developing children of the same mental ages. These researchers have considered it a given that children with mental retardation perform worse than chronological age matches on virtually every cognitive task. Instead, they see their job as one of determining whether these children show specific areas of relative strength or weakness. Or, as Cicchetti and Pogge-Hesse (1982, p. 279; emphasis in original) aver, children with mental retardation function below children of the same chronological age in most areas of cognition, but “*the important and challenging research questions concern the developmental processes.*” Such processes can be determined only by using mental age-matched typically developing controls, thereby showing which areas are more or less affected.

Contrast Groups in Etiology-Based Research

With the rise of etiology-based research, specifying the appropriate control-contrast groups has become more complex. We present six research approaches, organized around three research questions, that have been commonly used in etiology-based behavioral research (Hodapp & Dykens, 2001; see Table 12.3).

Do Children Show an Etiology-Related Profile?

Recall that children with Williams syndrome show relative strengths in language and weaknesses in visuospatial skills; that children with Prader-Willi syndrome show strengths in simultaneous processing (particularly

TABLE 12.3 Strengths and Weaknesses of Some Common Etiology-Based Research Approaches

Control Group	Characteristics	Strengths and Weaknesses
<i>Strategies to Determine Whether a Specific Disorder Has Strengths/Weaknesses</i>		
1. None	Performance “against self”	Shows etiology strength.
2. Typical	Equated on MA	Shows relative strength (versus MA) or intact functioning (versus CA); unclear if profile is unique, partially shared, or similar to all persons with MR.
	Equated on CA	
<i>Strategies to Determine Whether Behavioral Characteristics Differ from Others with Mental Retardation</i>		
3. Mixed MR	Mixed causes of MR	Shows that etiology strength/weakness is not due to MR. Control group changes across studies; mixed ≠ nonspecific.
4. Down syndrome	Down syndrome	Shows behavior not due to any syndrome, but DS has its own behavioral characteristics (may lead to inaccurate conclusions if DS = “all MR”).
<i>Strategies to Further Delineate Etiology-Specific Behaviors</i>		
5. Same-but-different MR	Etiology similar in behavior to group	Highlights fine-grained differences in behavior if two or more etiologies have similar behaviors to make contrast meaningful.
6. Special non-MR	Group with special behavior	Shows ways that etiology is similar to or different from (nonretarded) group with special problem or profile.

in putting together jigsaw puzzles); and that children with Down syndrome show relative weaknesses in linguistic grammar. The word “relative” relates to the child’s overall mental age; a relative strength denotes that children of a particular etiology perform significantly above mental age levels, a relative weakness denotes that group performance is below overall mental age levels.

Given this interest in relative strengths and weaknesses, a first, commonly used strategy is to have *no control or contrast group*. To determine whether children with Williams syndrome show strengths in language versus visuospatial processing, Bellugi et al. (1999) compared each child’s functioning on a language domain to that same child’s performance on another domain. Similarly, we have found simultaneous processing strengths in boys with fragile X syndrome (Dykens, Hodapp, & Leckman, 1987) and in children with Prader-Willi syndrome (Dykens et al., 1992) by comparing each child’s performance on domains of Simultaneous Processing versus Sequential Processing on the Kaufman Assessment Battery for Children (Kaufman & Kaufman, 1983). In Down syndrome, higher-level performance has been shown on tasks involving visual (as opposed to auditory) short-term memory (Hodapp et al., 1999; Pueschel et al., 1987). Children thus become their own controls, as their functioning levels in one domain are compared to more general, overall functioning levels.

Although widely used, this self-as-control technique has several limitations. Technically, one can compare the person’s performance only on one versus another domain on the same test. Different tests are standardized on different samples, and intelligence test scores tend to increase from decade to decade (the so-called Flynn effect; Flynn, 1999). At the very least, one should stick to different domains of the same test.

Another problem involves the existence of appropriate psychometric instruments. In areas such as IQ, adaptive behavior, and language functioning, many well-normed, standardized tests exist. Such tests easily lend themselves to comparisons between a single subtest and the overall age-equivalent score. But in other areas, few good tests exist. Such is the case for developmentally interesting areas such as emotional development, self-image, theory of mind, and empathy. In areas for which no psychometrically sound measures exist, researchers cannot use children with a specific etiology as their own control.

A second technique also attempts to answer the relative strength or weakness question. Here the researcher compares persons with mental retardation to *typically developing children of the same mental age* (mental age matches). Depending on the question of interest, the comparison might more generally be thought of as comparing the child with mental retardation to typical children of similar functioning levels. To determine areas of

adaptive strength or weakness, one might compare children with Down syndrome to typically developing children using the Vineland Adaptive Behavior Scales; to determine whether specific aspects of language are relative strengths (a major issue in current Williams syndrome work), one might match on the child's MLU to examine aspects of pragmatics or semantics. In each case, the researcher compares children with a particular genetic syndrome to typically developing children of identical age-equivalent performance.

Given our knowledge of etiology-based strengths and weaknesses, it is also important to sometimes use chronological age matches. Specifically, when certain etiological groups perform above mental age matches, one has evidence that the group shows a relative strength in that area of behavior. But it is only in comparison to typically developing children of similar chronological ages that one can determine if certain groups are spared in their functioning in a behavioral domain. The best example involves Williams syndrome, long thought to be spared in certain areas of language. To determine whether language in Williams syndrome is indeed spared, a typical, chronological age-matched group is needed. Although sparing now seems unlikely for groups (as opposed to for a few individuals) with Williams syndrome (Karmiloff-Smith et al., 1996; Mervis et al., 1999), the test for spared functioning involves comparing to typically developing age-mates either explicitly (using a typical chronological age-matched group) or implicitly (using standard scores from a standardization sample).

Finally, showing that a particular etiological group has a specific strength or weakness does not, by itself, show that such a profile is unique to one etiological group, is shared with several other etiologies, or is something that occurs in most children with mental retardation. Instead, all (or most) persons with mental retardation may show a particular pattern of cognitive, linguistic, adaptive, or other strengths and weaknesses. If so, then lowered intellectual abilities are the problem, and the profile is not etiology-related. Such conclusions require our second set of specific research techniques, to which we now turn.

Are Such Profiles Seen in Children with Mental Retardation More Generally? As Table 12.3 shows, this second general research question also features two often-used techniques. In the first, researchers compare persons with a particular mental retardation syndrome to a *mixed or nonspecific group* who are equated on both

mental age and chronological age. If behavioral phenotypes do indeed involve "the heightened probability or likelihood that people with a given syndrome will exhibit certain behavioral and developmental sequelae relative to those without the syndrome" (Dykens, 1995, p. 523), such a mixed or heterogeneous group best approximates "those without the syndrome."

As before, several issues arise. The first concerns the proper mixture of the mixed group, and how to ensure that one's sample does indeed approximate the larger retarded population. Unfortunately, in contrast to our knowledge about many psychiatric disorders, the field of mental retardation has performed few such epidemiological studies. Among all persons with mental retardation, what percentage has Down syndrome? Or Prader-Willi syndrome? At present, we do not have precise answers.

A second technique in this class compares one etiological group against *children with Down syndrome*. Although groups with Down syndrome are often used as a "mentally retarded control group," we consider this strategy to be inappropriate. As a group, persons with Down syndrome show relative weaknesses in grammar (Fowler, 1990) and in expressive language (Miller, 1999); most persons with Down syndrome also show articulation problems (Kumin, 1994). Compared to others with mental retardation, children with Down syndrome more often show "sociable" behaviors such as more looking and smiling at others (Kasari & Freeman, 2001; Kasari, Freeman, Mundy, & Sigman, 1995). So, too, may these children show psychopathology less often and less severely than others with mental retardation (Dykens & Kasari, 1997; Meyers & Pueschel, 1991). Especially in studies involving language, social skills, or maladaptive behavior-psychopathology, using samples with Down syndrome as a control group seems ill advised.

How Do Children in a Specific Etiological Group Compare to Nonretarded Persons with Similar Conditions or Behaviors? This final approach compares persons who have a genetic syndrome to "specialized" nonretarded persons in an area of specific interest. Here again, the general approach can be seen through the use of two specific research techniques. In the first, persons with a particular syndrome are compared to *nonretarded persons with a diagnosed psychiatric disorder*. Dykens et al. (1996) compared persons with Prader-Willi syndrome to nonretarded outpatients with obsessive-compulsive disorder. With very few exceptions, the two groups were very similar in their mean number and severity of compulsions and in percentages within each

group displaying most behaviors (e.g., cleaning, ordering/arranging, repeating rituals).

Such a specialized-group strategy can also be shown in a second technique, this one comparing to *nonretarded persons who show particular cognitive-linguistic profiles*. How, for example, might children with Prader-Willi syndrome—who show simultaneous over sequential processing abilities—compare to nonretarded persons who similarly show such simultaneous advantages? How do children with Prader-Willi syndrome compare to typically developing children who are “good puzzlers”? Are the two groups approaching problems in the same way? In many ways, this final research strategy best approaches Cicchetti and Pogge-Hesse’s (1982) call for research that examines developmental processes in children with mental retardation.

The single drawback is that, by using specialized nonretarded groups, one risks designing a “no-difference” study, a study in which the two groups do not show significant differences. For instance, when compared to typical children who are also high on simultaneous processing or on jigsaw puzzle abilities, children with Prader-Willi syndrome may look identical. Though interesting theoretically, no-difference findings are always more problematic statistically.

Comparisons in Studies of Families and Ecologies

In discussing control-contrast groups involving families and other ecologies, different issues arise. In fact, most studies compare families of children with mental retardation to families of typically developing children of the same chronological, not mental, age. The reasoning here involves family life cycles. Carter and McGoldrick (1988) identify six stages of family life, beginning with the young adult’s leaving home, then getting married, having young children, then seeing those children through adolescence, launching those children into adult life, and, finally, accepting shifting generational roles, as when children begin to take care of their parents. This type of stage theory also conceptualizes the family as multigenerational, with shifting roles and responsibilities for each member. Each person adopts different roles depending on which family member is the focus, with parents themselves leaving home at earlier ages, becoming grandparents many years later.

Like all theories of adult development, Carter and McGoldrick’s (1988) stages might be better conceptualized as general guidelines. Still, these stages do make salient that parents of different-age children have differ-

ent concerns. Parents worried about their 2-week-old infant’s eating, sleeping, and physical development differ greatly from parents concerned about their 16-year-old’s new peers and developing sexuality. Such parent-family differences based on the child’s chronological age are behind the decision to compare families of children with mental retardation to families of same-age typically developing children (Seltzer & Ryff, 1994). Mental-age comparisons seem most appropriate when considering children with mental retardation, chronological age comparisons when considering their families.

And how should one approach parent-child interactions? As noted earlier, early studies examined parental (mainly maternal) behaviors toward children of the same chronological age as typically developing children. In some studies, it was even strongly hinted that mothers were deficient in their input to their children, as they were speaking at lower levels than were mothers of typically developing children. Beginning with Rondal (1977), groups came to be equated more on age-equivalent scores, and the use of either mental age or language age comparisons has predominated over the past few decades.

As we gain in our knowledge of children with different types of mental retardation, such issues become even trickier. Consider the finding that children with Williams syndrome show relative strengths in language (compared to overall levels of mental age), or that children with Prader-Willi syndrome show excellent performance—even above typical children of identical chronological age—on jigsaw puzzles. What is the appropriate maternal input relative to these tasks?

One suggestion is that children with different genetic mental retardation syndromes might be used as proxies for particular emotional-behavioral problems, personalities, or skill levels on specific tasks (Hodapp, 2004b). In such analyses, one might use children with Down syndrome as a proxy for a sociable, upbeat personality. Conversely, one might use children with Prader-Willi syndrome versus with Williams syndrome as good versus poor jigsaw puzzlers, respectively. Other syndromes might also be used as proxies for one or another etiology-related behavior. One could then ask whether parents or others react similarly or differently to nonretarded children who have similar problems, personalities, or high or low skills on a specific task.

Granted, one must be careful in performing this type of analysis, as a single etiology often predisposes individuals to multiple behavioral characteristics. Children with Prader-Willi syndrome are excellent at putting together

jigsaw puzzles, but, in other contexts, such children might be thought of as proxies for children with extreme eating problems and obesity, or children with obsessive-compulsive disorder. Other genetic syndromes can similarly be considered to have more than one behavioral outcome, and reactions or interactive behaviors might also differ based on the interactor or the task.

Using genetic disorders as behavioral proxies extends the many applied developmental studies on so-called natural experiments. In each of these studies, one must essentially disentangle several factors. Consider Rutter's (Rutter, Pickles, Murray, & Eaves, 2001) work on psychiatric risks of such events-situations as maternal deprivation, early institutionalization, being a twin, or being adopted. In each case, the question is not only whether one or another of these situations increases the risks of psychiatric problems, but why.

Direction of Effects, Mediators-Moderators, and Associated Variables

Similar to Bell's (1968) original question many years ago, the direction of effects remains unclear in many studies of mother-child interaction and of family child relations. Does the mother influence the child, or the child the mother?

Under different circumstances, both directions seem to be operating. In a study examining children with mental retardation when children were 3, 7, and 11 years old, Keogh, Garnier, Bernheimer, and Gallimore (2000) found that the more likely direction of effects was from child to parent. In path analyses, the child's higher levels of behavior problems, greater degrees of cognitive impairment, and lower levels of personal-social competence affected parent and family adaptation. In contrast, parental changes and accommodations of the family routine usually did not influence later child behaviors.

From the other direction, parents and families may also influence children. Harris et al. (1996) found that mothers who more often followed the child's lead and prolonged joint attention episodes "produced" young children with Down syndrome whose language developed at a faster rate. Conversely, when mothers more often redirected the child's focus of attention and engaged in greater numbers of separate joint-attention episodes, children showed smaller gains in receptive language skills. Using hierarchical linear modeling to examine changes over the child's first 5 years of life, Hauser-Cram et al. (1999) found that more cohesive families and mothers who more sensitively interacted

with their children "produced" children with Down syndrome who showed greater amounts of development on the adaptive behavior domains of communication, daily living skills, and socialization. Depending on the study, then, children may influence parents or parents may influence children.

In considering these studies, one begins to appreciate just how rare are good, longitudinal studies of children with mental retardation and their parents, families, schools, and other surrounding environments. Even fewer studies examine mediators or moderators of developmental change, and little of what we know about longitudinal effects, mediators, or moderators has been examined in children with different genetic syndromes and their parents, families, or larger environments.

Finally, certain methodological issues pertain only to children with different genetic syndromes and their families. Consider so-called associated variables, those variables that go together with different syndromes but that are separate from the child's behavior per se. The best examples involve Down syndrome. In contrast to other syndromes or to mental retardation in general, Down syndrome is a widely known disorder, occurs more often in births to older mothers, is usually diagnosed at birth, and is fairly common. Parents have access to several well-known, active, and powerful parent groups, as well as books, articles, Web sites, and other informational supports.

One might be tempted to attribute all differences in parents or families of children with versus without Down syndrome to such associated characteristics. Although such differences exist between Down syndrome and other disabilities, they probably do not totally account for the Down syndrome advantage. Moreover, associated characteristics cannot account for changes with age in parent or family stress or perceptions of their children (Hodapp et al., 2003), or the connections between the child's personality and parental attributions (Ly & Hodapp, 2002). We currently know little about formal and informal supports vis-à-vis parents and families of children with different genetic mental retardation syndromes.

Summary

Mental retardation research has gaps that both include and transcend those found in studies of child development and applied child development. In one sense, studies on children with mental retardation mirror gaps found in studies of typically developing children. We

need more studies that are longitudinal, that look at moderators and mediators, that worry more about direction of effects, and that use more sophisticated statistical techniques.

Yet in other ways, research issues in mental retardation are specific to this population. Research on few other populations seems to have as much trouble in deciding how research groups should best be divided. Few feature as many as six or seven strategies concerning control or contrast groups. Similarly, few nowadays generally compare to typical children of the same mental age when examining children's functioning, but of the same chronological age when family functioning is the issue. Few fields struggle as mightily with what (if anything) their population's findings tell us about the typical or normative processes of children's development, or of the typical or usual reactions and behaviors of parents and families.

MAKING THE LEAP FROM KNOWLEDGE TO PRACTICE

Like the field of child development itself (Sears, 1975), mental retardation behavioral researchers have historically valued applied work, and basic and applied interests have existed side-by-side in the mental retardation field (Hodapp, 2003). Even the most basic of researchers strive, through their findings, to allow children with mental retardation to develop more optimally, to develop faster in one or another area of functioning, to avoid maladaptive behaviors that make everyday living more difficult. Similarly, those interested in parent-child interaction, families, schools, and neighborhoods desire to improve the developmental ecologies of children with mental retardation.

And yet, although basic and applied interests coexist in the mental retardation field, basic research findings have not always been easily translated into more sophisticated, appropriate interventions. This basic-to-applied gap may simply reflect the fact that, as a field, we know too little. But other issues relate to societal changes, mixing generic and specialized approaches, noncategorical philosophies, and cross-level and interdisciplinary issues. Before describing interventions, then, we first turn to each of these matters.

A Changing Society and a Changing Population

Both philosophically and demographically, American society is changing. Philosophically, over the past few

decades Americans have increasingly come to accept the full participation in society of individuals with disabilities. Such societal changes have been embodied in a series of legal and legislative changes that have come to be referred to as the disabilities movement. This movement followed the civil rights and women's movements in demanding full participation of all individuals in school, at work, in the community, and in the law. Major successes include the Education for All Handicapped Children Act, or Public Law 94-142, in 1975, and the Americans with Disabilities Act of 1990, which ensured full access in employment. Each act has codified into law that it is a right—not a privilege—for individuals with disabilities to take their full place in American society.

In addition to such societal changes, changes are also occurring in the American population itself. Not so many years ago, the United States could more or less accurately be considered a country in which the "usual" family was White and middle class, with two parents, one of whom worked outside (usually the father) and the other inside (usually the mother) of the family home. But in recent years, an increasing percentage of the American population has become non-White, most families (including many with young children) have mothers who work outside the family home, and divorced, single, and unmarried parents are all increasingly common. Each issue obviously affects children with mental retardation and their families, although service, research, and policy practices have all yet to catch up.

Consider the impact of another demographic change: the aging of the American population. Demographers note that the American population has gotten increasingly older over the past few decades; the median age of Americans rose from 26.5 years in 1930 to 35.3 years in 2000. In only a few years' time, the leading edge of the Baby Boomers (i.e., those born between 1946 and 1964) will begin retiring. Medicare payments will rise exponentially, health systems will face increased stressors, and few politicians have either the foresight or the courage to address such issues.

A corollary concerns the aging of the population with disabilities. Currently in the United States, 526,000 adults with disabilities are 60 years or older, and that number is expected to triple—to over 1.5 million—by 2030 (National Center for Family Support, 2000). Given that at least 60% of these adults live at home and are now cared for by aging parents, who will care for these adults with disabilities when their parents die or are no longer able to care for them? The adult siblings of adults with disabilities are the assumed future caregivers, but

the needs of adult siblings—and all issues relating to life-span development—have so far remained almost totally unexamined in the mental retardation field.

Generic and Specialized Issues

When considering interventions for children with mental retardation and their families, one must think in terms of three separate levels. First, certain programs and services are needed by everyone. All children require caregiving, adequate food and shelter, safe neighborhoods, decent schools, and affordable health care. Such services might be considered common needs of all children and their families.

A second level of services is general to all children with mental retardation and their families. Again, such services and interventions are mostly generic: early intervention programs, special education services, transition, family support, and adult services relating to the adults working and living in the community. Such interventions apply to all children with mental retardation, as well as to children with any disabling condition (deafness, blindness, motor, or emotional problems).

A final set of services and interventions are specific to children with specialized needs. Some children with mental retardation have specialized health care needs, often relating to heart problems or motor impairments. Although estimates vary, approximately $\frac{1}{4}$ to $\frac{1}{3}$ of children with mental retardation also show significant psychiatric impairment (Bouras, 1999; Dykens, 2000; Tonge & Einfeld, 2003).

Many of these health and psychiatric concerns also relate to specific etiological groups. Many children with Down syndrome show heart and respiratory problems, as well as higher prevalence rates of leukemia and (in early mid-adulthood) Alzheimer's disease (Leshin, 2002; Pueschel, 1990). Children with Prader-Willi syndrome are prone to obsessive-compulsive disorder (Dykens et al., 1996), those with Williams syndrome to clinically high levels of anxiety and fears (Dykens, 2003). Etiology-based interventions might address such health, psychiatric, and cognitive-linguistic concerns.

Obviously, each type of intervention is necessary, but the three types of intervention also mutually influence one another. Consider the connections between specialized health or habilitative services and services to help families survive economically. Birenbaum and Cohen (1993) note that families of children with more severe impairments often have associated expenses that, in

most cases, these families must pay for themselves. Compared to average health care costs of less than \$1,000 per year for all American children, Birenbaum and Cohen's families spent an average of \$4,000 a year on health care for their children with severe or profound mental retardation. For about 10% of these families, costs of home or car modifications for their children exceeded \$2,000 per year. Such expenses, while unknown to parents of typically developing children, are commonplace to parents of children with mental retardation (particularly those at severe or profound levels). Although Medicaid and state-run cash assistance programs can sometimes offset these costs (Agosta, 1989; Agosta & Melda, 1995), issues of shelter, safety, and well-being are not necessarily separate from intervention discussions within the mental retardation field.

Noncategorical Philosophies

Noncategorical programming refers to the intervention practice of considering together children with many different disabilities (Reynolds, 1990). Most prominent in the field of special education, the idea is that a category, or label, is rarely helpful in the educational process and that different types of children can therefore be educated together. Even if several disabilities do benefit from distinct educational approaches, Forness and Kavale (1994) contend that we could eventually reach the unwieldy situation of many groups requiring their own, specialized classrooms. Such a "Balkanization" of special education services would cause administrative nightmares for schools, teachers, and districts.

Although sympathetic to potential adverse effects of labeling or a Balkanization of special education, we nevertheless feel that certain labels, or genetic diagnoses, may matter. If children show etiology-related profiles of development, personalities, and maladaptive behavior or psychopathology, it seems possible to design interventions that might capitalize on such etiology-based information. To us, the noncategorical philosophy ignores the many etiology-related behavioral findings that have appeared over the past 10 to 15 years. Whether categories are beneficial should be an empirical issue, not one decided on the assertion that labels do not matter.

Cross-Level and Cross-Disciplinary Matters

A final issue relates to cross-level and cross-disciplinary matters. Table 12.4 gives a partial listing of several dis-

TABLE 12.4 Professions Associated with Different Syndromes of Mental Retardation

Profession	Syndrome	Issues
Pediatrics	All	Various pediatric concerns, some specific to particular syndromes.
Genetics	FX, PWS	Number of repeats and methylation status (FX); deletion-disomy (PWS).
Nutrition	PWS, DS	Weight control in PWS and DS; weight reduction in life-threatening cases.
Dentistry	WS, PWS, DS	Dental crowding, caries, saliva, and other issues.
Occupational and Physical Therapy	DS, WS, PWS	Joint stability and flexibility; help in fine- and gross-motor functioning; mobility, balance, movement.
Speech-Language Pathology	DS	Grammar and articulation.
Social Work	All	Mother, father, sibling, and family issues; help in dealing with state social service agencies, thinking and planning about future.
Genetics Counseling	DS, FX, other	Family risk assessment due to parent age, family history, or other.
Child Psychiatry and Clinical Psychology	WS, PWS, FX, Rett	Anxiety (WS), obsessive-compulsive disorder (PWS), autism or autistic-like behaviors (FX, Rett).
Psychopharmacology	PWS, WS	Pharmacological treatments for any maladaptive behavior or psychopathology.
Neurosciences	All	Brain-behavior connections involving brain regions, structures, interconnections, and development.

DS = Down syndrome; FX = Fragile X syndrome; PWS = Prader-Willi syndrome; Rett = Rett syndrome; WS = Williams syndrome.

ciplines interested in children with mental retardation. Although we present professions that deal with children with specific genetic disorders, an equally impressive list of professions and interests could be developed for children with mental retardation in general.

Although impressive in its numbers of disciplines, this list also highlights that mental retardation is not owned by any single discipline. Unlike, say, obsessive-compulsive disorder or depression, which are considered to fall mainly within the purview of mental health professionals, children with mental retardation are not predominantly the concern of child psychiatrists and clinical psychologists. Depending on the specific issues involved, many different professionals help persons with mental retardation. Some might even consider this large list a curse; unlike other disorders, mental retardation has no single professional group that is mostly or totally responsible or interested.

A related issue arises in research. To truly understand children with mental retardation, one needs to be comfortable working in an interdisciplinary fashion. But such collaborations are difficult. Consider even the problem of terminology. To geneticists, each of the following are common terms: cytogenetics and molecular genetics; imprinting; alleles; full versus partial mutation; deletion, disomy, and amplification; and trisomy, translocation, and mosaicism. Many subbranches of developmental psychology have equally strange-seeming terms and interests, and it is difficult to explain enough

of what one does to professionals from different disciplines to achieve some common understandings. But if we are ever to reach sophisticated understandings of behavioral development in many types of mental retardation, it seems essential to navigate such cross-cultural disciplinary divides.

Some Examples of Interventions

In the pages that follow, we provide examples of educational, clinical, and family-based interventions.

Educational Interventions: Reading Instruction for Children with Down Syndrome

Children with Down syndrome show relative weaknesses in grammar, expressive language, and articulation. Conversely, these children show relative strengths in visual (as opposed to auditory) short-term memory.

Using these findings, as well as several decades of intervention work, Buckley and her colleagues (Buckley & Bird, 2002) have long advocated teaching reading to these children. So far, the findings are mixed. On one hand, many children can establish reading vocabularies of numerous sight words, even during the preschool years (Buckley, 1995). Half of all children and adolescents may be able to read more than 50 words, with some reaching much higher levels (Buckley, Bird, & Byrne, 1996; Johansson, 1993).

In addition, reading may constitute an entryway into other areas of language. Laws, Buckley, Bird, MacDonald, and Broadley (1995) compared children with Down syndrome who were readers with those who were not. Over a 4-year span, readers were ahead of nonreaders on tests of receptive vocabulary, receptive grammar, auditory memory, and visual memory. For many measures, an interaction also occurred between receiving reading instruction and developmental changes from time 1 to time 2.

On the other hand, questions persist concerning the degree to which children with Down syndrome have or can acquire reading's component skills. Essentially, literacy intervention capitalizes on the relative strength of visual short-term memory for most children with Down syndrome. But reading is more than a visual skill; higher levels of reading can come about only when one attains various aspects of phonemic awareness. Through their ability to segment, delete, and count phonemes, children become able to identify and manipulate phonemes (Gombert, 2002). In typical children, phonetic decoding is a strong predictor of both first- and third-grade reading skills (McGuinness, 1997); levels of phonological awareness and reading also correlate in children with Down syndrome (Fowler, Doherty, & Boynton, 1995; Laws, 1998).

How good are children with Down syndrome at phonological awareness and, if not so good, can they read in some other way? In three studies, Snowling, Hulme, and Mercer (2002) compared typical children to children with Down syndrome on segmentation, nursery rhyme knowledge, rhyme detection, and phoneme detection. They also examined letter names and sounds, print in the daily environment, single-word reading, and nonword reading. Predictors of reading ability were different for the two groups. Although children with Down syndrome with good phonological skills were better readers than those with poorer skills, their letter-sound knowledge was not a concurrent predictor of reading performance. Children with Down syndrome performed worse than control children on rhyme judgment. Other studies have also documented deficits in specific phonemic awareness tasks by children with Down syndrome (Cardoso-Martins, Michalick, & Pollo, 2002; Gompert, 2002).

Compared to typical children, then, children with Down syndrome may follow a qualitatively different path in their development of reading and phonological skills. Children with Down syndrome identify initial syllable and onset phonemes, but have more difficulty

with rhyme ("rhyme deficit"). Letter-sound knowledge does not appear related to reading and/or phonological skills. Children with Down syndrome are therefore reading without the full understanding of all aspects of phonemic awareness. They use grapheme-phoneme strategies to some extent, but are also accessing such other strategies as whole-word recognition.

A related issue concerns whether developing literacy skills might constitute an entryway into language. Although several researchers have suggested that reading is the visual route to improved spoken language, longitudinal research does not support this relationship. In a 5-year longitudinal study of 30 individuals with Down syndrome on language, memory, and reading, Laws and Gunn (2002) found that readers performed better on language and nonverbal ability measures at both assessments. There were no significant interactions, however, between reading progress and progress in memory or language. Similarly, no interaction was found between reading skills (or progress) and developments in expressive language. In contrast to earlier formulations, in Down syndrome the direction of effects seems to be language to reading—language abilities influence reading acquisition—as opposed to reading influencing language acquisition.

Reading instruction for children with Down syndrome thus remains intriguing but in need of further study. We need to know more about how children with Down syndrome read, and whether their reading processes are the same as or different from those used by typically developing children. Given such knowledge, we then need to know which strategies might work best for children with Down syndrome who are beginning to read.

Interventions for Maladaptive Behavior-Psychopathology

As noted earlier, as many as $\frac{1}{4}$ to $\frac{1}{3}$ of children with mental retardation also show associated maladaptive behavior-psychopathology, and several different genetic syndromes seem predisposed to specific types of psychopathology. In response to the need for clinical, pharmacological, and other interventions, several etiology-based clinical services have arisen for children with specific types of mental retardation and their families.

University-Based Behavior Genetics Clinic. One example is the UCLA-Lili Claire Behavior Genetics Clinic at UCLA's Neuropsychiatric Institute. The clinic, which meets one morning per week, was founded in

1996. Its original focus was to serve the mental health and dietary needs of children and young adults with Prader-Willi syndrome. Since that time, the clinic has also served children with Down syndrome, Williams syndrome, and other genetic disorders, as well as these children's family members, teachers, group home workers, and others involved in the child's life.

Although housed in child psychiatry and focused mainly on the management of maladaptive behaviors, the clinic's focus is interdisciplinary. Children and families come for an initial 1- to 2-hour visit with a child psychiatrist, child clinical psychologist, social worker, and special educator. Given the dietary issues in Prader-Willi syndrome, a licensed nutritionist is also often on hand, and consultations are common to (and from) clinical genetics, pediatrics, cardiology, speech-language pathology, and other disciplines. The clinic's medical director has long experience in prescribing drugs to children and adults with mental retardation (and with these syndromes).

In their initial visit and in follow-ups every few months, the children, parents, and others receive numerous, interrelated services. The social worker helps navigate the social service system and brings along information about specific syndromes and parent support groups. The social worker and special educator advocate for the children and their families with the school and with state social service agencies, and the clinical psychologist and child psychiatrist assess child and family needs and strengths. Working together, clinic personnel offer parents with several different disorders practical advice and follow-up, knowledge and contact information about the syndrome, behavioral and pharmacological interventions, and other help as needed.

Behavior Analysis. A second intervention is more strictly behavior-analytic in orientation, successor to an approach that was earlier referred to as "behavior modification." This approach has been extremely helpful to children with mental retardation and their parents in three distinct ways.

First, behavior analysis has been remarkably successful in teaching adaptive skills to children and adolescents with mental retardation, many at the more severe to profound levels. Such behaviors as grooming, toileting, eating, and dressing have all been taught to individuals at the profound and severe levels of mental retardation (Carr et al., 1999). At later ages, techniques such as task analysis and token economies have allowed

many persons with mental retardation to work successfully in supported work environments (Wehman, Sale, & Parent, 1992). Again, such direct, labor-intensive interventions have allowed these individuals to achieve skills and produce in jobs that were previously beyond their reach.

Second, behavioral techniques have been helpful for parents. Parents of very impaired or difficult-to-control children are often at a loss as to how to proceed. Such parents are helped by the behavior analyst's specific behavioral interventions and charting of the environmental precursors of child behavior (and of the consequences of different parent behaviors). Parents have been taught how to model desired behaviors, break down complex tasks into smaller components, and chain together these components (Baker & Brightman, 1997).

Third, behavior analyses have been particularly helpful in eliminating maladaptive behaviors. Although maladaptive behavior-psychopathology is especially prevalent in children with mental retardation, the children's inability to use language to describe their feelings and needs often makes "talk therapies" less effective. In contrast, behavior-analytic techniques generally do not require high levels of communication from the client being treated.

Although many examples could be cited of successful behaviorally oriented treatments, one will suffice. Craig Kennedy has recently begun the Vanderbilt Kennedy Center Behavior Analysis Clinic to intervene with children and young adults who show severe aggressive behaviors. In their model, aggression is considered a form of communication that the aggressive person is giving to the outside world. The clinician must first decipher the exact communicative functions of the individual's aggressive acts, and then institute therapies that might eliminate such aggressive behaviors (Kennedy, 2003).

Two advances distinguish the Vanderbilt Kennedy Center Behavior Analysis Clinic from other interventions with a similar philosophy. First, in a clinical sense, the interventions are provided to the clients, but parents and group home workers are then taught how to continue these interventions in the community. This newly begun clinic is thus combining interventions with parent training. Second, the Vanderbilt group is also interested in the so-called setting conditions of aggressive behaviors. In a series of studies, Kennedy and his colleagues have begun to examine the possibility that such child characteristics as sleep deprivation (Harvey & Kennedy, 2002) or genetic status (having or

not having a genetic variant predisposing to aggression; May, Potts, Phillips, Blakely, & Kennedy, 2004) might make aggressive behaviors more likely. In essence, behavior-analytic approaches, which began as predominantly environmental in orientation, have begun to join both environmental and child-related characteristics of children showing aggressive behaviors.

Parent-Family Support Groups

Although many would not consider parent support groups as an intervention *per se*, these groups have become important, influential organizations for many parents and families of children with mental retardation. In addition, such groups range widely in their targeted population, their orientation, and their desired outcomes for the many parents who participate (see Table 12.2).

Although research on parent support groups is only beginning, preliminary findings are intriguing. In studying groups for parents of children with disabilities, Solomon, Pistrang, and Barker (2001) examined members of the United Kingdom's Contact a Family, a group whose aim was to encourage mutual support among families of children with disabilities. Examining 56 parents of 9-year-old children with a wide variety of disabilities, Solomon et al. discovered that parents (who, on average, had been in the group for 4 years) were very satisfied with their groups, found them helpful, and rated them high on group cohesion and task orientation.

Follow-up focus groups provide more detail about how parents benefited from these groups in three broad areas. First, parents felt that they achieved a sense of control from the information gained from other group members. As one parent noted, "When you have a child with special needs, you don't know the best services, the best care, and so on. You get that information from the group" (Solomon et al., 2001, p. 121). Second, parents felt a strong sense of belonging to a community. The authors thus note, "Parents reported feeling 'less alone,' 'less isolated,' 'not the only one,' 'not different anymore,' as a result of group membership" (Solomon et al., 2001, p. 123).

The third benefit of these parent self-help groups seemed to relate to parents' own emotional growth and development. Solomon et al. (2001) write:

Parents most commonly said that they felt "far more confident" when dealing with other people than they used to before coming to their group: they were more assertive, "tougher," and felt less intimidated, inhibited, embar-

rassed, awkward, and shy. The group helped them to feel "refocused" and "strengthened." (p. 124)

Other, analogous studies are also instructive. In these studies, parents and caregivers of persons with mental illness, Alzheimer's disease, or alcoholism all describe the benefits and limitations of parent support groups. Findings show that parents and families do benefit from these groups, mainly from receiving information and giving and receiving support. In addition, consumer-led versus professional-led groups focus more on advocacy than on emotional issues (Pickett, Heller, & Cook, 1998), and the two types of group differ greatly in cohesion, leader activities, group structure and task orientation, and fostering independence in group members (Toro, Rappaport, & Seidman, 1987).

Although much more research is needed, parent support groups seem an important ecology of families of children with disabilities. As with other self-help groups, the most effective groups probably involve high-quality relationships, high expectations for personal growth, and a moderate level of structure (Moos, 2003). Although all such groups have both strengths and weaknesses, "relatively cohesive, goal-directed, and well-organized intervention programs and life contexts can help distressed individuals recover and lead essentially normal lives" (p. 6).

CONCLUSION

Combining analyses of children and of their surrounding environments, mixing basic research with applications of that research, the mental retardation field seems almost the quintessential case of applied developmental psychology. From earlier days to today's studies of cognitive and language development, the specific issues may have changed, but the basic approaches have remained remarkably consistent. Such approaches can be summarized through the use of four related themes.

Perspectives and Approaches of Developmental Psychopathology

When most people think of developmental psychopathology, they date its origin to the 1970s and 1980s. In 1974, Thomas Achenbach published his landmark work, *Developmental Psychopathology*. A few years

later, Cicchetti (1984) began writing about the larger approach of developmental psychopathology, in 1989 Cicchetti and Nurcombe founded the journal *Development and Psychopathology*, and the nascent field's various handbooks began appearing in the early to mid-1990s (Cicchetti & Cohen, 1995; Lewis & Miller, 1990).

Although such recent inaugural dates may be accurate for developmental psychopathology overall, developmental approaches to children with mental retardation go back much further. Piaget, Werner, and Vygotsky all examined children with mental retardation, and Zigler's (1967) developmental approach to mental retardation dates to the mid- to late 1960s. More important, developmentally oriented researchers conceptualized these children's development as informing us about typical developmental processes. From the earliest days through to today's studies of cognition, language, modularity, and theory of mind, developmentally oriented researchers have adopted Cicchetti's (1984, p. 1) dictum that we "can learn more about the normal functioning of an organism by studying its pathology, more about its pathology by studying its normal condition."

The Changing Sense of Development

Particularly over the past few decades, the very meaning of the word "development" has changed, both for those studying typically developing children and for those studying children with mental retardation. Within the child development field more generally, interests in interactions, transactions, and ecologies were propelled by the researchers most tied to each term: Bell (1968), Sameroff and Chandler (1975), and Bronfenbrenner (1979), respectively. For the smaller field of mental retardation, especially for those interested in developmental issues of these children, the interactional, transactional, and ecological movements in developmental psychology proper have served as a point of reference, a way to extend, apply, and test out our (expanded) notions of development (Hodapp & Zigler, 1995).

As a result, developmental approaches to children with mental retardation now easily include analyses of mother-child interactions, parents, families, friends, schools, and neighborhoods. Just as developmental psychology now concerns itself with all things related to children and children's development, so, too, is a wider view of children's development now intrinsic to the mental retardation field. Although neighborhoods, families,

siblings, and intersystem connections may be less well-studied for children with mental retardation, developmental analyses include each of these issues.

Similar but Different Concerns and Complications

And yet, even as mental retardation's developmental studies simply apply and extend findings from typically developing children, so, too, does this area have its own, idiosyncratic issues and concerns. Consider the very issue of how one defines mental retardation, or how one classifies research groups within the population, or to what extent one should examine children with specific genetic syndromes. Each issue is specific to the mental retardation field.

Similarly, when one considers the wider ecology, mental retardation has its separable concerns. In mental retardation, one must concern oneself with the wider service-delivery systems and (at least implicitly) acknowledge how that system has changed dramatically over the years. Indeed, many studies in the 1950s and 1960s examined children with mental retardation who resided in large public institutions; nowadays, such children almost all live in their family home. Even today, almost every study in such journals as the *American Journal on Mental Retardation*, *Mental Retardation*, and the *Journal of Intellectual Disability Research* (the three main research journals in the mental retardation field) routinely note the types of classrooms their school-age subjects are attending (specialized, mainstreamed, fully integrated); such information is rarely provided for school-age subjects of articles in journals such as *Child Development* and *Developmental Psychology*.

Such field-specific issues also arise in separate, almost parallel histories and research concerns of particular issues in each field. For instance, the movement from negative to stress-and-coping views of parents and families of children with mental retardation has no counterpart in the larger child development field. Few family studies in child development need concern themselves with the outside formal supports offered to their families, or to the amount, costs, or availability of services the child is receiving outside of school. Similarly, few researchers of typically developing children need to worry about mental age versus chronological age comparison groups, different comparison groups when dealing with children's development versus the functioning

of their parents, or how to best classify different children with mental retardation. All are research issues specific to the field of mental retardation.

Simultaneous Concern with Basic and Applied Information

Still, if mental retardation research is “the same but different” relative to the wider child development field, it nevertheless shares with child development its status as a “mixed” discipline. Like researchers in mental retardation, most child development researchers would argue that their work has applied implications and that their ultimate goal is not simply to understand the processes of children’s development. Instead, most child development researchers would argue that their goals include using that knowledge to better educate children or to foster children’s development. So, too, is the field of mental retardation both basic and applied, simultaneously searching for information about the processes by which these children develop and considering how such basic information can be used to improve the lives of children and their families.

Mental retardation, then, is one among many areas of applied developmental psychology. Whether one is considering gene-brain-behavior relations, or mother-child interactions, or how to use basic research to best educate children, our respective concerns overlap greatly. Such similar basic and applied concerns, such similar uses of many disciplines to examine many domains of functioning, have remained constant over the years. One might argue that, in many ways, we have not advanced much from the days of Piaget, Werner, or Vygotsky. In the spiral-staircase view of development, however, we argue that, although we are in some ways at the same point, our questions and answers have become increasingly specific, increasingly interesting, and increasingly helpful to addressing a greater number of basic and applied issues. May we continue—even increase—our joint efforts as we further understand typical development and development of children with mental retardation, this “old and new” topic within the larger field of child development.

CHILD MALTREATMENT	502
Definitional Considerations in Child Maltreatment	503
The Need for a Nosology of Child Maltreatment	504
The Effects of Maltreatment on the Developmental Process	506
TRANSLATING MALTREATMENT RESEARCH INTO PRACTICE: THE DEVELOPMENT AND IMPLEMENTATION OF PREVENTIVE INTERVENTIONS	516

In this chapter, we focus on child maltreatment and the offspring of a parent with a Major Depressive Disorder as illustrative exemplars of how theory and research guided by a developmental psychopathology perspective can help to elucidate the etiology, course, and sequelae of these high-risk conditions and to inform the implementation of preventive interventions. We also address decision points and challenges that emerge when developing and implementing the intervention evaluations and when attempting to apply resulting findings to clinical contexts. Our discussion of these topics is guided by an adherence to an organizational perspective on development because we believe that sound theory is critical for organizing research and intervention efforts in the field. To begin our discussion, we provide a brief description of the field of developmental psychopathology as it applies to clinical practice. A more comprehensive description of the discipline, as well as an articulation of its similarities to and divergences from related fields of inquiry, is presented in *Developmental Psychopathol-*

PRINCIPLES OF DEVELOPMENTAL PSYCHOPATHOLOGY AND IMPLICATIONS FOR CLINICAL PRACTICE

Developmental psychopathology is an integrative scientific discipline that strives to unify, within a life span framework, contributions from multiple fields of inquiry with the goal of understanding the mutual interplay between psychopathology and normative adaptation (Cicchetti, 1984, 1989, 1993; Cicchetti & Toth, 1998b; Rutter, 1986; Rutter & Garmezy, 1983; Rutter & Sroufe, 2000; Sroufe & Rutter, 1984). Prior to the emergence of developmental psychopathology as an integrative perspective with its own integrity, the efforts of those working in these areas had been separate and distinct. Some of the lack of integration stemmed

from long-standing tensions between the philosophical traditions underlying clinical practice and academic training and between experimental versus applied research (see Cahan & White, 1992; Cicchetti, 1984; Cicchetti & Toth, 1991; Santostefano, 1978; Santostefano & Baker, 1972).

Developmental psychopathologists are as interested in individuals at high risk for the development of psychopathology but who do not manifest it over time as they are in individuals who develop an actual disorder (Cicchetti & Garmezy, 1993; Luthar, 2003; Luthar, Cicchetti, & Becker, 2000; Masten, 2001). Relatedly, developmental psychopathologists are committed to discovering pathways to competent adaptation despite exposure to conditions of adversity (Bonnano, 2004; Cicchetti & Toth, 1991; Luthar, 2003). For example, in a longitudinal investigation of the pathways to maladaptation and resilience from childhood to late adolescence, Masten and her colleagues (1999) found that better adolescent intellectual functioning and parenting resources were associated with good outcomes across a variety of competence domains, even in the context of severe, chronic adversity. Resilient adolescents had much in common with their low-adversity competent peers, including average or better IQ, good quality parenting, and higher psychological well-being. Comprehending the factors contributing to positive outcomes despite the presence of significant adversity (i.e., resilience) can help to broaden the understanding of developmental processes that may not be evident in "good enough" normative environments (Cicchetti & Rogosch, 1997; Masten, Best, & Garmezy, 1990). As researchers increasingly conceptualize and design their investigations at the outset with the differential pathway concepts of equifinality and multifinality as a foundation (cf. Cicchetti & Rogosch, 1996; Richters, 1997), we will come progressively closer to achieving the unique goals of the discipline of developmental psychopathology: to explain the development of individual patterns of adaptation and maladaptation (Cairns, Cairns, Xie, Leung, & Heane, 1998; Sroufe & Rutter, 1984).

A central principle of developmental psychopathology is that individuals may move between psychopathological and nonpsychopathological modes of functioning (Zigler & Glick, 1986). Additionally, developmental psychopathologists underscore that, even in the midst of psychopathology, patients may display adaptive coping mechanisms. Only through the consideration of both adaptive and maladaptive processes does it become pos-

sible to delimit the presence, nature, and boundaries of the underlying psychopathology.

Furthermore, developmental psychopathology is a perspective that is especially applicable to the investigation of transitional turning points in development across the life span (Rutter, 1990; Schulenberg, Sameroff, & Cicchetti, 2004). Rutter has conjectured that key life turning points may be times when the presence of protective mechanisms could help individuals redirect themselves from a risk trajectory onto a more adaptive developmental pathway (Elder, 1974; Quinton & Rutter, 1988). With respect to the emergence of psychopathology, all periods of life are consequential in that the developmental process may undergo a pernicious turn toward mental disorder at any phase (Cicchetti & Cannon, 1999; Cicchetti & Walker, 2003; Moffitt, 1993; Post, Weiss, & Leverich, 1994; Rutter, 1996; Zigler & Glick, 1986). In contrast to the often dichotomous world of mental disorder/nondisorder depicted in psychiatry, a developmental psychopathology perspective recognizes that normality often fades into abnormality, adaptive and maladaptive may take on differing definitions depending on whether one's time referent is immediate circumstances or long-term development, and processes within the individual can be characterized as having shades or degrees of psychopathology.

Additionally, there has been an intensification of interest in biological and genetic factors (Cicchetti & Cannon, 1999; Cicchetti & Walker, 2001, 2003; Marendo & Weinberger, 2000; Plomin & Rutter, 1998) and in social-contextual factors related to the development of maladaptation and psychopathology (Boyce et al., 1998; Cicchetti & Aber, 1998; Sameroff, 2000). There is increasing recognition of the dynamic interplay of influences over developmental time. Perhaps the most dramatic example of this is the work on experience-dependent brain development (Greenough, Black, & Wallace, 1987). The viewpoint is now widely shared that neurobiological development and experience are mutually influencing (Cicchetti & Tucker, 1994; Eisenberg, 1995; E. R. Kandel, 1998; C. A. Nelson & Bloom, 1997). Brain development exerts an impact on behavior, of course; however, the development of the brain itself is affected by experience (Black, Jones, Nelson, & Greenough, 1998; Cicchetti, 2002a; Francis, Diorio, Liu, & Meaney, 1999; Meaney, 2001; Ray, 2004). Specifically, it has been demonstrated that social processes and psychological experiences can modify gene expression and brain structure, functioning, and organization (Black

et al., 1998; E. R. Kandel, 1998). Alterations in gene expression induced by social processes and psychological experiences produce changes in patterns of neuronal and synaptic connections (E. R. Kandel, 1998, 1999; Sanchez, Ladd, & Plotsky, 2001). These changes not only contribute to the biological bases of individuality, but also play a prominent role in initiating and maintaining the behavioral anomalies that are induced by social and psychological experience.

There also has been a veritable explosion in our knowledge of developmental neurobiology, that area of neuroscience that focuses on factors regulating the development of neurons, neuronal circuitry, and complex neuronal organization systems, including the brain. In addition, advances in the field of molecular genetics (see, e.g., Lander & Weinberg, 2000; Lewin, 2004) have contributed to the understanding of neurological disease, allowing scientists for the first time to understand the genetic basis of certain diseases without requiring foreknowledge of the underlying biochemical abnormalities (Ciaranello et al., 1995). These accomplishments have helped to engender renewed excitement for the potential contributing role that the field of molecular genetics can make to comprehending the development of psychopathology (Caspi et al., 2002, 2003; Cowan, Kopnicky, & Hyman, 2002; Plomin & Rutter, 1998).

Likewise, as we have drawn the distinction between factors that initiate pathways and factors that maintain or deflect individuals from pathways, there is a growing recognition of the role of the developing person as a processor of experience (Cicchetti, 2002b; Cicchetti & Tucker, 1994). The environment does not simply act on the child; the child selects, interprets, and exerts an impact on the environment in a dynamic way (Bergman & Magnusson, 1997; Rutter et al., 1997; Wachs & Plomin, 1991).

Furthermore, developmental psychopathologists recognize that the milieu in which an individual develops is likely to profoundly influence the developmental course (Garcia Coll, Akerman, & Cicchetti, 2000; Garcia Coll et al., 1996; Hoagwood & Jensen, 1997; Richters & Cicchetti, 1993). The dynamic interplay of risk and protective processes may have differential impact depending on the cultural norms, practices, values, and beliefs. Cultures may be characterized on a continuum ranging from sociocentric (emphasizing community, family, and interconnectedness) to individualistic (emphasizing individuality, autonomy, and personal achievement; Garcia Coll et al., 2000; Shweder & Bourne, 1991). The

ideal self correspondingly varies with respect to the degree to which the self is defined in terms of relatedness to others versus in terms of autonomy and achievement. As such, cultural groups differ in their socialization goals for desired outcomes for well-functioning members of the culture. Norms for appropriate and inappropriate behavior have different thresholds, and discipline strategies vary in accord with what behaviors are regarded as desirable or unacceptable. Moreover, risk and protective processes and the manner in which they transact may vary depending on priorities of the culture. Consequently, the individual's response to an event, as well as the reactions of other members of the culture, will influence the salience of the event and how it is responded to. Culture also may influence the mode of symptom expression. Cultural values, beliefs, and practices may tend to suppress manifestation of distress in one domain (e.g., socioemotional) while tolerating the expression in another domain (e.g., physical). For example, Serafica (1997) noted a tendency for greater physical manifestations of distress to be tolerated among Asian American families, as compared with less acceptance of psychological expression.

Bridging Research and Practice

Throughout its evolution as an increasingly mature discipline, an ongoing goal of the field of developmental psychopathology has been to become a science that not only bridges fields of study and aids in the discovery of important new truths about the processes underlying adaptation and maladaptation across the life span, but also provides the best means of preventing and ameliorating maladaptive and psychopathological outcomes (Cicchetti, 1990, 1993; Cicchetti & Hinshaw, 2002; Cicchetti & Toth, 1992, 1998b, 1999). Moreover, developmental psychopathologists have sought to reduce the dualisms that exist between behavioral and biological sciences, between basic and applied research, and between empirical research and the clinical study and treatment of childhood and adult high-risk conditions and disorders.

In this vein, developmental psychopathologists believe that efforts to prevent the emergence of psychopathology or to ameliorate its effects also can be informative for understanding processes involved in psychopathological development (Cicchetti & Hinshaw, 2002; Cicchetti & Toth, 1992; Kellam & Rebok, 1992). For example, if the developmental course is altered as a

result of the implementation of preventive interventions and the risk for negative outcomes is reduced, then prevention research helps to specify processes that are involved in the emergence of psychopathology or other negative developmental outcomes. As such, prevention research can be conceptualized as true experiments in altering the course of development, thereby providing insight into the etiology and pathogenesis of disordered outcomes (Cicchetti & Hinshaw, 2002; Howe, Reiss, & Yuh, 2002).

Prevention research is based on theoretical models of how risk conditions are related to adverse outcomes, positing processes that link the risk conditions to the negative outcome (Institute of Medicine, 1994; Munoz, Mrazek, & Haggerty, 1996; Reiss & Price, 1996). For example, poverty and single and teenage parenthood constitute risks for adverse family functioning, such as child abuse and neglect, increased negative developmental outcomes, and welfare dependence (Coley & Chase-Lansdale, 1998; McLoyd, 1998). Olds and his colleagues (1997) posited that maternal isolation, lack of parenting skills, and poor understanding of child development were processes mediating or linking the risk conditions to negative outcomes. A pre- and postnatal home visitation program was implemented to reduce these intervening processes, and the long-term effects of the intervention have been studied. The effectiveness of the intervention helps to establish the importance of the specified mediators as processes explaining how the risk factors contribute to negative outcomes (Hinshaw, 2002; Kraemer, Wilson, Fairburn, & Agras, 2002). Kellam and colleagues (Kellam, Rebok, Ialongo, & Mayer, 1994; Kellam, Rebok, Mayer, Ialongo, & Kaloneder, 1994), in studying risk for negative outcomes among predominantly poor urban children, identified early disruptive classroom behavior as a process contributing to school failure and Conduct Disorder, and poor achievement (specifically, in reading) as a factor contributing to heightened depressive symptomatology. Interventions were implemented to decrease classroom disruptive behavior and to improve reading skills, with the goal of reducing Conduct Disorder and depression symptomatology, respectively. In summary, prevention research not only leads to support or lack of support for theoretical formulations accounting for the development of psychopathology, but also can contribute to the knowledge base of strategies that can be implemented to reduce psychopathology and promote positive adapta-

tion (see, e.g., Conduct Problems Prevention Research Group, 2002a, 2002b, 2002c).

Comparisons of treated individuals to normative groups on diverse aspects of functioning provide a stringent test of treatment efficacy beyond symptom remission, and knowledge of normal variation on various indicators of adaptation is vital for informing such evaluations (Cicchetti & Rogosch, 1999). Knowledge of developmental norms, appreciation of how developmental level may vary within the same age group, sensitivity to the changing meaning that problems have at different developmental levels, attention to the effects of developmental transitions and reorganizations, and understanding of the factors that are essential features to incorporate into the design and implementation of preventive interventions all may serve to enhance the potential for optimal intervention efficacy (Cicchetti & Hinshaw, 2002; Cicchetti & Toth, 1992, 1999; Coie et al., 1993; Institute of Medicine, 1994; Noam, 1992; Shirk, Talmi, & Olds, 2000; Toth & Cicchetti, 1999).

Unfortunately, inquiries regarding developmental theory and findings on basic developmental processes are all too often quite removed from both clinical practice and clinical research (Cicchetti & Toth, 1998b; Kazdin, 1999; Shirk, 1999; Shirk et al., 2000). Despite rhetoric directed to the principle that developmental theory should inform active clinical intervention—and the converse contention that treatment research should inform relevant theory—the gap between these two endeavors is still broad. Indeed, in many ways, those who perform basic developmental research and promote developmental theory appear to constitute a different culture from those who pursue prevention and intervention efforts. At the extremes, clinically oriented investigators and practitioners perceive “basic” academic developmental science as overly concerned with central tendencies and universal, developmental norms, to the exclusion of the rich variability and nonnormative behavior patterns that they confront on a daily basis. Conversely, theorists and academic scientists appear to construe much of the clinical endeavor as atheoretical, practical, and ungrounded in core scientific principles and theories (Cicchetti & Toth, 1998b).

This state of affairs is particularly distressing given the advances that have been made in a host of basic behavioral and biomedical sciences and the urgent clinical needs of large numbers of individuals and families afflicted by mental disorders (U.S. Department of Health

and Human Services [DHHS], 1999). Because of the field's still nascent ideas as to the underlying mechanisms of most forms of psychopathology, the need for direct application of basic research advances toward the enhancement of clinical efforts can only be described as essential. Yet, despite the increasing call for "translational" research that can bridge basic and applied efforts, barriers that exist regarding the application of such basic research advances to clinically relevant work are real (Institute of Medicine, 2000). It is essential that so-called basic investigators receive greater exposure to training in clinical realities and that clinical investigators receive updated information about fundamental processes that are relevant to clinical disorders. As Rees (2002) has noted with respect to medicine, basic science (e.g., genetics, biochemistry) and clinical science (e.g., patient-oriented research) are interdependent endeavors. Rees argued that both forms of science are complementary and essential; clinical investigations should not be replaced by basic research, nor should the provision of service be devoid of empirical support.

In addition to their basic scientific endeavors and their growing appreciation of the importance of conducting developmentally informed preventive interventions, from the outset of the field, developmental psychopathologists have been cognizant of the need to translate empirical research into action. From its inception, contributors to the flagship journal of the field, *Development and Psychopathology*, have been urged to consider and address social policy aspects of their research.

The parameters of developmental psychopathology lend themselves to fostering research with implications for society and for policymakers. The very subject matter of the field, which encompasses risk and psychopathology, the elucidation of precipitants of mental illness, the mediating and moderating processes that contribute to or mitigate against the emergence and maintenance of psychopathology, prevention and intervention, and the incorporation of principles of normal development into the conduct of empirical investigations, necessitates thinking clearly about the implications of the work and devising strategies that will remedy the problems being studied. In his discussion of normal child development, Zigler (1998, p. 530) maintains that "those of us who study children must recognize that they are not merely subjects but partners in our research and we owe something to them." To this sentiment we add that all participants in developmental psychopathology research, whether infants, children,

adolescents, adults with serious mental disorders such as Schizophrenia or bipolar illness, or the elderly, deserve to be beneficiaries of newfound knowledge, as well as contributors to initiatives that will promote societal good. We believe that it is essential for the field to move beyond trying to arrive at post hoc explanations of the relevance of research for policy and to design investigations with policy questions at the forefront. This century presents us all with a unique opportunity to translate rhetoric into action and to truly achieve a research-informed policy agenda that will benefit the welfare of all.

An Organizational Perspective: Implications for Investigating the Nature of the Relation between Normality and Psychopathology

Before turning to the specific risk conditions addressed in this chapter, it is important to provide a framework within which research and intervention can be understood. Much research conducted in developmental psychopathology utilizes an organizational perspective on development, a powerful theoretical framework for conceptualizing the intricacies of the life-span perspective on risk and psychopathology, as well as on normal development (Cicchetti & Schneider-Rosen, 1986; Cicchetti & Sroufe, 1978; Sroufe & Rutter, 1984).

The organizational perspective focuses on the quality of integration both within and between the biological and psychological systems of the individual. Moreover, the organizational perspective addresses how development occurs, specifically identifying a progression of qualitative reorganizations within and among the biological, psychological, and social systems that proceed through differentiation and subsequent hierarchical integration (Werner & Kaplan, 1963). In accord with the organizational perspective, development is not viewed as consisting of a series of tasks that need to be accomplished and that subsequently decrease in importance. Rather, development is conceived as comprising a number of age- and stage-relevant tasks. Although the salience of these tasks may wane in relation to newly emerging issues, the tasks remain important to adaptation over time (Cicchetti, 1993). A hierarchical picture of adaptation emerges in which the successful resolution of an early stage-salient issue increases the probability of subsequent successful adjustment (Sroufe & Rutter, 1984). As each new stage-salient issue comes to the fore, opportunities for growth and consolidation, as

well as challenges associated with new vulnerabilities, arise. Thus, an ever changing model of development in which newly formed competencies or maladaptations may emerge throughout the life course and transact with the individual's prior developmental organization is proffered (Cicchetti & Tucker, 1994). Although early adaptation probabilistically portends the quality of future functioning, the possibility of developmental divergence and discontinuity is recognized in this dynamic model (i.e., probabilistic epigenesis).

A principle of importance to developmental psychopathologists is that individuals exert an active role in directing the course of their development. Although more distal historical factors and current influences are important to the process of development, individual choice and self-organization have increasingly been viewed as exerting critical influences on development (Cicchetti & Rogosch, 1997; Cicchetti & Tucker, 1994). Across the developmental course, the evolving capacities of individuals and their active choices allow for new aspects of experience, both internal (e.g., genetic/biological) and external, to be coordinated in increasingly complex ways. Moreover, not only because biological factors can influence psychological processes, but also because social and psychological experiences exert actions on the brain by feeding back on it to modify gene expression and brain structure, function, and organization (Cicchetti & Tucker, 1994; Eisenberg, 1995; E. R. Kandel, 1998; C. A. Nelson & Bloom, 1997), developmental plasticity can be brought about by both biological and psychological self-organization (Cicchetti, 2002a; Cicchetti & Tucker, 1994). Thus, for example, the fact that most maltreated children evidence at least some self-righting tendencies in the face of extreme adversity attests to the strong biological and psychological strivings toward resilience that virtually all humans and living organisms possess (Cicchetti & Rogosch, 1997; Curtis & Cicchetti, 2003; Waddington, 1957). In contrast, the absence of such resilient self-strivings in some maltreated children attests to the deleterious and pernicious impact that traumatic experiences can exert on core biological and psychological developmental processes.

Now that we have described the parameters of the field of developmental psychopathology, provided a description of an organizational perspective on development, and addressed the relevance of these concepts for clinical research and practice, we direct our attention to high-risk conditions that have resulted in the development and evaluation of preventive interventions in our

laboratory at Mt. Hope Family Center. We begin this journey of discovery with child maltreatment and then turn our attention to offspring of mothers with Major Depressive Disorder.

CHILD MALTREATMENT

The study of maltreated children affords an opportunity to examine environmental experience that is far beyond the range of what is normatively encountered. Child maltreatment exemplifies a pathogenic relational environment that poses substantial risk for maladaptation across diverse domains of biological and psychological development (Cicchetti, 2002b; Cicchetti & Lynch, 1995; De-Bellis, 2001). Both the proximal environment of the immediate family and the more distal factors associated with the culture and the community, as well as the transactions that occur among these ecological contexts, conspire to undermine normal biological and psychological developmental processes in maltreated children (Cicchetti & Lynch, 1993; Cicchetti & Toth, 2000).

Research on the biological and psychological sequelae of child maltreatment is extremely important for enhancing the quality of clinical, legal, and policymaking decisions for maltreated children (Cicchetti & Toth, 1993; Toth & Cicchetti, 1993, 1998). Decisions concerning such issues as whether to report a child as maltreated, whether to coercively remove a child from the home, how to develop services and interventions to meet the specific psychological and medical needs of maltreated children, and how to evaluate the efficacy of these services and interventions all benefit from a solid and sophisticated database on the biological and psychological sequelae of child maltreatment (Cicchetti & Toth, 1993; Toth & Cicchetti, 1993, 1998). Thus, conducting research that elucidates the developmental processes by which maltreatment exerts its deleterious impact on children, as well as developing theoretically and empirically informed interventions for maltreated children and their families, should be a national priority (Cicchetti & Toth, 1993; National Research Council, 1993).

Moreover, in times of fiscal austerity, human services in general, including social and psychological services for maltreated children and their families, come under the scrutiny of budget-conscious government administrators and legislators. Increasingly, service providers are asked to document the beneficial impact of their service efforts. The inability to provide documentation through scientific research renders the

services in question more vulnerable to the budget-cutter's knife. Thus, basic research on the psychological and biological development of maltreated children potentially can contribute to the development of the kind of evaluation research methodology required to justify service dollars to skeptical administrators and legislators and to modify ineffective programs to better serve maltreated children and their families. Clearly, closer collaboration between researchers and decision makers is warranted and in the long-term interests of better research and service on behalf of maltreated children.

Likewise, the investigation of developmental processes in maltreated children may affirm, augment, or challenge extant theories of biological and psychological growth in normally developing children. Child maltreatment may represent the greatest failure of the environment to provide opportunities for normal development. By investigating the effects of severe environmental disturbances, such as child maltreatment, on individual development, it may be possible to examine processes that normally occur so subtly and gradually that they are not readily observed (cf. Cicchetti & Pogge-Hesse, 1982; Cicchetti & Sroufe, 1976). Although maltreatment is a heterogeneous phenomenon (Cicchetti & Barnett, 1991b; Cicchetti & Rizley, 1981), it is unified by an experience of caregiving that does not optimize normal development. Through the examination of atypicalities in the developmental process of maltreated children, our theories of normal development may be enhanced.

According to the most recently published U.S. government statistics (DHHS, 2001), over 2.9 million children were reported as abused or neglected in the United States in 1999, and an estimated 826,000 children were confirmed as having been victims of maltreatment. There is no doubt that child maltreatment is an enormous problem that exerts a toll, not only on its victims, but also on society more broadly (Cicchetti & Rogosch, 1994). In a National Institute of Justice report (Miller, Cohen, & Wiersema, 1996), the direct costs (e.g., medical expenses, lost earnings, public programs for victims) as well as indirect costs (e.g., pain, diminished quality of life) of child abuse and neglect were estimated at \$56 billion annually. Furthermore, a 2001 study funded by the Edna McConnell Clark Foundation and conducted by Prevent Child Abuse America estimated that the total cost (i.e., direct and indirect costs combined) of child abuse in the United States is over \$94 billion per year. Annual direct costs, estimated at \$24,384,347,302, include hospitalization, chronic physi-

cal health problems, mental health care, welfare costs, law enforcement, and court action. Yearly indirect costs (i.e., long-term costs), estimated at \$69,692,535,227, include special education, mental and physical health care, delinquency, criminality, and lost productivity to society. The investigative team at Prevent Child Abuse America utilized stringent inclusion criteria for child maltreatment in their study. Specifically, children had to manifest documented harm as a result of child abuse and/or neglect in order to be included in the sample of maltreated children utilized to generate annual and long-term cost estimates of child maltreatment.

Definitional Considerations in Child Maltreatment

To adequately address the needs of maltreated children, an accurate and agreed upon definition of what constitutes maltreatment must be present. According to the developmental psychopathology perspective, a recognition of the developmental and contextual aspects of maltreatment is a requisite for understanding its causes and consequences. A caregiver must be able to adapt to the changing needs of a child. Failure to do so could constitute an act of maltreatment, depending on the developmental level of the child. Thus, whereas close monitoring and physical proximity are expected with a newborn, a similar parenting style with an adolescent would be inappropriate and, taken to extremes, emotionally abusive. The actual consequences of child maltreatment also manifest themselves differently according to a number of factors, including the perpetrator and the child's developmental level. Accordingly, methods of documenting psychological harm will need to vary with the child's age for an accurate assessment of possible sequelae. In addition to child-relevant considerations, alterations in the parent, the family, and the broader extrafamilial environment need to be considered in any definition of maltreatment (see Barnett, Manly, & Cicchetti, 1993).

Because extensive research information is required if it is to be useful in making policy decisions, researchers must be able to communicate their findings and compare their results across laboratories and across samples. Standardizing and unifying definitions of child maltreatment reflect fundamental steps toward improving research and hence the knowledge base about abuse and neglect. Systematized definitions also represent an essential aspect of ensuring consistent and

adequate services to children in need. The problems in constructing effective operational definitions include a lack of social consensus about what forms of parenting are unacceptable or dangerous; uncertainty about whether to define maltreatment based on adult behavior, child outcome, or some combination of the two; controversy over whether criteria of harm or endangerment should be included in definitions of maltreatment; and disagreements about whether similar definitions should be used for scientific, legal, and clinical purposes.

The last issue in particular has proved to be a continuing source of disagreement because scientists, lawmakers, and clinicians all use separate definitions of maltreatment to best suit their particular needs. In legal settings, for example, definitions focusing on the demonstrable harm done to the child may be useful in prosecuting cases (Juvenile Justice Standards Project, 1977). However, a number of investigators have argued that for research purposes, definitions of maltreatment that focus on the specific acts that endanger children may be more appropriate (Barnett et al., 1993; Cicchetti & Barnett, 1991b). This allows researchers to concentrate on identifiable behaviors that make up part of the child's caretaking environment rather than the uncertain consequences of those parental actions, such as some form of harm that may or may not be demonstrable. The challenge for researchers, though, is to develop precise operational definitions that minimize relying on professional opinion. This lack of consensus about what constitutes maltreatment makes clear communication and collaboration among the respective fields difficult.

In general, four categories of child maltreatment are usually distinguished from each other:

1. *Physical abuse*: The infliction of bodily injury on a child by other than accidental means.
2. *Sexual abuse*: Sexual contact or attempted sexual contact between a caregiver or other responsible adult and a child for purposes of the caregiver's gratification or financial benefit.
3. *Neglect*: The failure to provide minimum care and the lack of appropriate supervision.
4. *Emotional maltreatment*: Persistent and extreme thwarting of a child's basic emotional needs.

Each of these subtypes of maltreatment represents a clear deviation from the average expectable environment. However, even an issue as seemingly straightforward as identifying maltreatment subtypes can become unclear. It would be a mistake to think that maltreatment always occurs in discrete subtypes. There is a high degree of comorbidity among maltreatment subtypes, indicating that many maltreated children experience more than one form of maltreatment (Cicchetti & Barnett, 1991b). In many instances, it may be theoretically or clinically necessary to focus on the major subtype of maltreatment in a particular case; however, the actual experience of many children is much more complicated, and this presents significant challenges for both researchers and clinicians. For more detailed operational definitions of subtypes of maltreatment, the reader is referred to Barnett et al. (1993).

Moving toward uniform agreement on what constitutes maltreatment and instituting a standardized means of recording the pertinent information regarding identified maltreatment are essential steps for the future. Despite some important groundbreaking work in this direction, much research remains to be conducted. The challenge is to adopt a consistent method of systematizing maltreatment that is feasible and that satisfies the needs of individuals addressing various related issues.

The Need for a Nosology of Child Maltreatment

A fundamental difficulty inherent in the investigation of child maltreatment is that the range of phenomena covered by the term is enormously varied. We believe there are four primary types of heterogeneity that merit our foremost attention: (1) symptom pattern or type of maltreatment, (2) etiology, (3) developmental sequelae, and (4) response to treatment. The first type acknowledges the fact that a spectrum of different problems is subsumed under the term child maltreatment (Giovannoni & Becerra, 1979). The second recognizes that etiological pathways or causal networks exist, giving rise to the spectrum of different types of maltreatment. The third type of heterogeneity is revealed in the existing data on the consequences of maltreatment on child developmental outcome (Cicchetti & Lynch, 1995). Not surprisingly, there is no specific single pattern exhibited by maltreated children that can be described as the profile of abuse or neglect. Children of different ages, at different developmental stages, from diverse environments, and with differing experiences, who are exposed to vastly different forms of maltreatment, are likely to manifest vulnerabilities and disabilities in a wide vari-

ety of age-specific ways. The fourth type of heterogeneity underscores the observation that there is wide variability in response to treatment interventions among families where there has been maltreatment (Daro, 2000; Toth & Cicchetti, 1993; Wolfe, 1987). We believe that the failure to attend to these four sources of heterogeneity, each of which also is interrelated, has contributed to our less than complete understanding of this important problem.

As one solution to alleviating these definitional concerns, in our laboratory we have developed and implemented an operational system for classifying the subtypes, severity, frequency/chronicity, perpetrator(s), and developmental period(s) during which maltreatment occurred (Barnett et al., 1993; Cicchetti & Barnett, 1991b). Our nosological approach, known as the Maltreatment Classification System (MCS), is utilized by raters who code official maltreatment incidents that are reported to Child Protective Services (CPS) units and that are kept as permanent records. Both maltreating and nonmaltreating parents grant permission for us to examine their CPS files.

There are several advantages to utilizing only legally identified protective service cases of abuse and neglect. First, the field of social work has a longer and more extensive history of documenting occurrences of child maltreatment than the psychological or medical professions (B. Nelson, 1984). Second, all maltreatment filings in the state registry are legally substantiated. By having the abuse and neglect reports verified by an outside party and not by individuals conducting the research, investigators avoid the risk of alienating families who otherwise might have participated in the research program. In addition, studies of legally identified occurrences of child maltreatment are more representative of cases in protective services and therefore more directly applicable to this broad segment of the population.

The MCS is presently being used in more than 40 research laboratories across the United States. Because 49 of the 50 states, as well as the District of Columbia, have state registries for logging child abuse and neglect reports, the MCS has been able to be used on state record keeping procedures that vary from those employed in New York State, where the MCS was developed. The MCS has demonstrated excellent reliability and validity in all laboratories that have utilized it (Manly, 2005; Manly, Cicchetti, & Barnett, 1994; Manly, Kim, Rogosch, & Cicchetti, 2001).

The use of protective service families for research has not gone uncriticized. Gelles (1982) argued that researchers' reliance on official reports of maltreatment results in the study of the factors that lead to being "caught" as much as, if not more than, the study of maltreatment *per se*. We acknowledge this criticism but also believe that coding child protective records is the best currently available approach and it contributes to our understanding of the families that social service agencies, clinicians, and the courts deal with most frequently. In addition, it is likely that the reports that are brought to the attention of CPS are among the most severe instances of maltreatment. This is especially true as limited community resources force only the most severe instances of maltreatment to receive attention and treatment. More broadly, the problem is that protective service records underrepresent the true incidence of child maltreatment (Giovannoni & Becerra, 1979; DHHS, 1988). In addition to the unspecifiable number of maltreated children who go unreported, many incidents of maltreatment are difficult to substantiate and thus go unproven.

To reduce some of these problems, we also administer the Maternal Maltreatment Classification Interview (MMCI; Cicchetti, Toth, & Manly, 2003) to mothers in the families who participate in our research. Both maltreating and nonmaltreating comparison mothers are interviewed with the MMCI. Nonmaltreating comparison families must be matched with maltreating families on a variety of sociodemographic indices to differentiate the effects of maltreatment from the consequences of poverty and its associated risk factors (Elmer, 1977; Trickett, Aber, Carlson, & Cicchetti, 1991). Accordingly, it is highly probable that some percentage of nonmaltreated comparison participants may, in reality, be undetected maltreaters or that, over time, some may receive an indicated CPS report. To address these issues, we check the child abuse registry at 6-month intervals as part of our ongoing cross-sectional and longitudinal research projects. This approach enables us to ascertain whether any participants in our comparison groups have become maltreaters.

Likewise, we reexamine the CPS records of the maltreated children in all of our investigations. Especially in longitudinal studies, additional subtypes of maltreatment incidents may occur, and such chronic, severe, and diverse experiences of malevolent care may exert deleterious effects on biological and psychological developmental processes (Cicchetti & Manly, 2001; Cicchetti & Rogosch, 2001; English, 2003; Manly et al., 2001).

The Effects of Maltreatment on the Developmental Process

We next provide illustrative evidence on how growing up in an environment that deviates from the average expectable conditions affects maltreated children's individual development and functioning. It is in children's ontogenetic (i.e., individual) development that the effects of maltreatment, and the environmental failure that maltreatment represents, can be seen. Our research on the biological and psychological consequences of child maltreatment is guided by the organizational perspective described earlier.

In our presentation of the developmental sequelae of child maltreatment, we present only research that helped to inform our preventive interventions for maltreated infants, toddlers, and preschoolers. This entails a focus on infancy through early childhood and on those domains of development that have been addressed in our evaluations of interventions for maltreated children. For a more extensive review of extant research on the sequelae of child maltreatment across the life span and in additional biological, psychological, and socioemotional domains of development, the reader is referred to Cicchetti (2002b), Cicchetti and Toth (2000), Cicchetti and Valentino (in press), DeBellis (2001), and Trickett and McBride-Chang (1995).

Affect Regulation

Affect regulation is defined as the intra- and extraorganismic mechanisms by which emotional arousal is redirected, controlled, modulated, and modified so that an individual can function adaptively in emotionally challenging situations (Cicchetti, Ganiban, & Barnett, 1991). Appropriately developed affect regulation helps the individual to maintain arousal within a manageable range, thereby optimizing performance. Because the infant relies on the caregiver for external scaffolding and support, the quality of care and interactions with the caregiver contributes to *experience-dependent* individual differences in patterns of affect differentiation, expression, and regulation that emerge (Schore, 2003a, 2003b; Sroufe, 1996). Because early affect regulatory processes arise in the context of the caregiver-child relationship, it is not surprising that disruptions in the development of affect regulation occur more commonly in maltreated children than in nonmaltreated comparison youngsters. Thus, in accord with a developmental psychopathology perspective, adequate affect regulation serves as a foundation for the development of secure at-

achment relationships, an autonomous and coherent self system, and effective relations with peers, whereas early affect-regulatory failures increase the probability that a child will develop future insecure attachment relationships, self system impairments, and peer difficulties (Cicchetti & Lynch, 1995; Cicchetti, Lynch, Shank, & Manly, 1992).

The roots of affect regulation deficits have been noted in maltreated infants. Gaensbauer, Mrazek, and Harmon (1981) observed four patterns of affect differentiation in infants who had been maltreated: developmentally and affectively retarded, depressed, ambivalent and affectively labile, and angry. These investigators believed that the pattern displayed was dependent on an interaction between the caregiving experienced and the infant's biological predisposition. In a case study design, different types of maltreatment were related to the development of various affective patterns (Gaensbauer & Hiatt, 1984). Infants who were physically abused were found to demonstrate high levels of negative affects such as fear, anger, and sadness, and a paucity of positive affect, whereas emotionally neglected infants presented as affectively blunted, evincing little negative or positive affect.

This early emergence of negative affect in physically abused infants is in contrast to the normal pattern seen in nonmaltreated infants, where fear, anger, and sadness do not appear until approximately 7 to 9 months of age (Sroufe, 1996). It is likely that early malevolent care accelerates the development of negative affect pathways in the brains of maltreated infants. We believe that this may be accomplished by excessive synaptic pruning of the positive affect neurobiological pathways as a result of inadequate or insufficient early positive experiences by abused babies.

In a related investigation, Pollak, Cicchetti, Hornung, and Reed (2000) conducted two experiments on the recognition of emotion among physically abused, physically neglected, and nonmaltreated preschoolers to examine the effects of atypical experience on emotional development. In the first study, children were required to match a facial expression to an array of emotion-recognition vignettes. Neglected children had more difficulty discriminating emotional expressions than did the physically abused and the nonmaltreated comparison youngsters. Signal detection analyses revealed that neglected children used a more liberal bias for selecting sad faces and that physically abused children displayed a response bias for angry facial expressions (see also Pollak & Kistler, 2002; Pollak & Sinha, 2002). For the physically abused child, displays of

anger may be the strongest predictor of threat; however, increased sensitivity to anger could result in decreased attention to other emotional cues (Pollak & Tolley-Schell, 2003). In contrast, the physically neglected child may suffer from an extremely impoverished emotional learning environment.

The findings from the second experiment indicated that maltreatment appears to affect children's understanding of particular emotional displays. Neglected children saw greater similarity between happy and sad expressions than did the other groups. This outcome is especially surprising because recognition of happiness usually emerges developmentally early (Sroufe, 1996), suggesting that even relatively simple aspects of emotional recognition are affected through neglectful parenting. Physically abusive environments appear to compromise children's ability to recognize and differentiate some emotions, while concurrently heightening their awareness of other emotions. For example, physically abused children were as able as nonmaltreated preschoolers to perceive dissimilarities between anger and other negative expressions. In comparison, neglected children perceived fewer distinctions between anger and other negative expressions than did either nonmaltreated or physically abused children. Another compelling finding was that, unlike nonmaltreated children, both physically abused and physically neglected children rated expressions of both anger and sadness as very similar to an exemplar of an emotionally neutral face. Pollak et al. (2000) conjectured that maltreated children may have attributed anger or sadness to the neutral face or that maltreated children may interpret happy or neutral faces as masks for more malevolent emotions.

In addition to the early affect expression, regulation, and regulatory anomalies found among maltreated infants, physically abused children also demonstrate later affect regulatory problems in the coping that they employ when confronted with interadult anger. For example, physically abused preschool-age boys who observe simulated anger directed at their mother by an adult female confederate evidence more aggression (e.g., physical and verbal expressions of anger directed toward the female confederate) and more coping designed to minimize their mother's distress (e.g., helping mother, comforting mother) than do nonabused boys (Cummings, Hennessy, Rabideau, & Cicchetti, 1994). It appears that physically abused boys do not habituate to anger as a result of being exposed to familial hostility; rather, they are more aroused and angered by it and more likely to try to stop it. In general, the hypervigilance and arousal

in response to hostility seen among abused children might contribute to the development of their aggressive behavior, especially if conflict in the home is chronic.

Likewise, Maughan and Cicchetti (2002) examined the unique and interactive effects of child maltreatment and interadult violence on preschool children's developing strategies of emotion regulation and socioemotional adjustment, as well as the mediational role of emotion dysregulation in the link between children's pathogenic relational experiences and behavioral outcomes. Person-oriented emotion regulation patterns (EMRPs) were determined based on children's emotional, behavioral, and self-reported responses to simulated interadult anger. Maltreatment history was found to predict children's EMRPs, with approximately 80% of the maltreated preschoolers exhibiting dysregulated emotion patterns (i.e., undercontrolled/ambivalent and overcontrolled/unresponsive types) compared with only 37% of the nonmaltreated comparison youngsters. Undercontrolled/ambivalent EMRPs were associated with maternal reports of child behavior problems, and this type of EMRP was found to mediate the link between maltreatment and children's anxious/depressed symptoms.

In a related study, physically abused and nonabused school-age boys were presented with videotaped vignettes of adults in angry and friendly interactions (Hennessy, Rabideau, Cicchetti, & Cummings, 1994). After viewing these vignettes, abused boys reported experiencing more distress than nonabused boys in response to interadult hostility, especially when the hostility involved unresolved anger between adults. Moreover, physically abused boys described more fear in response to different forms of angry adult behavior. These results support a sensitization model in which repeated exposure to anger and familial violence leads to greater, rather than less, emotional reactivity. Similarly, the distress responses to interadult anger that abused children display may provide an early indication of an increased potential for developing internalizing problems among children exposed to high levels of familial violence (cf. Kaufman, 1991; Toth, Manly, & Cicchetti, 1992).

Additional evidence about the affective coping strategies of maltreated children can be seen in studies of cognitive control functioning. Rieder and Cicchetti (1989) found that maltreated children are more hypervigilant to aggressive stimuli and recall a greater number of distracting aggressive stimuli than do nonmaltreated children. Maltreated children also assimilate aggressive stimuli more readily, even though this impairs their efficiency on

tasks. Although hypervigilance and quick assimilation of aggressive stimuli may emerge as adaptive coping responses in a maltreating environment, these strategies become less adaptive when children are faced with nonthreatening situations. Eventually, such a response pattern may adversely affect children's adaptation under normal conditions and impair their ability to negotiate subsequent tasks of development successfully.

In support of this assertion, Shields, Cicchetti, and Ryan (1994) have shown in an observational study that maltreated children are deficient in affective and behavioral regulation, and that this attenuated self-regulation mediates the negative effects of maltreatment on children's social competence with peers. As an organizational perspective would predict, although affective and behavioral self-regulatory processes were interrelated, each appeared to represent a distinct developmental system that differentially and individually affects children's competence.

Corroboration for the prediction, emanating from the organizational perspective, that maltreated children are at increased risk for evidencing a developmental progression from affect-regulatory problems to behavioral dysregulation has been obtained in a number of cross-sectional investigations. Maltreated toddlers have been shown to react to peer distress with poorly regulated and situationally inappropriate affect and behavior, including anger, fear, and aggression, as opposed to the more normatively expected response of empathy and concern (Main & George, 1985; Troy & Sroufe, 1987). Likewise, maltreated preschool and school-age children have been found to exhibit a range of dysregulated behaviors that are frequently characterized by disruptive and aggressive situations (Cicchetti & Manly, 2001; Cicchetti & Toth, 1995).

In an investigation conducted in the context of a research summer day camp, Shields and Cicchetti (1998) examined the interplay among emotion, attention, and aggression in a sample of school-age maltreated and nonmaltreated children. A central focus of this investigation was to examine mechanisms underlying maltreatment's deleterious effects on behavioral and emotional dysregulation.

Shields and Cicchetti (1998) found that maltreated children were more verbally and physically assaultive than were the nonmaltreated comparison children, with physical abuse placing children at heightened risk for aggression. Maltreated children also were more likely than comparison children to exhibit the distractibility, over-

activity, and poor concentration characteristic of children who experience deficits in attention modulation. Physically and sexually abused children also displayed attention disturbances suggestive of subclinical or nonpathological dissociation, including daydreaming, blank stares, and confusion. Deficits in emotion regulation also were evident, in that maltreated children were less likely than comparison children to show adaptive regulation and more likely to display emotional lability/negativity and contextually inappropriate emotion expressions. Such pervasive deficits in maltreated children's regulatory capacities are cause for special concern, as the ability to modulate behavior, attention, and emotion underlie children's adaptive functioning in a number of key domains, including self-development, academic achievement, and interpersonal relationships (Cicchetti, 1989, 1991; Shonk & Cicchetti, 2001).

Shields and Cicchetti (1998) also demonstrated that impaired capacities for attention modulation contribute to emotion dysregulation in maltreated children. Specifically, attention deficits mediated maltreatment's effects on emotional lability/negativity, inappropriate affect, and attenuated emotion regulation. Attention processes that suggest subclinical or nonpathological dissociation also contributed to maltreated children's deficits in emotion regulation. Thus, abuse seems to potentiate disruptions in attention that result in both a relative detachment from and unawareness of one's surroundings, as well as in hyperattunement and hyperreactivity to the social surround (Pollak & Tolley-Schell, 2003; Rieder & Cicchetti, 1989). Together, these deficits appear to compromise maltreated children's ability to regulate behavior and affect in social settings.

In another investigation, Shields and Cicchetti (2001) examined children who were maltreated by their caregivers in order to ascertain whether these children would be more likely to bully others and to be at increased risk for victimization by peers than would nonmaltreated comparison children. An additional focus was to investigate emotion's role in bullying and victimization among maltreated children. Maltreated children were found to be more likely than nonmaltreated children to bully other children. Bullying was especially prevalent among abused children who experienced maltreating acts of commission (physical or sexual abuse). Maltreatment also placed children at risk for victimization by peers. As expected, both bullies and victims evidenced problems with emotion regulation. Furthermore, logistic regression analyses suggested that emotion dys-

regulation made a unique contribution to differentiating bullies and victims from children who did not evidence bully or victim problems. In addition, maltreatment's effects on children's risk for bullying and victimization were mediated by emotion dysregulation.

In summary, investigations of preschool and school-age maltreated children reveal that emotion regulatory abilities may mediate the link between maltreatment experiences and developmental outcomes. Difficulties with emotion regulation have been shown to adversely affect maltreated children's peer relations and to contribute to the emergence of behavior problems and psychopathology. Moreover, an organizational perspective on development suggests that, in the absence of adaptive self-organization, positive experiences with other adult figures, and/or successful intervention, these difficulties are likely to persist across the life span, resulting in future difficulties in the relationship arena and in overall functioning.

The Development of Attachment Relationships

The capacity for preferential attachment originates during early affect regulation experiences and interactions with the caregiver. These early parent-child experiences provide a context for children's emerging biobehavioral organization (Hofer, 1987; Pipp & Harmon, 1987). Specifically, the preattachment parent-child environment helps to shape children's physiological regulation and biobehavioral patterns of response (Gunnar & Nelson, 1994; Schore, 1994, 2003a; Sroufe, 1996).

More overt manifestations of attachment become salient toward the end of the 1st year of life, when infants derive feelings of security from their caregivers and use them as a base from which to explore the environment (Sroufe, 1996). Parent-child interactions characterized by synchrony and relatedness and by appropriate affective interchange are associated with successful adaptation during this stage of development. The knowledge that a caregiver is reliable and responsive also is critical because the absence of contingent responsiveness on the part of the caregiver can impede infants' ability to develop feelings of security in their primary attachment relationship (Cummings & Davies, 1996; Sroufe & Waters, 1977). Ultimately, the task for the child is to enter into a goal-corrected partnership, where the caregiver and the child share internal states and goals (Bowlby, 1969/1982). Based on the relationship history with their primary caregivers, children form representational models of attachment figures, of themselves, and of them-

selves in relation to others (Bowlby, 1969/1982; Bretherton, 1985; Crittenden, 1990). Through these mental representational models, children's affects, cognitions, and expectations about future interactions are organized and carried forward into subsequent relationships (Sroufe & Fleeson, 1988).

Although maltreated children do form attachments, the main issue concerns the quality of their attachments and their internal representational models of attachment figures, the self, and the self in relation to others. Studies conducted to date converge in revealing that the attachments maltreated children form with their caregivers are significantly more likely to be insecure than are those of nonmaltreated children (see, e.g., Egeland & Sroufe, 1981; Schneider-Rosen, Braunwald, Carlson, & Cicchetti, 1985). Utilizing the traditional Ainsworth, Blehar, Waters, and Wall (1978) tripartite classification system, approximately 70% of maltreated children have been classified as insecure anxious/avoidant (Type A) or insecure anxious/resistant (Type C). The remaining 30% of children were classified as securely attached (Type B).

Careful observation of a number of videotapes from several laboratories with samples of maltreated infants and young children led to the discovery that the behavior of these children in the Strange Situation (Ainsworth & Wittig, 1969) did not readily conform with the criteria of the Ainsworth et al. (1978) classification system (see, e.g., Egeland & Sroufe, 1981; Main & Solomon, 1990). Unlike infants with the more typical Type A, B, or C patterns of attachment, maltreated infants were often found to lack organized strategies for dealing with separations from and reunions with their caregivers. Main and Solomon (1986, 1990) described this pattern of attachment as disorganized/disoriented (Type D). In addition, these infants displayed bizarre behaviors in the presence of their caregiver, such as interrupted movements and expressions; dazing, freezing, and stilling; and apprehension.

In a related vein, Crittenden (1988) has identified another atypical pattern of attachment in her observations of children who have experienced various forms of maltreatment. Crittenden discovered that a number of maltreated children displayed unusual patterns of moderate to high levels of avoidance of the mother in combination with moderate to high levels of resistance. She labeled this pattern avoidant-resistant (Type A-C). Although theoretical distinctions exist between Main and Solomon's (1986, 1990) and Crittenden's views of

disorganization, most investigators have chosen to consider the A-C category as a subtype of the disorganized/disoriented Type D attachment pattern (Cicchetti, Toth, & Lynch, 1995). All researchers consider the A-C and D classifications to represent atypical patterns of attachment.

In a revised attachment classification scheme that includes these atypical patterns, maltreated infants and toddlers demonstrate a preponderance of insecure and atypical attachments (Barnett, Ganiban, & Cicchetti, 1999; Carlson, Cicchetti, Barnett, & Braunwald, 1989; Crittenden, 1988; Lyons-Ruth, Connell, Zoll, & Stahl, 1987). Studies that incorporate atypical attachments into their classification scheme typically reveal rates of attachment insecurity for maltreated youngsters to be as high as 90%. Furthermore, approximately 80% of maltreated infants and toddlers exhibit disorganized attachments, a rate that far exceeds those observed in nonmaltreated infants and toddlers from similar low-socioeconomic status (SES) backgrounds (Barnett et al., 1999; Carlson et al., 1989; Lyons-Ruth, Repacholi, McLeod, & Silva, 1991).

Moreover, maltreated infants and toddlers show substantial stability of insecure attachment, whereas securely attached maltreated youngsters evidence instability of attachment organization (Cicchetti & Barnett, 1991a; Schneider-Rosen et al., 1985). In contrast, for nonmaltreated youngsters, secure attachments are highly stable, whereas insecure attachments are more likely to change (Thompson, 1998). Furthermore, substantial stability of disorganized attachments has been shown across the ages of 12, 18, and 24 months (Barnett et al., 1999).

The Development of an Autonomous Self System

During the second half of the 2nd year of life, children experience an increased sense of themselves as autonomous. Before this age, processes of emotion regulation are primarily sensorimotor in origin. As a sense of self emerges, an increase in representational capacities arises (Sroufe, 1996). Consequently, children become able to use symbolic capacities such as play and language to convey their needs and feelings. This developmental transition also marks a shift in the burden of self-regulation from the caregiver to the child. However, caregiver availability and responsiveness continue to remain necessary to the facilitation of this developmental task. Throughout this period, children are able to rely on representations of caregivers to alleviate their distress

during separations. Thus, the representational models of self and other that had their origins in the early caregiving relationship exert a significant impact on the continued development of the self system.

As self-organization is brought forward to the new tasks of development, a number of aspects of maltreated children's self-development are likely to be affected, with possible implications for their subsequent interpersonal relationships. Studies on the development of self-recognition of maltreated children provide some insight into their emerging self-concept. Although there are no deficits in maltreated infants' ability to recognize their rouge-marked selves in a mirror, they are more likely than nonmaltreated infants to display neutral or negative affect on visual self-recognition (Schneider-Rosen & Cicchetti, 1991).

Other impairments in maltreated children's self systems have been noted as well. For example, maltreated children talk less about themselves and about their internal states than do nonmaltreated children (Beeghly & Cicchetti, 1994). Maltreated children with insecure attachments display the most compromised internal state language (Beeghly & Cicchetti, 1994). The ability to talk about internal states and feelings is a development of late toddlerhood that is believed to reflect toddlers' emergent self-other understanding and to be fundamental to the regulation of social interaction (Beeghly & Cicchetti, 1994). Maltreated children's negative feelings about themselves and their inability to talk about their own activities and states may impede their ability to engage in successful social relationships.

In particular, maltreated children appear to be most reluctant to talk about their negative internal states (Beeghly & Cicchetti, 1994). This finding is corroborated by reports that maltreated children may actually inhibit negative affect, especially in the context of their relationship with their caregiver (Crittenden & DiLalla, 1988; Lynch & Cicchetti, 1991). It is possible that some maltreated children adopt a strategy designed to suppress the expression of their own negative feelings to avoid eliciting adverse responses from their caregiver (Cicchetti, 1991). Although this approach may be adaptive in the context of a maltreating relationship, it can become maladaptive and lead to incompetence in other interpersonal contexts. Additionally, the inability of maltreated children to identify and discuss their own distress may play a major role in these children's difficulties in displaying empathy toward their peers (Main & George, 1985; Troy & Sroufe, 1987).

In another investigation of self-development, Alessandri and Lewis (1996) examined the self-conscious emotion expressions of shame and pride in maltreated children. These self-conscious emotions evolve, in part, from the child's burgeoning cognitive abilities between the 2nd and 3rd year of life. Included among the self-conscious emotions are embarrassment, pride, shame, and guilt. In particular, the ability to mentally represent standards for comparison, objective self-awareness and self-evaluation, and the capacity to reflect on and attribute outcomes to personal competence appear to be the prerequisite cognitive capabilities for the development of shame and pride (Kagan, 1981; Lewis & Brooks-Gunn, 1979; Sroufe, 1996).

Alessandri and Lewis (1996) found that maltreated girls displayed more shame and less pride than nonmaltreated girls. On the other hand, maltreated boys exhibited less shame and pride than nonmaltreated boys. Notably, the finding that maltreated girls manifested less pride and more shame in the achievement-like situations used to evoke these self-conscious emotions suggests that these girls are at high risk for developing dysfunctions or disorders of the self and for adapting poorly to school (cf. Cicchetti, 1989). In contrast, maltreated boys displayed a reduction of the self-conscious emotions of shame and pride, developed strategies that attributed their difficulties to characteristics of others, and employed acting-out behaviors to cope with their interpersonal difficulties.

Koenig, Cicchetti, and Rogosch (2000) examined child compliance and noncompliance behavior in maltreated and nonmaltreated comparison preschoolers. These children were observed with their mothers during a toy cleanup situation that followed a semistructured free play. Features of child compliance/noncompliance involve a shift from reliance on external controls to internal mechanisms, thereby reflecting child internalization of the maternal agenda (Kochanska, Aksan, & Koenig, 1995). Two subtypes of maltreated preschoolers were investigated: physically abused and neglected. Compared with nonmaltreated children, abused youngsters were found to exhibit less internalization, whereas neglected youngsters displayed significantly more negative affect. Specifically, abused children were more likely to show situational rather than committed compliance. The strategy of situational compliance involves suppression of negative behaviors and immediate compliance with the maternal directive. Because abused children appear to distort their own perceptions and

emotional responses, these youngsters could develop a "false self," wherein the overt presentation does not accurately reflect internal states. This could impede physically abused children's ability to express their true needs to others, thus contributing to lack of need fulfillment and difficulties in emotion regulation.

In addition, the increased negative affect seen in neglected children could prove to be highly detrimental to these children's moral development because turning anger or negative feelings inward, instead of directing them toward others, is crucial for the development of guilt. Internalized guilt is essential to motivate children to inhibit antisocial and engage in prosocial behaviors. Alternatively, instead of indicating anger, the negative affect seen in neglected children may represent feelings of shame or embarrassment, thereby placing these children at risk for the development of depression. Furthermore, maltreated and nonmaltreated groups differed in the maternal variables that predicted child internalization. A lower level of maternal negative affect was linked to child internalization in maltreated children, whereas a lower level of maternal joy predicted internalization for the nonmaltreated children.

Intervention directed at aiding maltreated children in the identification and expression of their cognitions and emotions, especially with regard to their attachment figures, can decrease disturbances to the self system. Interventions focused on improving mothers' sensitivity and responsiveness to their children's feelings and needs also is crucial.

In a further investigation of self-related development, Cicchetti, Rogosch, Maughan, Toth, and Bruce (2003) examined false belief understanding, an aspect of a theory of mind (TOM), in low-SES maltreated, low-SES nonmaltreated, and middle-SES nonmaltreated 3- to 8-year-old children. The development of false belief understanding, the ability to make inferences about what other persons believe to be the case in a specific situation, is a capacity regarded as a critical component of mature social skills and thought (Perner, 1991; Wellman, 1990). Possessing the knowledge that different individuals can have different thoughts about the same situation is an important achievement that makes it possible to predict what other persons will do across a variety of scenarios. As such, false belief understanding has been conceived as a hallmark of a representational theory of mind (Perner, 1991). Although young children have knowledge about mental states as early as the 2nd year of life, they fail to comprehend representational

states necessary to infer the thoughts of others until age 4. This conceptual advance has been described as a shift from a situation-based to a representation-based understanding of behavior (Perner, 1991). Moreover, the acquisition of false belief understanding by age 4 is a well-replicated and remarkably robust experimental finding (Wellman, Cross, & Watson, 2001).

Among children with a verbal mental age of 49 months or greater, maltreatment was related to delays in the development of TOM, beyond the influence of chronological age and SES (Cicchetti, Rogosch, et al., 2003). The occurrence of maltreatment during the toddler period, onset during the toddler period, and physical abuse were features of maltreatment associated with delay in the development of TOM. The centrality of the relation between maltreatment during the toddler period and TOM deficits flows from the importance of self-development for false belief understanding. Internal state language, increased individuation and self-other differentiation, advances in language, conceptual development and symbolic maturity, and the development of self-conscious emotions all occur during early childhood. Maltreated youngsters manifest difficulties in these aspects of self-development, each of which is a precursor of TOM development (Cicchetti, 1991). Thus, harsh caregiving, especially early in a child's life, impairs the development of TOM abilities.

In summary, child maltreatment exerts harmful effects on the development of an autonomous and coherent self system. In the most extreme cases, maltreatment experiences may lead to basic and severe disturbances in self-definition and self-regulation (Fischer & Ayoub, 1994; Westen, 1994), including the development of dissociative disorders.

Representational Models

Representational models (Bowlby, 1969/1982; Bretherton, 1985; Crittenden, 1990) are thought to play an important role in the continuity of development across different domains of functioning. For example, in normative populations, the quality of children's attachment relationships to their primary caregiver has been associated with the complexity of their knowledge of self and others (Beeghly & Cicchetti, 1994; Sroufe, 1996). Among maltreated children, their attachment histories contribute to the victimization observed in these children's relationships with their peers (Main & George, 1985; Shields & Cicchetti, 2001; Troy & Sroufe, 1987).

Additionally, maltreated children's perception of the quality of their relationships with their mother exerts a significant effect on these youngsters' feelings of relatedness to others (i.e., peer groups, best friend, teacher; Lynch & Cicchetti, 1991, 1992; Toth & Cicchetti, 1996).

Initially, the young child develops expectations about the nature of future interpersonal contacts through repeated interactions with the caregiver. These expectations form the basis of representational models of the self, others, and the self in relation to others (Bowlby, 1969/1982). Children's models reflect expectations about the availability and probable actions of others with complementary models of how worthy and competent the self is.

It has been theorized that children are able to form independent representational models of different relationship figures with their complementary models of the self (see, e.g., Lynch & Cicchetti, 1991; Toth & Cicchetti, 1996). Representational models of individual relationships contain information that is specific to those relationships. Expectations about the availability of the other person, how effective the self is likely to be in eliciting desired responses from that person, attitudes and commitment toward the relationship, and the affective tone of the relationship are the kinds of information that may be incorporated into models of specific relationships.

During the course of development, information from these *specific models* may become integrated as part of more *generalized models* of relationships (Crittenden, 1990). These generalized models of self and other allow the individual to forecast how others will act and react and how successful the self is likely to be in the broader social context.

Given their caregiving experiences, maltreated children are highly likely to develop negative expectations of how others will behave and of how successful the self will be in relation to others. In generating these expectations, maltreated children may evaluate information both from models that are specific to a given relationship and from more generalized models of relationships.

Initially, both specific and general representational models remain more or less open to new input and consequent readjustment (Crittenden & Ainsworth, 1989). Open models such as these are akin to Bowlby's (1969/1982) notion of a "working" model. With increasing verbal and cognitive abilities, however, children's representational models may become more closed to ex-

perience (Crittenden & Ainsworth, 1989). Conceptual processes and symbolic function replace actual episodes of experience in the formulation and integration of representational models. In the absence of effective intervention, it may not be until adolescence, when children attain formal operations, that a rethinking of previous experiences is likely to occur.

Having representational models that are closed to new interpersonal information may be especially detrimental to children who have experienced insecure attachments and maltreatment. Parents' explanations that their harsh behavior is for their children's own good become organizing principles for children's models of themselves and others. Moreover, some children may begin to employ a form of cognitive screening for relationship-relevant information to avoid the emotional discomfort of an angry relationship (Bowlby, 1980). It has been shown, for example, that abused children tend to split off from consciousness the more negative aspects of their perceptions (Beeghly & Cicchetti, 1994; Stovall & Craig, 1990). As a result, these children's representations of themselves and others may not be open to alternative and potentially positive experiences with others. Instead, they approach their interactions with others with more generalized negative expectations, leading to less competent dealings with others. Repeated experiences of incompetent interactions with others serve to confirm their negative representational models, making it even less likely that they will be open to positive interpersonal experiences in the future.

Research has begun to document differences in maltreated and nonmaltreated children's representational models. Maltreated children differ from nonmaltreated children in their perceptions of self and other on a variety of projective assessments and in the negativity of their view of the relational world, as demonstrated in projective stories (McCrone, Egeland, Kalkoske, & Carlson, 1994; Stovall & Craig, 1990). Additionally, maltreated children tell fewer stories in which adults and peers reciprocate the kind acts of children than do nonmaltreated children; they also relate more stories in which they justify their parents' unkind acts on the basis of their own bad behavior (Dean, Malik, Richards, & Stringer, 1986).

In our laboratory, we have conducted several studies on preschool- and school-age maltreated children's representations of their caregivers, of themselves, and of themselves in relation to others. These investigations typ-

ically have utilized the MacArthur Story Stem Battery (MSSB; Bretherton, Ridgeway, & Cassidy, 1990). The MSSB contains story beginnings that describe a range of emotionally laden interactions among family members. Each story stem involves a combination of family dolls, including a mother, a father, and two same-sex children. The gender and race of the dolls are matched to those of the child. For each narrative, the child is instructed to listen to the beginning of a story told by the experimenter and then to finish it using the characters and simple toy props. Narratives are videotaped and coded according to the MacArthur Narrative Coding Manual (Robinson, Mantz-Simmons, & Macfie, 1991), with a system that involves a presence-absence method of rating content, representation, and child performance. Content areas include, for example, codes for aggression, child injury, oppositionality, and empathy (Robinson et al., 1991). Representations of parents and of self, as well as the child's behavior, also are coded. Among the dependent variables that have been reliably coded across a number of investigations with normal and high-risk children are positive and negative maternal representations, positive and negative self-representations, controllingness, and relationship with the examiner (see, e.g., Emde, Wolf, & Oppenheim, 2003; Oppenheim, Emde, & Warren, 1997).

Toth, Cicchetti, Macfie, and Emde (1997) utilized the MSSB to examine maternal and self-representations in neglected, physically abused, sexually abused, and nonmaltreated preschool children. The narratives of the maltreated youngsters contained more negative maternal representations and more negative self-representations than did the narratives of nonmaltreated children. Maltreated preschoolers also were more controlling with and less responsive to the examiner. In our investigation of the differential impact of maltreatment subtype differences on maternal and self-representations, physically abused children evidenced the most negative maternal representations; moreover, they also had more negative self-representations than did nonmaltreated children. Sexually abused youngsters manifested more positive self-representations than did the neglected children. Despite the differences exhibited in the nature of their maternal and self-representations, physically and sexually abused preschoolers both were found to be more controlling and less responsive to the examiner than were the neglected and nonmaltreated children.

The examination of the different patterns evidenced by physically abused, sexually abused, and neglected

children on the self-representation variables suggests interesting interpretations for the representational models of these respective groups. The finding that the sexually abused children had a high level of positive self-representations raises the possibility that these representations are not genuine but are more consistent with the "false self" that has been described in the literature (Calverly, Fischer, & Ayoub, 1994; Crittenden & DiLalla, 1988).

Whereas physically abused children have high levels of negative self-representation, it was the neglected children who had low levels of positive self-representation. Thus, these two groups of maltreated children differ in the positive versus negative valence of their self-views. The fact that neglected children have restricted positive self-representations is consistent with the reality of these children's lives, in which they most likely receive minimal attention to their basic needs. Conversely, physically abused children, although also confronted with parenting dysfunction, may experience periods during which they are responded to, possibly even positively, by their physically abusive parents. Thus, it may well be that physically abused children are more likely to develop some sense of self as positive, whereas neglected children have far fewer opportunities to do so. Additionally, the tendency for neglect to be a more ongoing, chronic condition involving parental acts of omission, whereas physical abuse may involve intermittent acts of commission, also may be influencing the differences evidenced between these groups of children. The fact that physically abused children also seem to accurately perceive the negativity of their caregiving environments, as evidenced by their elevated negative maternal representations, attests to a possible strength that they possess. It may be more realistic to help children move beyond a history of maltreatment if they are in touch with its negativity than if they are prone to deny the realities that confront them.

In view of the differences evidenced among maltreated children, some interesting implications for intervention also can be derived from this investigation. Specifically, for sexually abused children, intervention may need to address the genuineness of their representations of parent and of self, especially if the children are evidencing behavioral difficulties such as might be suggested by their controllingness and lack of responsiveness to the examiner. For physically abused children, their high levels of negative representations and the

possible generalization of these negative representations to other relationship figures might best be addressed by utilizing a therapeutic relationship to foster a more positive self-representation, which, in turn, could result in greater receptivity to developing positive relationships with others. Finally, the low levels of positive self-representation evidenced by neglected children, in conjunction with their relatively average levels on other variables (e.g., differing neither from nonmaltreated children nor from other maltreated children), suggest that these children are at considerable risk for falling between the cracks of intervention systems that could bolster their sense of self. It is these children who may be most easily ignored, thereby perpetuating the experiences of neglect that have permeated their lives.

In a related investigation, Macfie et al. (1999) examined the narrative representations of preschool-age maltreated and nonmaltreated youngsters. Utilizing the MSSB narratives, Macfie and colleagues found that, compared with nonmaltreated youngsters, maltreated children represented both parents and children as responding less often to relieve distress in child characters. Moreover, it was discovered that maltreated children broke the narrative frame and stepped in more often to relieve distress in the narrative child characters. In addition, the maltreatment subgroups showed different patterns. Both abused children (sexually or physically, or both; most also were neglected) and neglected children (without sexual or physical abuse) depicted parents as responding less often to relieve distress in children than did nonmaltreated children. Furthermore, neglected children portrayed children responding less often to relieve distress in child characters than did the abused or the nonmaltreated children. It also was found that the abused children interjected themselves more often to relieve distress in child characters than did the nonmaltreated children or the neglected children. Moreover, it was the abused children who portrayed more role reversal than did the nonmaltreated children.

If neglected children who have not been sexually or physically abused do not represent parents or other children as likely to respond to children in distress, then these neglected children may grow up relatively passive in the face of others' distress. If, however, abused (particularly physically abused) children portray parents as unlikely to respond to children's distress, yet see children as taking on a role reversal with their parents, then

the abused children may develop representational models that associate relationships with the need to give care rather than to receive it (Cicchetti, 1989). Normative development appears to depend on the internalization of responsive parents without children being expected to assume the role of excessive responding to parents' needs. Role reversal may superficially simulate maturity; however, while feeling compelled to understand and care for others, maltreated children may not learn how to meet their own needs. What is adaptive in the maltreating environment may prove to be maladaptive in the wider world (Cicchetti, 1991).

In another investigation of maltreated children's representational models, Shields et al. (2001) discovered that maladaptive representations are related to a continuity in relationship disturbances across the family and peer domains. Specifically, these investigators found that maltreated school-age children's representations, coded from the Rochester Parenting Story Narratives developed in our laboratory, were more negative/constricted and less positive/coherent than those of nonmaltreated children. Furthermore, children's representations of their parents mediated maltreatment's influences on peer rejection.

Shields and colleagues (2001) also identified a mechanism whereby representations appear to exert their influences: by undermining children's emotion regulation on entry to new social groups. Anxiety, arousal, and angry reactivity serve important functions when attachment relationships are disrupted, thereby helping children regulate proximity to caregivers and to mobilize resources in response to danger or threat (Cassidy, 1994; Kobak, 1999; Thompson & Calkins, 1996). However, maladaptive representations can trigger similar emotional reactions in even neutral or friendly peer contexts because representations provide a filter through which information about new social encounters is processed. Maladaptive defense styles, which presumably underlie the lack of coherence in children's representations, would also compromise children's ability to manage their emotional arousal in social contexts. Peers, in turn, may respond to maltreated children's dysregulated emotions and behaviors with avoidance, rejection, and even victimization (Rogosch & Cicchetti, 1994; Shields & Cicchetti, 2001). Thus, maladaptive representations may contribute to the emotion dysregulation that has been documented among maltreated children (Shields & Cicchetti, 1998), setting in motion a complex chain of transactions that reinforce and main-

tain poor peer relationships and negative representations of social relationships.

How, then, might prevention and intervention interrupt these intergenerational cycles of disturbed relationships? One potentially fruitful arena might be to enhance the accuracy and efficiency of social information processing in maltreated children, with a special focus on how processing patterns influence children's emotional responsiveness in relationships outside of the family (Dodge, Bates, & Pettit, 1990; Dodge, Pettit, & Bates, 1997; Rogosch, Cicchetti, & Aber, 1995). Interventions that enhance maltreated children's coping and problem solving with peers also may increase the likelihood that abused and neglected children will develop and experience more positive peer relationships.

In a longitudinal investigation of the representational models of maltreated children, Macfie, Cicchetti, and Toth (2001) found that maltreated preschoolers evidenced more dissociation in their MSSB story-stem completions than did nonmaltreated children. Further, maltreatment subtype analyses revealed that the sexually abused and the physically abused youngsters displayed more dissociation than the nonmaltreated group; however, the neglected children did not. Thus, it appears that maltreatment that reflects the commission of abuse is more likely to be associated with dissociation than is maltreatment that reflects deficiencies of care.

Additionally, dissociation trajectories during the preschool period differed for maltreated and nonmaltreated children. Maltreated children, especially those who had experienced sexual or physical abuse, exhibited increasingly more dissociation over the course of this 1-year longitudinal investigation, whereas nonmaltreated children showed a decrease in dissociation. Thus, in maltreated children, there was no evidence for the self becoming more coherent during the preschool period (cf. Cicchetti, 1991). However, nonmaltreated children did maintain a more coherent self than did the maltreated children.

Toth, Cicchetti, Macfie, Maughan, and VanMeenan (2000) conducted an additional 1-year longitudinal investigation of the narrative representations of parents and of self, as well as of child behavior during the MSSB assessment, in maltreated and nonmaltreated comparison youngsters. Interestingly, at the first measurement period, when children were approximately 4 years old, the only significant difference obtained was that the maltreated preschoolers evidenced fewer

positive representations of parent and of self. However, 1 year later, maltreated and nonmaltreated children were found to exhibit more negative representations of parent and of self as well as more negative behavior with the examiner. Consequently, during the preschool period, a time noted for developmental transformations in the self, the representational models of maltreated children appear to become increasingly more negative.

These findings suggest that it may be critical to intervene with maltreated children early in the preschool period, when their representational models may be more open to being modified by experiences with relationship partners who challenge their negative experiences with caregivers. As we discussed earlier, several investigations have revealed that there is substantial concordance in maltreated children between relationship insecurity with primary caregivers and with noncaregiving figures. The fact that maltreated children are likely to generalize such negative representational models of attachment figures to future relationship partners underscores the need for intervening before relationship models become less open to change. Therefore, the initiation of intervention prior to the consolidation of negative representational models of self and other may be much more effective than would intervention that is begun subsequent to the crystallization of negative representational models.

TRANSLATING MALTREATMENT RESEARCH INTO PRACTICE: THE DEVELOPMENT AND IMPLEMENTATION OF PREVENTIVE INTERVENTIONS

Empirical research has documented that maltreatment in the early years of life poses severe risks for the development and adaptation of young children. Efforts to prevent further maltreatment and its deleterious consequences are thus of critical importance. Guided by an organizational perspective on development, and by empirical research that documents that maltreated children manifest impairments in attachment organization, self-development, and representational models, in our laboratory we have implemented two randomized controlled intervention trials early in the life course of maltreated children, one in infancy and the other during the preschool period, to prevent the compromised developmental attainments that accompany maltreatment and that are precursors to later maladjustment. Due to space constraints, our selective research review focuses on aspects of individual development that are compromised

as a function of child maltreatment. However, it is important to note that maltreatment and its effects involve transactions across multiple levels of an individual's social ecology. Our broader programs of research take these ecological influences into account and, where relevant, they also have guided the development of our preventive interventions. These intervention trials are discussed next.

Preventive Interventions for Maltreated Infants

A number of interventions informed by attachment theory have been developed for high-risk, multiproblem populations (Egeland & Erickson, 1990; Erickson, Korf-macher, & Egeland, 1992; Lieberman, Weston, & Pawl, 1991; Lyons-Ruth, Connell, Grunebaum, & Botein, 1990). With respect to attachment, theoreticians continue to debate whether modifying parents' attachment organization, including their representations of their child, will result in improved parenting or, conversely, whether improving parenting may, independent of attention to parental attachment representations, lead to more secure attachment relationships between parent and child. In a meta-analysis of 12 studies of the effectiveness of preventive or therapeutic interventions in enhancing parental sensitivity or children's attachment security, van IJzendoorn, Juffer, and Duyvesteyn (1995) concluded that interventions were more effective in improving maternal sensitivity than in fostering children's attachment security. Of particular importance, van IJzendoorn et al. also found that the link between parental representational models and infant attachment was stronger than the link between maternal sensitivity and attachment and that the former remained significant after sensitivity was included as a moderator variable. In a more recent meta-analysis of the effectiveness of preventive interventions for enhancing parental sensitivity and infant attachment security, Bakermans-Kranenburg, van IJzendoorn, and Juffer (2003) concluded that the most effective interventions used a moderate number of sessions and a behavioral focus. However, within the meta-analysis, only three randomized studies, all conducted with multiproblem populations, were described as intensive and having numerous sessions. These interventions also were very broad and included a combination of behavioral, representational, and supportive interventions. Therefore, we believed that the effectiveness of specific types of behavioral versus nonbehavioral interventions remained open to further in-

vestigation and we provided competing models of intervention, one being more problem-oriented and the other being more focused on maternal representation.

With the common goals of improving attachment insecurity to avert maladaptive development in maltreated infants, we implemented two interventions that differed in their strategies for attaining this goal. The first model, psychoeducational parenting intervention (PPI), is consistent with an ecological perspective; it is based on etiological models of maltreatment that emphasize the role of parental stress and parenting skills deficits in maltreatment and that therefore advocate for the provision of increased social support and parent training to alleviate stress, promote more positive parenting, and decrease child maltreatment. The second model, infant-parent psychotherapy (IPP), is based on research that points to the importance of parent-child attachment in fostering positive child development, improved parent-child interaction, and decreases in child maltreatment. This model involves dyadic mother-infant therapy sessions designed to improve the parent-child attachment relationships by altering the influences of negative maternal representational models on parent-child interaction. We compared the pre- and postintervention functioning of mothers and maltreated infants in both models of intervention with the functioning of mothers and maltreated infants who were receiving services typically available in the community (community standard [CS] group). A fourth, nonmaltreated comparison (NC) group, comprising demographically comparable mothers and their nonmaltreated infants, also were assessed. All maltreated infants and their mothers were randomly assigned to either the PPI, IPP, or the CS group.

Interventions were initiated when infants were approximately 12 months of age and continued for a period of 1 year. Assessments of the quality of attachment, utilizing the Strange Situation, were conducted at baseline (12 months) and at the conclusion of the intervention (24 months) to evaluate the efficacy of the interventions.

The group of mothers and infants who participated in this investigation were demographically comparable with respect to gender, SES, race/ethnicity, and household composition. All babies resided with their biological mother. In addition, the mothers of the maltreated infants were identified as perpetrators of maltreatment. Families were not excluded from study participation because of ethnic or racial considerations, and the racial/ethnic backgrounds of the participants were reflective of the national demographics of victims of child

maltreatment. To be included in the preventive intervention, mothers and infants could not have any significant cognitive or physical limitations that would hamper their ability to understand and/or participate in the research or clinical interventions.

Rather than relying solely on substantiated reports of maltreatment as made by DHHS (i.e., those deemed to be cases of legally designated maltreatment), we made independent determinations of maltreatment on all reports received by DHHS. Although this strategy is a departure from a more legalistic approach to the classification of maltreatment, we considered it to be the best course of action for a number of reasons. Perhaps most important, the past decade has witnessed a decrease in substantiated reports of maltreatment as a concomitant of decreasing financial resources that have been available to address this societal problem. Moreover, this decrease in substantiated reports has been evidenced even in the midst of the increased numbers of reports being made. These trends suggest that authorities are substantiating only the most severe cases of maltreatment, leaving many children vulnerable and without services. This is of significant concern in view of the findings of Manly et al. (1994) that more severe maltreatment is not necessarily related to worse child outcome. Rather than excluding maltreated children due to the false negative approach suggested by current DHHS actions, where children who have been maltreated are not classified as such, we made independent evaluations of the events that were reported to authorities or considered to suggest high risk for maltreatment. To this end, DHHS records were coded using the structured nosological system developed by Barnett et al. (1993).

To facilitate enrollment of maltreated infants and their mothers into our program, DHHS agreed to allow one of their child protective team supervisors to be retained by us and to serve as the liaison between families and our program. We paid a portion of the DHHS person's salary to ensure that his or her allegiance was to the goals of our investigation, not simply to his or her DHHS role. Moreover, due to constraints imposed by confidentiality, only a DHHS staff member had knowledge of families being assessed due to maltreatment concerns. Thus, the initial gatekeeper for approaching families had to be a staff member employed by DHHS. We asked our DHHS liaison to approach all families who met our inclusion criteria and ask if they were willing to be contacted by our project staff; thus, the DHHS liaison did not use any selection biases to determine

whom to approach. We also requested the DHHS liaison to record information on all families who refused to be contacted by our staff. Finally, our project staff, not DHHS, was solely responsible for randomization of families to treatment condition. All mothers of maltreated infants who met our enrollment criteria were informed of our investigation and asked whether they were willing to participate.

To avoid any possible perceptions of coercion, the voluntary nature of the program was stressed, and mothers were assured that their refusal to participate would have no adverse effects on their status with DHHS. Rather, the benefits of participation through the potential provision of supplemental services for the mother and her infant were emphasized. By working closely with a DHHS liaison, timely recruitment in conjunction with the maintenance of family confidentiality was assured. A family's name was released to our project's staff only after a consent release form was signed. It is important to clarify that because we also examined the CS group, referral to our project did not necessarily result in assignment to one of our intervention models. Rather, referral indicated a willingness to participate in our research project and the possibility of receiving enhanced services.

All families, maltreating and nonmaltreating alike, were informed that, as mandated reporters, our project staff was obliged to report any suspected cases of child maltreatment to DHHS. Based on our experience conducting research with maltreating and nonmaltreating families from low-SES backgrounds, we have found that families are generally accepting of these reports if they are conducted in an open, sensitive fashion and framed as efforts to get the family the support it needs.

Nonmaltreating families were chosen randomly from the county list of recipients of Temporary Assistance to Needy Families (TANF). Because prior experience has revealed that the majority of maltreating families referred to DHHS are socioeconomically disadvantaged, utilization of TANF lists provided us with access to a demographically similar population. Although all families were asked whether they had ever received protective services, we have learned that families are not always forthcoming with this information. Therefore, during our initial contact, consent was obtained to verify nonmaltreatment status by accessing DHHS central registry data. Additionally, we also administered the MMCI to mothers in the NC group as an independent

verification of nonmaltreating status. If a family refused to consent to this procedure, then they were not enrolled in the investigation. Only those families who had never received child protective or preventive services through DHHS were included in the comparison sample. Throughout the intervention trial, DHHS records were accessed annually for both maltreatment and comparison participants to determine whether any maltreatment reports had been filed; the MMCI also was administered annually.

Challenges to Implementation

To begin, it is important to underscore that, because this intervention evaluation involved a randomized controlled clinical efficacy trial, rigorous inclusion and exclusion criteria were necessary to ensure sufficient homogeneity among participants. Treatment was manualized, and all therapists received extensive training and ongoing supervision. In all of our intervention evaluations, we conducted weekly individual supervision, weekly group presentations, and discussions of videotaped cases. Moreover, checklists were utilized to assess adherence to the parameters of the intervention. This approach is very different from clinical effectiveness trials that are carried out in real-world clinical settings and that provide much less latitude regarding who constitutes a "case." Unfortunately, much of our current evidence regarding the effectiveness of interventions for children has been derived from efficacy trials; studies that have tried to determine the effectiveness of clinic treatments have found much lower success rates that are not substantially different from outcomes for children not receiving treatment (Weisz, Donenberg, Han, & Weiss, 1995; Weisz, Rudolph, Granger, & Sweeney, 1992). This reality underscores the importance not only of establishing efficacy, but also of determining how best to transfer the knowledge gained from efficacy trials into implementation in real-world clinical settings.

In conducting efficacy trials such as this, initial recruitment can be challenging. To begin, it often is difficult for community partners to understand why someone is not eligible for the intervention. Efforts to adhere to strict inclusion/exclusion criteria can come across as off-putting to community service providers. Moreover, explaining randomization procedures to individuals not accustomed to conducting research can be difficult. We have found that it is important to try to convey that, initially, the intervention is conceived in the best possible

way to optimize the likelihood of establishing its efficacy. Once this occurs, the intervention can be utilized with more heterogeneous groups of multiproblem clients. Unless the intervention evaluation adheres to scientific standards, efforts to demonstrate its efficacy will not be credible and its ultimate translation into clinic settings will be compromised.

Similarly, potential clients may have difficulty understanding why they cannot receive their treatment of choice. From an ethical practice standpoint, families were told that the treatment that they might be eligible for would "be determined by the flip of a coin," and we sought their agreement to accept this chance outcome. If a potential participant was not willing to accept randomization to treatment condition, then they were ineligible to continue in the research program and were referred to other community providers.

Once they are enrolled, retaining participants in intervention evaluations is especially important. Transportation was provided for all research visits; even so, cancellation and no show rates were approximately 50%. Given the population served, attrition can be a major consideration. Frequent moves, involvement in illegal activities and incarceration, and placement of the child in foster care all may erode the number of participants available for the conduct of a longitudinal investigation. A case example is helpful in illustrating this point.

During a home-based research visit, our research assistants arrived at the residence of a single mother; at the time of the visit, the child enrolled in our project was 24 months of age and the family had been participating in the project for 1 year. The researchers heard a baby crying when they knocked, but repeated loud knocking and calling went unanswered, and the baby continued to wail. Concerned, our staff approached a policeman who was in the vicinity and explained the situation. The dwelling was entered by the police and an infant of 8 months was found alone. The mother returned home shortly with her 2-year-old child to find the police taking her unsupervised infant into custody. She shared that she had left the infant briefly to go to the store. There was a history of neglect in the family, and the infant was subsequently placed in foster care and the mother charged with lack of supervision and incarcerated. The 2-year-old also was placed in care. Our research staff was distraught and felt very bad. We contacted the mother while she was in jail and she conveyed that she understood what had transpired; she acknowledged that

she needed help to care for her children adequately. Although we remained in contact with her, she did not regain custody in time to allow for continued participation in the evaluation.

Unfortunate on many levels, this case description conveys the reality of conducting intervention evaluations with maltreating populations. All staff are trained in the ethics of reporting suspected maltreatment. When possible, we talk with caregivers first and let them know that we are legally and ethically bound to file a report if we suspect child maltreatment.

The fact that the families enrolled in our preventive intervention were primarily members of ethnic and racial minority groups also required knowledge of cultural mores and expectations. Although we tried to recruit a diverse staff, the majority of our research staff were nonminorities. Moreover, as recent college graduates, their backgrounds were such that they had limited experience traversing inner-city environments. We stressed the criticality of nonjudgmental attitudes and sensitivity to the contexts in which the families resided. However, at times, cognition and training gave way to panic. One particularly poignant event was recalled by a mother who had participated in our research over a number of years. She laughingly repeated a story about being interviewed in her home when a car back-fired on the street; fearing that gunshots had occurred, one of our young researchers jumped to the floor. We incorporated this vignette into our training sessions to help young staff members understand that their actions are not unnoticed and that they can convey derision by subtle looks or actions, even if unintentionally.

We also exert considerable effort in retaining contact with participants. Newsletters with community events and child activities are sent out regularly. We also send birthday cards and holiday cards and periodically hold raffles for self-care products. Raffle numbers are listed in our periodic newsletters, and we ensure that all participants win at least one of the raffles. It has been enlightening to see how meaningful these gestures are to an impoverished, generally isolated population. We have found that even nonintervention cases benefit from the attention they receive and from feeling part of an important endeavor.

Description of the Interventions

Now that we have provided examples of challenges that arise in the evaluation of preventive interventions with

low-income maltreating populations, we turn our attention to the interventions themselves. As previously described, two theoretically informed models of intervention were evaluated in the proposed investigation. Manuals were developed and implemented for each of the two interventions. Because DHHS becomes active via case monitoring, management, or referral when reports of child maltreatment are received, this served as a constant across all conditions. Therefore, all families in which maltreatment had been identified received some services, even if they were not randomized to our theoretically guided intervention conditions.

The provision of intervention to multiproblem populations such as those with whom we intervened requires flexibility and responsiveness to the frequent crises and challenges that confront these families. Because DHHS was active with all families, they provided a consistent monitoring function with respect to issues such as adequate food and housing. Although we strove to evaluate the potential efficacy of two theoretically different models of treatment, from an ethical practice standpoint, issues such as domestic violence, inadequate housing, and substance abuse needed to be addressed as they arose. Our models of treatment were focused on the improvement of parenting and the elimination of maltreatment and its sequelae, but we also had to be responsive to myriad related issues that we encountered during our clinical contacts with this population. To this end, therapists in both intervention models not only received extensive training on the respective models of treatment that they were providing, but also on the importance of cultural sensitivity and on how to deal with the extensive needs experienced by these families. In our view, neither treatment model could be effective in the absence of responsibility to the needs of maltreating families. The ability to respond to such needs also increases the portability of the models into clinic settings. Because the interventions were home-based, comfort and skill in navigating inner-city neighborhoods where drug use and violence were normative were necessary.

Community Standard. In the CS condition, DHHS managed cases in accord with their standard approach. Although variability existed, with service provision ranging from no service to referral to existing community clinics, this condition represents the community standard with which the PPI and IPP models were compared. The use of a CS comparison group en-

abled us to determine the effects of standard practices on child and family functioning, as compared with theoretically informed delivery of services. Such an approach is consistent with that of other treatment studies, such as the National Institutes of Health MTA study of children with Attention-Deficit/Hyperactivity Disorder (Arnold et al., 1997). The approaches that DHHS used with families who have been reported for maltreatment and are participating in the proposed investigation were systematically recorded via a standardized services questionnaire.

Psychoeducational Parenting Intervention Model.

In addition to services typically made available to maltreating parents (CS), weekly home visitation was provided via the PPI model. This intervention approach has reemerged in recent years as an effective model for preventing damage to vulnerable children (National Commission to Prevent Infant Mortality, 1989; Shirk et al., 2000; U.S. Congress, 1988). In fact, the U.S. Advisory Board on Child Abuse and Neglect (1990) identified home visitation services as the best documented strategy for preventing child maltreatment. Data on the effectiveness of home visitation have emerged (Olds et al., 1997, 1998); yet to be conducted are studies on the effectiveness of home visitation services for families where maltreatment has already occurred, as well as assessments of whether home visitation services can alter the future life course development in infants who have been maltreated.

The PPI model utilized in this investigation was provided by therapists on a weekly basis in 1-hour home-based sessions, with a focus on two primary goals: the provision of parent education regarding infant development and developmentally appropriate parenting skills and the development of adequate maternal self-care skills, including assisting mothers with personal needs, fostering adaptive functioning, and improving social supports.

In accord with the home visitation model of Olds and his colleagues (Olds & Kitzman, 1990), therapists were trained in the provision of an ecologically informed model of influences on mother and child. This model strives to address how factors at different levels of proximity to the mother and child interact to form a system of influences on functioning. Practically, this results in the simultaneous examination of maternal personal resources, social support, and stresses in the home, family, and community that can affect maternal caregiving. We employed as interveners master's-level therapists

who were adept at attending to the needs of multiproblem families, were knowledgeable regarding accessing community resources, and had expertise in addressing intrafamilial violence. Weekly 60-minute home visits were conducted over a period of 12 months.

The PPI model was a psychoeducationally based model grounded in the present that strives to educate, improve parenting, decrease maternal stress, and increase life satisfaction. The approach is didactic in nature, providing mothers with specific information, facts, procedures, and practices. Within a core agenda of topics on parenting and improved social skills to be addressed, flexibility and latitude in the amount of time spent on various topics was stressed in order to respond to individual needs of each mother. This flexibility is consistent with that utilized by other home-based interveners working with disadvantaged populations. An initial assessment of client needs within the domains of parenting and maternal self-care was conducted to delineate specific areas most in need of intervention. Thus, although there was a consistent range of issues to be addressed with each mother, the model allows for special emphasis on areas particularly germane to individual mothers.

Infant-Parent Psychotherapy Model. In addition to services typically available for maltreating parents (CS), mother-infant dyads in this intervention received weekly IPP. This intervention approach emanated from the seminal writings of Selma Fraiberg in her classic article, "Ghosts in the Nursery" (Fraiberg, Adelson, & Shapiro, 1975). Building on the work of Fraiberg, Albert Solnit, and Sally Provence, to name a few pioneers in the field, Alicia Lieberman (1991) provided the first evidence-based investigation of infant-parent psychotherapy.

Proponents of IPP believe that parent skills training alone is insufficient to alter the complex matrix of influences that lead to maladaptive mother-infant attachment relationships and future maladaptation. Although in our IPP intervention, developmental guidance was provided as necessary, it is important to stress that such guidance reflected responsivity to issues raised by the mother and did not involve didactic teaching, parent skills training, or modeling. Rather, IPP focused on the relationship between mother and infant and the effect of maternal history on current caregiving.

In accord with the IPP approach, the following goals were addressed:

1. The therapist expanded the mother's empathic responsiveness, sensitivity, and attunement to her infant.
2. The therapist promoted maternal fostering of infant autonomy and positive negotiation of maternal and child goals.
3. Distorted perceptions and reactions to the infant stemming from maternal representational models were altered and more positive representations of the infant were developed.

Each mother-child dyad was seen on a weekly basis by a master's-level therapist who was supervised by a PhD-level clinical psychologist. Sessions were home-based in order to experience mother-child interaction and its challenges in a real-world context. Reaching out to mothers in their homes also conveys respect and sensitivity for their situations. Meetings were 60 minutes in duration. The joint observation of the mother and infant is vital to this approach. As comments about the infant's behavior and the mother's experience of the infant emerge through this naturalistic observation, the therapist becomes able to respond empathically to the mother and expand parental understanding of stage-salient issues as they arise, as well as explore maternal misperceptions of the infant.

Unlike the PPI model, which focused on current behavior, the core of the IPP model resides in the mother's interactional history and its effect on her representation of relationships, most significantly that of her infant. Thus, rather than focusing only on the present, this model of therapy links the maternal past with current maternal perceptions of, and responses to, her infant. Unlike the PPI model, where therapist and mother meet to address parenting issues and caregiver self-care, the IPP approach relies on the mother-infant dyad as the "port of entry" (Stern, 1995) for therapeutic work. Therapeutic insights into the influence of maternal representation on parenting can be gained as maternal representations and distortions are enacted in the context of infant-parent interaction.

A number of aspects of IPP distinguish it as a unique approach to intervention. To begin, the "patient" in IPP is not a person, but a relationship that exists between mother and baby. Because many mothers may not wish to be seen individually in more traditional therapies, the focus on the relationship reduces the stigma and self-blame that might engender resistance to seeking treatment (Stern, 1995). Because much of the action of early mother-child relationships

occurs preverbally in interactions, the value of being able to observe interactions is critical to understanding and being able to address relationship disturbances.

In the language of attachment theory, the intervention is designed to provide the mother with a corrective emotional experience in the context of the relationship with the therapist. Maltreating mothers, with their childhood histories of disturbed parent-child relationships and frequent negative experiences of social services helpers, typically expect rejection, abandonment, criticism, and ridicule. Overcoming these negative expectations in the course of establishing a positive therapeutic alliance with the therapist is essential. Often, initial concrete support and service provision create the opportunity for mothers to begin to trust the therapist. The therapist, through empathy, respect, concern, accommodation, and unfailing positive regard, creates a holding environment for the mother and infant in which new experiences of self in relationship to others and to the infant may be internalized. Evolving positive representations of the therapist can then be utilized to contrast with maternal representations of the self in relationship to parents. As the mother is able to reconstruct representations of the self in relationship to others through the therapeutic relationship, she also is able to reconstruct representations of herself in relationship with her infant.

Intervention Outcome

One of our primary intervention outcome measures was that of attachment. The Strange Situation was utilized and subsequently coded by individuals unaware of maltreatment status or treatment condition. Different coders rated baseline and postintervention tapes and interrater reliability was established. At baseline, there were no differences among the three maltreatment groups (IPP, PPI, CS) in the percentage of infants who were securely attached to their mother in the Strange Situation procedure (Ainsworth et al., 1978). This finding attests to the success of our randomization procedure. Notably, 3.6% of the infants in the IPP, and 0% of the babies in PPI and CS groups, had secure attachments at baseline. Thus, consistent with the prior maltreatment literature that included the coding of Type D attachments (Barnett et al., 1999; Carlson et al., 1989), very few maltreated babies had developed secure attachments with their mother.

Although significantly more of the nonmaltreated comparison babies were securely attached than were any

of the babies in the maltreatment groups, the 39% rate of security in the nonmaltreated group underscores that this is a very high-risk comparison group. Indeed, their lower than average rate of attachment security (most nonrisk samples manifest security rates between 50% and 60%) is not surprising. Recall that these comparison youngsters were very closely matched to the maltreated infants on a variety of sociodemographic indices.

Additionally, at baseline, the three groups of maltreated infants all displayed extremely high rates of attachment disorganization. In particular, the Type D attachment organizations were 86% for the IPP, 82% for the PPI, and 91% for the CS groups. These high rates of disorganized attachment are consistent with findings in the literature on maltreated infants (Bakermans-Kranenburg et al., 2003; Barnett et al., 1999; Carlson et al., 1989; Lyons-Ruth et al., 1991). In contrast, the rate of disorganized attachment in the NC group was 20%.

The postintervention findings were quite compelling. The maltreated infants in the CS group had a 1.9% security rate, a nonsignificant improvement over their 0% baseline security results. In contrast, infants in each of the two interventions exhibited large increases in attachment security from baseline to postintervention (IPP: 3.6% to 60.7%; PPI: 0% to 54.5%). Finally, the percentage of attachment security in the NC group was 39% at both baseline and postintervention assessments.

Statistical analyses revealed that the IPP and the PPI interventions were equally successful in modifying attachment insecurity. This finding is interesting given the meta-analysis of Bakermans-Kranenburg et al. (2003), where the PPI model would have been predicted to be more effective. The attachment security rates in the IPP and PPI interventions were significantly greater than those found in the CS group. Furthermore, there were no statistically significant differences among the IPP, PPI, and NC groups, even though the intervention groups attained higher percentages of attachment security than did the NC group.

Furthermore, assessments conducted at the conclusion of the intervention revealed that the percentage of Type D attachment had declined from 86% to 32% for the IPP group and 82% to 46% for the PPI group. Conversely, the infants in the CS group continued to exhibit high rates of disorganization (91% to 78%); the percentages of Type D attachment in the NC group at baseline and postintervention were virtually identical (20% and 19%).

An examination of the stability of attachment organization across the four groups of infants provides further corroboration of the efficacy of the two interventions. Specifically, 57.1% of the infants in the IPP intervention and 54.5% of the infants in the PPI intervention changed their attachment organization from insecure to secure. In contrast, only 1.9% of the infants in the CS group evidenced a similar progression from insecure to secure attachment.

Likewise, 57.1% of the babies who received the IPP intervention and 45.5% of the infants who were in the PPI intervention exhibited a change in their attachment classification from Type D disorganized/disoriented to an organized pattern of attachment. Both of the intervention groups evidenced a greater diminution in Type D attachment than either the CS or NC groups.

The results of this randomized preventive intervention trial demonstrate that an intervention informed by attachment theory (IPP) and an intervention that focuses on improving parenting skills, increasing maternal knowledge of child development, and enhancing the coping and social support skills of maltreating mothers (PPI), both were successful in altering the predominantly insecure attachment organizations of maltreated infants. Thus, following Bowlby (1969/1982), the representational models of attachment figures and of the self in relation to others of the maltreated infants in intervention became positive as a function of the provision of the preventive intervention.

Given the success of this intervention, it becomes important to consider why these therapeutic models were effective in altering attachment security when previous investigations did not yield such findings. A number of components of these interventions may have contributed to their success. First, all therapists received extensive training before implementing the interventions, and they were familiar not only with the intervention modality, but also with the theory from which the interventions was derived. All therapists also had considerable prior experience working with low-income maltreating families. Both models were manualized, weekly individual and group supervision was provided, and therapists' adherence to their respective model was monitored for each case throughout the provision of the intervention. Caseloads were maintained at levels considerably lower than is typical of outpatient mental health settings; therapists were therefore able to devote considerable time to engaging mothers and to conceptualizing treatment

plans. The positive outcome of this investigation supports the importance of investing in more costly interventions, including allowing therapists sufficient time for training and supervision.

Clearly, as predicted by the organizational perspective, the early insecure, generally disorganized attachments displayed by maltreated infants do not doom these youngsters to have poor-quality relationship expectations and negative self-representations throughout development. The success of the interventions, informed by basic research knowledge on the etiology and developmental sequelae of child maltreatment, suggests that attachment organization is modifiable, even if a high percentage of Type D attachment is initially characteristic of the sample. Following the organizational perspective, it is expected that these maltreated youngsters, now that they are traversing a more positive developmental trajectory, will be more likely to continue on an adaptive pathway and successfully resolve future salient developmental tasks (cf. Sroufe, Carlson, Levy, & Egeland, 1999). The preventive interventions have demonstrated that behavioral plasticity is possible, at least in the early years of life.

Preventive Interventions for Maltreated Preschoolers

The preschool years are an especially important time for symbolic and representational development; it is during this period that representational models of self and of self in relation to others evolving from the attachment relationship become increasingly structured and organized. Although developing children are likely to maintain specific models of individual relationships, these models become increasingly integrated into more generalized models of relationships over time (Crittenden, 1990), thereby affecting children's future relationship expectations. Because maltreated children internalize relational features of their caregiving experiences, they are likely to generalize negative representations of self and the self in relation to others to novel situations and relationship partners (Howes & Segal, 1993; Lynch & Cicchetti, 1991; Toth & Cicchetti, 1996).

As documented in our literature review earlier in this chapter, a considerable body of research has documented the deleterious effects of maltreatment on the representational development of abused and neglected children. The cross-sectional and longitudinal studies

reported provide a solid foundation on which to conclude that maltreatment does exert negative effects on representational development, that these effects become more entrenched as development proceeds, and that the representational themes enacted in children's narratives are reflective of their maltreatment experiences and are related to child behavior problems (see Toth et al., 2000). Based on our empirical work, we concluded that it made sound sense to develop and implement interventions designed to modify maladaptive representational development in maltreated preschoolers.

Participant Recruitment

Procedures consistent with those described for the recruitment of maltreated and comparison infants were employed to enlist mothers and their preschool-age children.

Intervention Outcome

At baseline and at postintervention, 11 narrative story-stems, selected from the MSSB (Bretherton et al., 1990) described previously, were individually administered to child participants. The narratives utilized depicted moral dilemmas and emotionally charged events in the context of parent-child and family relationships. Narrative story-stems included vignettes designed to elicit children's perceptions of the parent-child relationship, of self, and of maternal behavior in response to child transgressions, intrafamilial conflicts, and child accidents.

Maternal representations were coded from the children's narratives. These included *positive mother* (the maternal figure is described or portrayed in the narrative as protective, affectionate, providing care, warm, or helpful); *negative mother* (the maternal figure is described or portrayed in the narrative as punitive, harsh, ineffectual, or rejecting); *controlling mother* (the maternal figure is described or portrayed in the narrative as controlling the child's behavior, independent of disciplining actions); *incongruent mother* (the maternal figure is described or portrayed in the narrative as dealing with child-related situations in an opposite or inconsistent manner); and *disciplining mother* (the maternal figure is described or portrayed in the narrative as an authority figure who disciplines the child; inappropriate and harsh forms of punishment were not scored here, but rather were coded as negative mother). A presence/absence method of coding was used to score children's maternal representations.

Self-representation scores were also coded from the children's narratives and were derived from coding any

behaviors or references that were made in relation to any child character or when the child participant appeared to be experiencing relevant feelings in response to narrative content. Representational codes of self included *positive self* (a child figure is described or portrayed in the narrative as empathic or helpful, proud, or feeling good about self in any domain); *negative self* (a child figure is described or portrayed in the narrative as aggressive toward self or other, experiencing feelings of shame or self-blame, or feeling bad about self in any domain); and *false self* (a child figure is described or portrayed in the narrative as overly compliant or reports inappropriate positive feelings, for example, in an anger- or fear-producing situation). Consistent with maternal representation coding procedures, a presence/absence method of scoring was used to assess children's self-representations.

In addition to maternal and self-representation codes, a modified version of Bickham and Fiese's (1999) global relationship expectation scale was utilized to capture children's expectations of the mother-child relationship. For the current investigation, the scale was modified to assess children's global expectations of the mother-child relationship as portrayed in the children's 11 narratives. In accord with Bickham and Fiese's coding procedures, children's expectations of the mother-child relationship were determined by the overall degree of predictability and trustworthiness portrayed between mother and child characters across all 11 narrative administrations. Specifically, the following five relationship dimensions were used to aid in coding children's overall expectation of the mother-child relationship; predictable versus unpredictable, disappointing versus fulfilling, supportive or protective versus threatening, warm or close versus cold or distant, and genuine or trustworthy versus artificial or deceptive. Global mother-child relationship expectation ratings were based on a 5-point scale, ranging from very low (participant's narratives describe or portray the mother-child relationship as dissatisfying, unpredictable, and/or dangerous) to very high (participant's narratives describe or portray the mother-child relationship as fulfilling, safe, rewarding, and reliable).

Clinical Relevance of Results

Because a considerable body of prevention and intervention research has emerged based on attachment theory (cf. Lieberman, 1991; Lieberman et al., 1991; Lieberman & Zeanah, 1999), efforts designed to examine the implications of prevention and intervention for developmental

theory are especially timely. Congruent with Bowlby's (1969/1982) theory and the organizational perspective on development (Cicchetti & Schneider-Rosen, 1986; Sroufe & Rutter, 1984), maltreated children, who develop insecure attachment relationships with their caregivers, also manifest impairments in self system functioning and in their representational models of attachment figures, the self, and the self in relation to others (Cicchetti, 1991). Thus, an intervention aimed at altering representational models of maltreated children is of vital importance. However, decisions needed to be made regarding the type of intervention that would be most likely to improve attachment security in maltreated children.

Children in the preschooler-parent psychotherapy (PPP) intervention evidenced a greater decline in maladaptive maternal representations over time than did children in the PPI and CS interventions. Moreover, children who took part in the PPP intervention displayed a greater decrease in negative self-representations than did children in the CS, PPI, and NC groups. Additionally, the mother-child relationship expectations of PPP children became more positive over the course of the intervention as compared with children in the PPI and NC groups. These results suggest that a model of intervention informed by attachment theory (PPP) is more effective at improving representations of self and of caregivers than is a didactic model of intervention (PPI) directed at parenting skills. Again, these results are contrary to predictions that would emanate from the meta-analysis of interventions targeting maternal sensitivity and child attachment (Bakermans-Kranenberg et al., 2003). Because the intervention focused on changing representational models utilizing a narrative story-stem measure, outcomes that might be expected to improve more dramatically in the PPI model (e.g., parenting skills, knowledge of child development) could not be addressed. Consistent with the approach described in our discussion of factors contributing to the success of the mother-infant interventions, we believe that the utilization of skilled and well-trained therapists, adherence to manualized treatment models, and monitoring of the fidelity of the provision of the interventions contributed to the efficacious findings. Moreover, given prior research that has found that the type of maternal attachment insecurity that is present may affect maternal responsiveness to various intervention strategies (Bakermans-Kranenburg, Juffer, & van IJzendoorn, 1998), it will be important to assess baseline attachment organization of mothers in relation to intervention outcome.

These intervention results point to the potential malleability of these representations of self and of self in relation to others most significantly when an intervention derived from attachment theory (PPP) is provided. Rather than assuming that "sensitive" periods exist during infancy when the attachment relationship becomes less amenable to change, our findings suggest that, at least during the preschool years, the internalized mother-child relationship continues to evolve and remains open to reorganizations.

The fact that maltreated children in the PPP intervention evidenced increases in positive and decreases in negative self-representations is consistent with the findings of Cicchetti and Rogosch (1997) on pathways to resilience in maltreated school-age children. Differential predictors of resilient functioning were found in maltreated versus nonmaltreated children, with the former being more resilient when positive personality and self-system processes were present, and the latter being linked more to relationship variables. The improvements found in the self system processes of children in the PPP intervention are a positive sign that resilient strivings may have been initiated. If so, then the gains evidenced by these youngsters may continue to serve beneficial protective functions in future years. The positive changes in the PPP children's representations of maternal figures also bode well for these children's future receptivity to peers and other potential relationship partners, thereby moving them forward on a more adaptive relationship trajectory.

Next, we direct our attention toward another group of children at risk for maladaptive development and psychopathology: the offspring of depressed mothers.

DEFINITIONAL AND EPIDEMIOLOGICAL CONSIDERATIONS IN DEPRESSION

Point prevalence estimates for Major Depressive Disorder (MDD) in investigations that utilize structured diagnostic interviews yield rates of current Major Depression of less than 1% in samples of children, approximately 6% in samples of adolescents, and 2% to 4% in samples of adults (Kessler, 2002). Additionally, epidemiological surveys utilizing diagnostic interviews report lifetime prevalence rates of MDD that range from as low as 6% to as high as 25% by the end of adolescence and in adulthood (Kessler, Avenenoli, & Merikangas, 2001).

The National Comorbidity Study, the only nationally representative general population data in the United States based on a structured diagnostic interview, discovered that nearly 16% of respondents met diagnostic criteria for a lifetime episode of MDD (Kessler, Davis, & Kender, 1997; Kessler, McGonagle, Zhao, & Nelson, 1994). Furthermore, recurrent episodes of depression are quite common; existing estimates are that more than 80% of persons with a history of MDD experience recurrent episodes. When one also factors in the documented high rates of subsyndromal depression (Kessler, 2002), it is clear that a high percentage of individuals are confronted with the pain, suffering, and other dire consequences that depression and its variants engender.

Over the past several decades, as we have witnessed the managed care revolution in the field of mental health, economists and behavioral scientists alike have begun to substantiate the societal costs of illness (Gold, Hughes, & Swingle, 1996). Consequently, far more attention is being paid to investigating the consequences of mental illness such as MDD than on estimating prevalence and discovering modifiable risk factors, as has traditionally been the case in psychiatric epidemiology (Kessler, 2002).

In this new focus, depression has been shown to exert a major cost on individuals and on society. The World Health Organization's Global Burden of Disease (GBD) study ranked depression as the most burdensome disease in the world (Murray & Lopez, 1996). Among all diseases, the GBD study found that depression was the leading cause of the number of years individuals worldwide lived with disability, and the second leading cause of disease burden in terms of disability adjusted life years (DALYs) in developed regions of the world. Moreover, unipolar depression was documented to be the leading cause of disease burden DALYs among people in the middle years of life. Projecting to the year 2020, the GBD investigators predicted that unipolar depression will become the leading cause of disease burden in females and in developing countries (Murray & Lopez, 1996). The high burden of disease for depression is due to the combination of relatively high prevalence, high impact on quality of life and morbidity, early age of onset, and high likelihood of recurrence and chronicity (Wells, Subkoviak, & Serlin, 2002).

The social and economic effects of depression include stigmatization and discrimination, impairment in functioning, lower educational attainment, lost work productivity, greater marital instability, and increased

utilization of health services (Hinshaw & Cicchetti, 2000; Simon, 2003). Depression also imposes a substantial burden on individuals through the pain and suffering it inflicts, not only on individuals, but also on the family.

Given the deleterious consequences that often accompany depressive disorder, it is not surprising that the children of depressed mothers are at increased risk for developing maladaptively. In the next section, we examine the known effects that maternal depression exerts on biological and psychological developmental processes in the early years of life. Subsequently, we illustrate how we have translated this research, much of which was undertaken in our laboratory, into the development and implementation of preventive interventions for young offspring of mothers with MDD.

A Developmental Psychopathology Perspective on Maternal Depression

Depressive conditions may be viewed as forming a spectrum of severity from transient and universally experienced dysphoria, to elevated levels of depressive symptoms that do not meet the diagnostic criteria for disorder, to extended periods of Dysthymic Disorder (i.e., chronic, low-level depression), to episodes of Major Depressive Disorder. Given the prevalence of depressive disorders across extensive periods of development and the various risk factors associated with depression, it is critical to have a firm grasp of the developmental processes that contribute to the emergence and maintenance of depressive disorders.

Because of the complex interplay among psychological (e.g., affective, cognitive, socioemotional, social-cognitive), social (e.g., cultural, community), and biological (e.g., genetic, neurobiological, neurophysiological, neurochemical, neuroendocrine) components, developmentalists have begun to invest great attention in examining the pathways, mechanisms, and sequelae involved in the ontogenesis and perpetuation of mood disorders (Beardslee, Versage, & Gladstone, 1998; Cicchetti & Toth, 1995, 1998a; Goodman & Gotlib, 2002). In this section, we focus on the effects of maternal MDD on two major developmental processes in the early years of life that have been investigated in our laboratory: attachment and the self system. We chose to focus on these topics because research investigations have shown that these issues have played an instrumental role in the generation, development, and implementation of interventions with depressed caregivers and their young children. Given the

multiplicity of systems affected by depressive disorders, a developmental psychopathology approach serves to direct attention to the early developmental attainments that may be related to later-appearing patterns of Depressive Disorder. In adaptively functioning children, a coherent organization among diverse developmental systems is expected. In contrast, offspring of depressed mothers are at increased risk for either an incoherent organization among these developmental systems, or an organization of pathological structures, that is, a depressotypic organization (Cicchetti & Toth, 1998a).

The development of Depressive Disorder, as well as the individual's age at onset, is influenced not only by the emergence of salient issues that must be confronted and successfully resolved, but also by timed genetic events that create challenges and provide new opportunities as they figure prominently in every developmental phase. Moreover, two biological systems have received attention in research on the effects of maternal depression on offspring: EEG hemispheric activation asymmetry and stress regulatory dysfunction. At birth, hemispheric interconnections are incomplete and continue to develop. Davidson and Fox (1982) demonstrated that relatively greater left-sided activation was observed when infants were shown a happy video, and greater right-sided activation was observed when a sad video segment was presented. Early individual differences among infants in tendencies to approach versus withdraw from novelty and concomitant emotionality may reflect variations in the relative dominance and reactivity of the left and right hemispheres to stimulation, respectively (Fox & Davidson, 1984). Furthermore, experience may influence the manner in which the hemispheric connections develop. Infants with greater right hemisphere activation may be prone to overstimulation, with greater sensitivity and distraction to environmental change contributing to distress; conversely, infants with greater left activation may appear less distressed by environmental change and may have difficulty shifting and refocusing attention.

Infants as young as 1 month of age whose mothers were depressed have been found to exhibit greater relative right-frontal EEG asymmetry (due to reduced left-frontal activation) than 1-month-old infants of non-depressed mothers (Jones, Field, Fox, Lundy, & Dava-los, 1997). These asymmetries were found to persist upon longitudinal follow-up when the babies were 3 months of age. Additionally, Field, Fox, Pickens, and Nawrocki (1995) discovered that depressed mothers and their 3- to 6-month-old infants both displayed right-

frontal EEG asymmetry. Dawson and her colleagues (Dawson, Grofer Klinger, Panagiotides, Hill, & Spieker, 1992; Dawson, Grofer Klinger, Panagiotides, Spieker, & Frey, 1992) examined the EEGs of 14-month-old babies of mothers with elevated depressive symptomatology and of same-age babies of nonsymptomatic mothers during various emotion-eliciting situations. Infants of the symptomatic mothers were found to display reduced left-frontal brain activation during baseline and playful interactions. Securely attached infants of symptomatic mothers evidenced left-frontal EEG hypoactivation, whereas securely attached babies of nonsymptomatic mothers did not. Further, during distress-eliciting maternal separation, the infants of the symptomatic mothers did not display a greater right-frontal activation or the same degree of distress that was observed in the babies of the nonsymptomatic mothers; these group differences were obtained regardless of the attachment status of the infants of the symptomatic mothers. Taken together, the results of the studies on hemispheric activation asymmetries in young offspring of depressed mothers suggest that a genetic diathesis for depression and the quality of caregiving experienced by the infant both exert an impact on neurobiological development.

Relatedly, empirical evidence with rodents and non-human primates suggests that disruptions in early caregiving can exert long-term effects on the limbic-hypothalamic-pituitary-adrenal axis, which mediates the stress response (Francis et al., 1996; Gunnar, Morrison, Chisholm, & Shchuder, 2001; Plotsky & Meaney, 1993; Sanchez et al., 2001). To determine whether these findings were applicable to humans, Ashman, Dawson, Panagiotides, Yamada, and Wilkinson (2002) collected salivary cortisol samples from young school-age children of depressed and nondepressed mothers. Samples were collected immediately upon arrival to the research laboratory and after a mild laboratory stressor; in addition, samples were collected at home after awakening and before bedtime. Children who were reported to have elevated levels of internalizing symptoms and whose mother had a history of Depressive Disorder displayed elevated laboratory baseline cortisol levels. Children reported as having clinically significant internalizing symptoms also were more likely to evidence an elevated stress response to the mild laboratory stressor. Interestingly, the best predictor of elevations in children's baseline cortisol at age 7 was the presence of maternal depression within the first 2 years of the child's life. These findings suggest that, as has been demonstrated

in the animal literature, early caregiving may be related to later dysregulation in neurobiological stress systems (see also Gunnar et al.'s, 2001, work with Romanian orphans). Future longitudinal investigations that integrate biological assessments, such as EEG hemispheric activation asymmetry and stress-reactivity paradigms, with psychological measurements hold great potential for elucidating mechanisms underlying the efficacy of preventive interventions.

The Development of an Attachment Relationship

Mothers who suffer from MDD are likely to struggle with the demands of providing early care for their infants. The features of the disorder, including anhedonia, difficulty regulating negative affect, feelings of worthlessness, helplessness, and hopelessness, sleep disturbances, and decrements in role functioning, conspire to generate an early relational context that may impair parenting and the development of the mother-child relationship and consequent child adaptation (Cicchetti, Rogosch, & Toth, 1998; Goodman & Gotlib, 2002). Moreover, depressive disorders frequently have evolved from difficulties in mothers' own childhood attachment experiences (Bowlby, 1980). Linkages between disturbances in parent-child relations and the emergence of depression have been made by theoreticians operating in the tradition of psychoanalytic and object relations theory (Arieti & Bemporad, 1978; Bowlby, 1980). Additionally, many retrospective studies have found that depressed adults report histories involving inadequate or abusive parental care (Bemporad & Romano, 1992).

Thus, insecurity in childhood attachment relationships of depressed mothers not only may contribute to their depressive disorders, but also may influence the manner in which they are able to relate to their young offspring via the operation of their representational models of attachment relationships. In attempting to understand the effects of maternal depression on the attachment relationship with a child, the issue of psychological unavailability must be considered. From the perspective of attachment theory, physical absence of a caregiver may be much less important than the child's experience of the parent as psychologically unavailable. Moreover, during periods of parental depression, children are likely to be confronted with caregivers who are inconsistent, unpredictable, insensitive, hostile, and/or intrusive (Cummings & Cicchetti, 1990; Egeland &

Sroufe, 1981). Such behavior in depressed caregivers may interfere with the capacity to relate to their child in a way that promotes the development of a secure attachment relationship.

Although children of depressed caregivers are more at risk of experiencing deviations in care as a consequence of their caregivers' struggles with their disorder, these children also may experience a sense of loss, akin to actual loss of a parent (Bowlby, 1980), when caregivers suffer from episodes of Major Depression. Insecure representational models may place these children in a more tenuous position in terms of coping with the experience of psychological loss of the availability of the caregiver as MDD episodes occur. Prolonged anxiety, sustained grieving, and difficulty in resolving the loss may further contribute to aberrations in the organization of cognitive, affective, representational, and biological systems. Subsequent loss experiences, either real or symbolic, may precipitate depressive episodes (Beck, 1967).

The quality of attachment in infants and children of mothers with depressive disorders has been examined in a number of investigations. To date, the results are varied (Martins & Gaffan, 2000). In view of the heterogeneous outcomes evidenced by children with depressed mothers, developmental researchers have been confronted with the challenge of specifying the processes underlying this diversity.

Because children with depressed parents are especially likely to be faced with the parents' psychological unavailability, the role of depression in contributing to insecure attachment relationships has been a fertile area of inquiry. In general, investigations of attachment security in infants, toddlers, and preschoolers with depressed caregivers suggest that offspring of depressed mothers are more likely to evidence increased rates of insecurity (Martins & Gaffan, 2000) than are offspring of nondepressed mothers from comparable SES backgrounds. With respect to the type of insecure attachment experienced, a meta-analytic investigation conducted by Martins and Gaffan concluded that the young offspring of depressed mothers have increased rates of anxious-avoidant (Type A) and disorganized (Type D) attachments. However, findings regarding attachment insecurity vary as a function of sample characteristics (e.g., depressed poverty-stricken mothers versus depressed middle-SES mothers; hospitalized versus community samples of depressed mothers), as well as transient versus more prolonged exposure to maternal de-

pression (Cicchetti et al., 1995). Specifically, chronic maternal depression that occurs during their offspring's infancy and toddlerhood has been demonstrated to be associated with lags in verbal abilities, a lack of school readiness skills, and behavior problems (National Institute of Child Health and Development [NICHD], 1999). Additionally, issues such as the presence or absence of other supportive individuals (e.g., nondisordered fathers), as well as the overall family context in which the depressed mother resides, are likely to exert a major impact on the child's ultimate functioning (Cicchetti et al., 1998; Downey & Coyne, 1990).

The Development of the Self System

Toddlerhood may be a particularly sensitive period for the formation of a depressotypic organization because many of the social, emotional, and cognitive competencies implicated in the development of later Depressive Disorder (e.g., the development of autonomy, the emergence of the affect of shame, and the construction of a representational model of the availability of the self and of the self in relation to others) are at crucial stages of development.

The quality of attachment relationships contributes to the development of representational models of self and other that organize cognition, affect, and behavior, and these models serve to canalize perceptions and experiences as ontogenesis proceeds. Consistent with the propositions of an organizational perspective, the representational models of insecurely attached offspring of depressed mothers are likely to contribute to the development of a depressotypic organization of psychological and biological systems (Cicchetti & Toth, 1998a). Affect regulation and expression are less optimal, and significant others are perceived as unavailable or rejecting, while the self is regarded as unlovable. These attachment-related aspects of a depressotypic organization may contribute to a proneness to self-processes that have been linked to depression (e.g., low self-esteem, helplessness, hopelessness, negative attributional biases).

In a study conducted by Rogosch, Cicchetti, and Toth (2004), expressed emotion was examined in families of toddlers whose mothers had experienced MDD occurring since the child's birth and contrasted with expressed emotion in demographically comparable families with no history of parental mental disorder. Mothers provided 5-minute speech samples on their child, their spouse, and themselves and completed measures of toddler behavior

problems. Expressed emotion scores of criticism and emotional overinvolvement were determined for mothers for each of the individuals noted. Depressed mothers expressed significantly higher criticism in regard to self, spouse, and toddler than did nondepressed mothers. No depression group differences were found for emotional overinvolvement. Thus, higher levels of criticism across relationships mark the emotional climate in the families of the depressed group. Moreover, mothers with MDD reported significantly higher levels of child behavior problems than did mothers in the nondepressed group. However, high expressed emotion levels of maternal criticism did not serve as a mediator of the relation between depression group status and higher maternal report of child behavior problems.

The greater criticism of depressed mothers in regard to their toddlers is consistent with previous research demonstrating that depressed mothers express more criticism toward their school-age and adolescent children (Brennan, Hammen, Katz, & Le Broque, 2003; Schwartz, Yerushalm, & Wilson, 1993). The findings of Rogosch et al. (2004) demonstrate that the negativity and criticism expressed are likely to emerge earlier in development than suggested by prior work. Furthermore, toddlers also are more likely to be exposed to criticism communicated between their parents, resulting in a family emotional climate rife with negativity across relationships.

Even when the young child is not the object of maternal criticism, the toddler in the families of mothers with MDD is nevertheless likely to be subjected to family system processes operating in response to criticism in other relationships. Children in families with depressed mothers are more likely to be exposed to reciprocal criticism between their parents, and such a conflicted marital relationship poses risks for these children's socioemotional development (Cummings & Davies, 1999; Rogosch et al., 2004). The highly negative and critical relational environment of families with a depressed mother likely influences emerging self-representations of the toddler and may inculcate a negative self-structure that may form the foundation for a depressotypic developmental organization (Cicchetti & Toth, 1998a).

A number of empirical studies attest to the difficulties in self-development and corresponding affective functioning in toddlers of depressed mothers. Maternal attribution patterns have been shown to affect the types of self-attributions that young children make. For example, Radke-Yarrow, Belmont, Nottelmann, and Bottomly

(1990) found that mothers with mood disorders conveyed significantly more negative affect in their attributions, particularly in regard to negative attributions about child emotions. Moreover, among the mood disordered mothers and their toddlers, there was a higher correspondence in the affective tone of attributions and statements about the self. This finding suggests a heightened vulnerability among these children for negative self-attributions, with negative implications for an increased risk for the development of later depression.

The development of self-knowledge during early toddlerhood has been examined most extensively through studies of visual self-recognition (M. Lewis & Brooks-Gunn, 1979). These investigations have relied on the presence of mark-directed behavior involving touching the nose while inspecting oneself in a mirror after a spot of rouge has been applied as the criterion for self-recognition. This capacity to recognize oneself visually emerges during the 2nd year of life and is considered to be one of the early precursors in the ontogenetic sequence of self-awareness. Cognitive, social, and experiential factors have been examined as they relate to individual differences in the development of visual self-recognition. Consistent with Kagan's (1981) conclusion, based on cross-cultural research, that self-awareness is a maturational attainment, findings to date coalesce to demonstrate that self-recognition is primarily a cognitive maturational phenomenon. This assertion has been further substantiated through investigation of atypical populations (cf. Mans, Cicchetti, & Sroufe, 1978; Schneider-Rosen & Cicchetti, 1991).

Research conducted with normative samples has revealed that visual self-recognition is predominantly accompanied by positive affective displays. Despite the fact that the attainment of visual self-recognition does not differ in high-risk populations, empirical investigations have revealed a high percentage of neutral or negative affect accompanying self-recognition in these youngsters (Schneider-Rosen & Cicchetti, 1991; Spiker & Ricks, 1984).

Because the offspring of mothers with MDD are exposed to a nonnormative, affectively extreme rearing environment, Cicchetti, Rogosch, Toth, and Spagnola (1997) examined visual self-recognition in the toddlers of depressed and nondepressed mothers. These investigators discovered that the achievement of visual recognition was not related to differences in level of cognitive development, timing of rouge application, affective expression, or maternal depression. However, toddlers who

exhibited self-recognition and who had mothers with MDD were more likely than toddlers of nondepressed mothers to display nonpositive affect and to shift affect from positive to nonpositive in the rouge condition.

Within the group of toddlers of mothers with MDD, toddlers who did not evidence self-recognition and who shifted affect from positive to nonpositive had lower attachment Q-Sort (Waters, 1995) security ratings and had mothers with less positive affect characteristics. These findings are consistent with the predictions of the organizational perspective on development (Cicchetti & Schneider-Rosen, 1986), which posits relations between attachment security and self-development. Furthermore, self-recognition and affective instability from the non-rouge to the rouge condition were related to differences in cognitive developmental level among toddlers of depressed mothers. Whether the differing patterns of affect-cognition relations discovered in the toddlers of depressed mothers in this investigation will influence the development, quality, or stability of emerging self-cognitions is an important empirical question that is currently being investigated in our laboratory. Such work will enable an examination of how affective components of the self (e.g., self-esteem) that are relevant to the development of depressive disorders relate to growing cognitive and representational components of the self (e.g., self-understanding, self-cognitions, self-schemata; see Cicchetti & Toth, 1995).

Cole, Barratt, and Zahn-Waxler (1992) observed a group of toddlers during two mishaps: a doll breaking and juice spilling. In general, toddlers exhibited two reactions to these mishaps: concerned reparation, and tension and frustration. Consistent with Kagan's (1981) notions that self-awareness, the appreciation of standards, and a moral sense emerge during this period, most toddlers tried to repair the mishap. The presence of depressed and anxious symptomatology in mothers was associated with a suppression of frustration and tension in their toddlers. It may be that the toddlers' exposure to mothers with depressed and anxious symptomatology served to inhibit the development of more normal affective expression, thereby contributing to a sense of lack of efficacy in interfacing with the environment.

Cicchetti, Maughan, Rogosch, and Toth (in press) investigated false belief understanding, an important aspect of a representational theory of mind and an aspect of self-other differentiation that is typically acquired during the preschool period (Wellman et al., 2001). Early maternal depression was found to have a signifi-

cant effect on children's false belief understanding at age 5, with fewer children of depressed mothers passing the false belief criteria than youngsters with nondepressed caregivers. Interestingly, mothers who experienced depression during the first 2 years of their child's life and during the year prior to the false belief assessments had children who performed most poorly on the TOM tasks. These findings suggest that the experience of both early and recent maternal depression exerted a more detrimental effect on the development of TOM in preschool offspring.

Our review of research on the effects of maternal depression on offspring underscores the deleterious effects that this major mental disorder may exert on the developing child. It also highlights the importance of intervening not just directly with the depressed mother, but also with offspring exposed to maternal depression. Therefore, we next discuss a program of intervention that has incorporated results derived from studies of attachment and self in offspring of depressed mothers.

Preventive Interventions for Toddlers of Depressed Mothers

Based on our knowledge of the effects of maternal depression on the functioning of their young offspring, we sought to examine the efficacy of a preventive intervention to promote mother-child attachment security and positive child adaptation. The intervention was predicated on the importance of addressing the interplay among maternal representational models of their attachment experience in childhood, the mother's representations of her child, and the quality of the developing attachment relationship between mother and child.

Although a number of attachment-informed interventions have been developed (Bakermans-Kranenburg et al., 2003; van IJzendoorn et al., 1995), they typically have involved the provision of treatment to multiproblem populations (see, e.g., Egeland & Erickson, 1990; Erickson et al., 1992; Lieberman et al., 1991; Lyons-Ruth et al., 1990). Consequently, an array of services has been provided to meet the extensive needs of the families being served. This diversity in service outcomes has made it difficult to evaluate outcomes that may be attributed to changes in representational models versus results that may be due to other factors, such as a reduction of environmental stressors. Therefore, the application of attachment-informed interventions to populations with more circumscribed problems, such as mothers experi-

encing MDD without co-occurring risk factors, can be informative through more effectively isolating the specific factors that influence outcome.

To date, two interventions have been conducted that have sought to modify attachment security in the young offspring of depressed mothers. Gelfand, Teti, Seiner, and Jameson (1996) found that a home-based intervention designed to improve maternal self-efficacy was not effective in improving attachment security in offspring. Similarly, Cooper and Murray (1997) evaluated four types of intervention for mothers with postpartum depression. Mothers were assigned randomly to either routine primary care, nondirective counseling, cognitive-behavioral therapy, or attachment theory-guided dynamic psychotherapy. With the exception of the primary care condition, all treatment groups evidenced fewer relationship difficulties with their children postintervention. However, improvements in attachment security did not occur. Thus, preventive interventions have yet to demonstrate the ability of attachment-informed therapies to foster attachment security in diverse groups of high-risk populations, including the offspring of depressed mothers.

An Attachment Theory-Informed Preventive Intervention for Toddlers with Depressed Mothers

In view of the potential challenges to the development of secure attachment relationships that confront children with depressed caregivers, the continued provision and evaluation of preventive interventions for this population are extremely important. Although it is not uncommon for depressed women to receive therapeutic interventions for their depression that involve pharmacological treatments, individual therapy, or both, it is much less likely that such interventions recognize the woman as a mother and, consequently, address the relationship that is forming between mother and child. Unfortunately, disregard for this evolving relationship may result in greater risk for the emergence of an insecure attachment relationship and associated developmental difficulties for the child. Inattention to mother-child relationship issues in depressed mothers, in turn, may serve to perpetuate maternal depression, as the caregiver may be confronted with current and future child behavior problems and the associated guilt resulting from the fear that her depression has interfered with effective parenting.

In our laboratory, we conducted a controlled randomized preventive intervention trial with mothers with

MDD and their toddler offspring. Participants in this preventive intervention were recruited for a longitudinal study designed to evaluate the efficacy of a preventive intervention (toddler-parent psychotherapy [TPP]) for toddlers of depressed mothers and to examine the effects of maternal depression on child development, including child attachment. The sample included 168 mothers and their toddlers. At the time of enrollment, the average age of the toddlers was 20.4 months. Of the toddlers, 102 had mothers with a history of MDD that minimally involved a major depressive episode occurring at some time since the toddler had been born. The remaining 66 children had mothers with no current or prior history of major psychiatric disorder. The mean maternal age of the sample was 31.6 years.

To minimize the co-occurring risk factors that often accompany parental depression (Downey & Coyne, 1990), we decided not to recruit families from low-SES backgrounds. Initially, we wanted to conduct this intervention with low-SES mothers and their young offspring; however, because no study had succeeded in demonstrating that an attachment-informed intervention could successfully alter attachment security and child functioning in the offspring of depressed mothers, we concluded that it was first necessary to ascertain whether such an intervention could be effective with depressed mothers from the middle-SES population. Accordingly, parents were required to have at least a high school education and families could not be reliant on public assistance. A community sample of mothers with a history of Depressive Disorder was recruited through referrals from mental health professionals and through notices placed in newspapers, community publications, and medical offices and on community bulletin boards. In addition to having a child of approximately 20 months of age, mothers in the depressed groups had to meet diagnostic criteria for MDD occurring at some period since the birth of their toddler. The depressed mothers also had to be willing to accept random assignment to either the intervention or the nonintervention group following completion of baseline assessments. Among depressed mothers, 92.8% had been depressed during the postpartum period. Only 12.4% had been depressed exclusively in the postpartum period since the toddler was born. Forty-six depressed mothers were randomly assigned to receive the TPP intervention. The length of the intervention period averaged 57 weeks, and the mean number of intervention sessions conducted was 45.

Recruitment of control group mothers without a history of psychiatric disorder was achieved by contacting families living in the vicinity of the families of depressed mothers. Names of potential families with a toddler of the targeted age were obtained from birth records. In addition to the same demographic characteristics required for families with depressed mothers, the control group mothers were screened for the presence or history of major psychiatric disorder using the Diagnostic Interview Schedule III-R (Robins et al., 1985); only mothers without a current or past history of major psychiatric disorder were retained. Thus, this control group constitutes a "super normal" comparison group, given what is known from epidemiological studies about the prevalence of mental disorders in the general population.

We based our decision to recruit depressed mothers when their offspring were approximately 20 months of age on research as well as clinical considerations. Because several studies have found shifts from secure to insecure attachment between 12 and 18 months of age in offspring of depressed mothers, it appears that the toddler period confronts the mother-child dyad with challenges that are not met effectively. The chronicity of maternal depression may impede the toddler from being able to rely on the mother as a secure base. During toddlerhood, depressed mothers may become especially overwhelmed by the demands associated with parenting an active, inquisitive, and increasingly independent child who strives for initial individuation from the mother (Cicchetti & Toth, 1995). As these strivings for autonomy reach ascendancy, a depressed mother may feel rejected by her child's increased interest in aspects of the world not related to the dyadic relationship. This tendency might be especially likely to occur in women who themselves had histories of rejection and who therefore are sensitized to perceiving rejection even in generally benign circumstances. To prevent the coalescence of insecure attachment and to help mothers accurately interpret the changes associated with toddlerhood, we felt that the provision of a preventive intervention during this developmental period was especially important.

Participants in the depressed intervention (DI), depressed control (DC), and nondepressed control (NC) groups were comparable on a range of basic demographic characteristics. Mothers were predominantly Caucasian (92.4%), and minority representation did not differ across groups. Maternal education also was comparable across groups. Overall, 53.8% of the mothers

were college graduates or had received advanced degrees. Family SES based on Hollingshead's (1975) four-factor index also was consistent across groups: 73.4% were ranked in the two highest socioeconomic group status levels (IV and V).

Baseline assessments took place when toddlers were approximately 20 months of age and depressed mothers were randomly assigned to the intervention group (DI) or the nontreatment control (DC) group. Postintervention assessments occurred subsequent to the child turning 3 years old, when the DI group had completed the course of intervention. Extensive analyses of baseline measurements were conducted and differences between the DI and DC groups, in contrast to the normative group of non-depressed mothers (NC), were examined. Consistently, across diverse measurements, including stress, social support, parenting hassles, marital harmony and satisfaction, and levels of conflict, the two groups of depressed mothers were found to be indistinguishable, verifying the effectiveness of the randomization procedures. In all cases, the two groups of depressed mothers were found to have less adaptive functioning (Cicchetti et al., 1998); moreover, each of the features on which the depressed mothers differed from the mothers in the control group are detrimental to facilitating optimal child development and secure attachment relationships. Although not all mothers in the depressed groups were experiencing a depressive episode at the initiation of the preventive intervention, it was apparent that vulnerabilities in the two groups were substantial and continued beyond the confines of depressive episodes. These findings underscore the adverse emotional climate in which the toddler offspring of depressed mothers are immersed.

TPP is consistent with the IPP intervention described earlier in the chapter, with therapeutic adjustments made for the child's developmental level (Lieberman, 1992). Modifications in the treatment model also were made based on the socioeconomic status of participants. For example, rather than providing the intervention in homes, as was the case with low-income maltreating mothers, TPP was provided in the office setting. We found that our middle-income participants were not comfortable having someone provide services in their home, as they viewed it as somewhat intrusive. They also were much more accustomed to professional settings. Thus, although we initially considered providing the treatment in the homes as has been done in other seminal studies of this model of intervention (cf. Lieberman et al., 1991), it quickly became apparent that this would

be counterproductive. This realization is an important one, as it underscores the importance of tailoring an intervention to the needs of the population being served rather than rigidly adhering to a model developed with another population.

Challenges to Implementation. Although initially we expected the implementation of a preventive intervention with middle-income families in which fewer co-occurring risks were present to be much easier than our experiences in providing and evaluating services to low-income multiproblem families, we quickly learned that a different set of challenges was present. Our description of the modification to the provision of TPP provides one example of how a new population required a different approach. A number of other issues also emerged, many of them directly related to the diagnosis of depression.

First, we needed to ascertain how best to communicate with women regarding their depression. Although some women clearly self-identified as depressed, others had never actively sought treatment for depression. Thus, challenges posed by enrolling a sample that was recruited from the community and that was not necessarily comfortable with the utilization of diagnostic nomenclature needed to be addressed. Although we decided not to focus on the clinical diagnosis, we did describe symptoms and discussed how the symptoms were consistent with the presence of depression. The fact that the symptom pattern could affect parenting also was discussed. Sharing information that we were "preventing" something also proved to be a very delicate issue. We found that many of the mothers who were depressed feared that they had somehow "damaged" their offspring. Thus, even though we carefully described our randomization procedures, when contacted regarding participation in intervention, many women became alarmed. After completing baseline visits and being invited to participate in the intervention based on random assignment, one mother anxiously responded, "I knew there was something wrong with my son because I took antidepressants when I was pregnant. I know you're calling me because he looks really bad." We consistently needed to emphasize that not all children exposed to maternal depression had problems and that participation in the preventive intervention might just maintain an already positive developmental trajectory.

Actual recruitment of the population of depressed women also posed challenges. Initially, we planned to enlist participants from providers who were treating the

maternal depression. Because we were focusing on the mother-child relationship and not on maternal depression per se, this approach seemingly posed no interference with any treatment being provided to the mother for her depression and also ensured that all women would be receiving necessary treatment for their depressive disorders. Surprisingly, we found that despite extensive outreach efforts, community providers of services to depressed women were reluctant to refer possible participants. In fact, we received a much more positive response from non-mental health providers. In retrospect, we realized that despite protestations to the contrary, many providers feared that they would lose their clients if they referred them to our program. Therefore, we modified our recruitment strategy to reach out directly to mothers.

The reputation of Mt. Hope Family Center as a facility serving low-income populations also posed obstacles. We needed to establish a separate name for the intervention program, relying on our university affiliation, which we minimized in our work with low-income participants, for whom that affiliation was typically off-putting. We also obtained a separate phone line, utilized a different entrance, and provided more upscale décor in efforts to decrease perceptions of stigmatization that our participants might feel attending a clinic-like setting known for treating child abuse and neglect. Our location in an urban community also resulted in some resistance, with suburban mothers fearing for their safety when venturing into the city. Procedures needed to be developed to increase comfort with traveling to our facility. Research staff would meet mothers in the parking lot and offer to pick them up if they were uncomfortable with the drive.

Because mothers were struggling with depression, concerted outreach needed to occur to ensure that they had the energy to meet the demands of participation in the research. We provided a single point of contact for mothers so that they could develop a relationship with a member of our staff. The designated "mom experimenter" was a constant who guided participants through all aspects of the longitudinal research program. Unfortunately, staff turnover is unavoidable over the course of a longitudinal project; when staff attrition occurred, we made great efforts to have the departing staff member introduce the new contact person.

Interestingly, the remission of MDD also posed a challenge to the conduct of the longitudinal investigation. We found that well mothers sometimes wanted to

distance themselves from the period during which they had been clinically depressed. Remaining involved with a research program that had recruited them because of their mental illness reminded them of a difficult period in their lives. Moreover, as offspring became older, we found that some mothers were reluctant to discuss their history of depression with their children for fear of stigmatizing either themselves or their children. Efforts to help these women understand that both research and clinical case studies (e.g., Beardslee, 2000; Hinshaw, 2002) suggest that honest disclosure and the provision of information about past and current mental illness is helpful for children met with mixed results. Although some mothers expressed a willingness to continue involvement in the project as a function of this information, others adamantly insisted that they did not want their or their child's life in any way linked with the history of depression. The latter scenario was most typical in families where significant life changes, such as divorce and remarriage, had occurred. The fear of stigmatization was very real, and its presence speaks to the need for increased efforts to battle the societal stigmatization of mental illness.

Finally, our project staff struggled with how best to share the results of the project when mothers requested information. Because we were working with bright women who utilized library and Internet resources, they were interested in reading publications that emanated from their involvement. However, we were concerned that depressed mothers who had not participated in the intervention would be alarmed about the effects of their depression on their child, given our positive findings for intervention. Therefore, we prepared synopses of our results, always emphasizing that conclusions were based on group data and did not apply to individuals.

Intervention Efficacy. Given the centrality of attachment organization to early personality development and competent adaptation, a critical question involved whether the toddlers of a middle-class group of depressed mothers would evidence heightened rates of attachment insecurity at baseline. At baseline and at postintervention completion at 36 months, attachment was assessed via the attachment Q-set (AQS; Waters, 1995), a measure that has been found to provide a valid assessment of attachment. Mothers were given detailed instructions and training on how to complete the AQS prior to the baseline assessment and were asked to observe their child for 2 weeks before completing the

AQS. In accordance with the findings of others, toddlers with depressed mothers evidenced higher rates of insecurity than toddlers of nondepressed mothers. Subsequently, the effectiveness of the attachment theory-based intervention for fostering attachment security of toddlers with depressed mothers was examined (Cicchetti, Toth, & Rogosch, 1999).

Although, at baseline, the toddlers in the DI and DC groups evidenced equivalent rates of insecure attachment and both groups had higher rates of insecure attachment than the NC group, at follow-up the DC group continued to have higher rates of insecure attachment than the NC group. In contrast, the DI group at postintervention follow-up was not significantly different from the NC group in terms of the rate of insecure attachment. For toddlers who had taken part in the intervention, there was greater maintenance of secure attachment organization among those who were initially secure, as well as a greater shift from insecure to secure attachment groupings. These findings demonstrate the efficacy of TPP in promoting secure attachment organization among young offspring of depressed mothers and are among the first in the literature to demonstrate the effectiveness of a preventive intervention for altering attachment organization.

Maternal sorts of the AQS have been shown to relate to Strange Situation attachment classifications, as well as in theoretically expected ways to maternal internal working models and child security (Eiden, Teti, & Corns, 1995; Vaughn & Waters, 1990). It is unlikely that the maternal reports were biased because the Q-set method, unlike face-valid, self-report measures, requires the respondent to make forced-choice decisions across items, thereby reducing potential for biased responding. Moreover, mothers were not informed as to what constitutes secure attachment and they were unaware of our experimental hypotheses. In addition, mothers were neither trained in attachment theory nor knowledgeable about the security criterion ratings for the AQS. Consequently, it is improbable that demand characteristics affected maternal ratings of attachment security. In this regard, the nondidactic nature of the intervention provided becomes important. Unlike interventions that strive to teach sensitive responding or utilize modeling, the TPP intervention never provided such techniques.

In addition to AQS assessments, attachment security also was examined in the Strange Situation; this paradigm was utilized at baseline and postintervention to further elucidate the impact of TPP on attachment orga-

nization (Toth, Cicchetti, & Rogosch, *in press*). At baseline, toddlers in the DI and DC groups were significantly more likely to be insecurely attached to their mother than were toddlers in the NC group. Specifically, 13% of the toddlers in the DI and 20% of the toddlers in the DC group exhibited insecure attachment. Although their insecurity rates were not significantly different from each other, the security rate of 55% in the NC group differed significantly from both depression groups. Consistent with the extant literature, the toddlers in the DC group also had significantly greater rates of disorganized (Type D) attachment than the toddlers in the NC group. There also was a trend for toddlers in the DI group to manifest higher rates of Type D attachment than was the case for youngsters in the NC group. Specifically, the rates of disorganized attachment were 45%, 37%, and 20% for the DC, DI, and NC groups, respectively.

At postintervention, statistically significant differences were obtained in security of attachment between the DI (67%) and the DC (17%) groups. Furthermore, the DC group had significantly less attachment security than the NC group (48%). Of particular importance, despite the large differences in security that existed between the DI and NC groups at baseline, upon completion of the intervention, toddlers in these two groups showed no differences in attachment security. Whereas, at baseline, there were no statistically significant differences between the DI and NC groups in attachment disorganization, at postintervention there was less Type D attachment in the DI than in the DC group and a greater rate of Type D attachment in the DC than in the NC group. The percentages of Type D attachment at postintervention were 11%, 41%, and 21% in the DI, DC, and NC groups, respectively.

An examination of change in attachment security from baseline to postintervention revealed striking findings. The toddlers in the DI group displayed a greater percentage of change in attachment from baseline to postintervention than did either of the nonintervention groups. Specifically, toddlers in the DI group were more likely to change from attachment insecurity to attachment security. In addition, the toddlers in the DC group were more likely to change from attachment security to insecurity than were toddlers in the NC group.

Clinical Implications of Attachment Results. The results of the TPP intervention for toddlers of mothers with MDD provide compelling support for the potential malleability of attachment insecurity. The TPP intervention was effective at modifying attachment insecurity

and in maintaining existing security in the toddler offspring of depressed mothers. Conversely, offspring of depressed mothers not receiving the TPP intervention were less likely than intervention offspring to maintain secure attachments at the postintervention assessment. These findings emphasize the importance of providing preventive interventions to offspring of depressed mothers so as to minimize the likelihood that insecurity will emerge over time. That is, even if offspring of mothers with MDD are securely attached early in life, the parenting milieu and the emotional climate of the home that accompany maternal depression, even once an active episode has remitted, may militate against the continuance of their secure attachment.

In view of the findings on the effectiveness of TPP, it is important to try to ascertain why this is one of the first interventions found to effectively improve security of attachment in young children. One possibility lies in the characteristics of the sample. Even though these mothers were struggling with MDD, they had fewer stressors than typical in populations frequently participating in preventive interventions. For example, the majority of women were married, had a postsecondary education, and were not members of the lower socioeconomic strata. Therefore, they may have been better able to utilize an insight-oriented mode of therapy than women confronted with a multitude of daily living challenges.

Additionally, the selection of a sample with fewer risk factors than that present in multiproblem populations allowed therapists to provide a “pure” form of therapy without needing to depart from the intervention protocol to address crisis situations. Because TPP sessions revealed that many of the depressed mothers in this investigation themselves had histories of negative caregiving and accompanying unresolved issues from childhood, the ability to maintain a focus on the dynamic roots of intergenerational patterns and to explore the current impact of past history on caregiving is considered to be of paramount importance in the success of this intervention. We speculate that as mothers became freed from the ghosts from their pasts, their representational models became more positive and they were increasingly able to focus on the present, including their relationship with their child. Moreover, as this occurred, we believe that mothers were better able to derive pleasure from their offspring and that, consequently, caregivers were invested in fostering and maintaining positive interactions. As mothers became more grounded in the present, we believe that they were more sensitive to their children and better able to

respond to the cues of their offspring. It remains an open, and critical, question as to whether this intervention would be equally effective with a more high-risk population of depressed women (e.g., depressed and impoverished mothers).

After the intervention, youngsters in the DI, DC, and NC groups were followed up 1 year later to determine whether the youngsters in the DI group would continue their positive trajectory and manifest more positive representations of their mother than youngsters in the DC group. At the age of 4, youngsters were individually administered a story-stem completion task by examiners unaware of group diagnosis, intervention status, and child attachment organization (Toth, Maughan, Manly, Spagnola, & Cicchetti, 2002). Consistent with the predictions of an organizational perspective, it was found that the children in the DI group were significantly more likely than those in the DC group to display positive expectations of their relationship with their mother.

The percentage of children with positive representational models of their caregivers was equivalent in the DI and NC groups; moreover, the DI and NC groups both exhibited more positive representations of their mother than did the youngsters in the DC group. Furthermore, the positive relationship between attachment security and positive self-representations demonstrates that the positive effects of the intervention were maintained 1 year after the conclusion of TPP.

The Efficacy of Toddler-Parent Psychotherapy for Fostering Cognitive Development in Offspring of Depressed Mothers. Offspring of depressed mothers are frequently confronted with a caregiver who has cognitive difficulties, including negative self-cognitions, concentration and memory impairments, and delayed information-processing abilities (American Psychiatric Association, 1994). Not surprisingly, a number of investigations have examined the impact that maternal depression has on young children’s cognitive development. Although some evidence has emphasized the significance of maternal depression during the postpartum period and found that cognitive impairments remit over time, other investigations have found continued cognitive difficulties into the preschool years (Cicchetti, Rogosch, & Toth, 2000).

The role of preventive interventions in remediating the detrimental effects of maternal depression on cognitive development has been examined. Neither Cooper

and Murray (1997) nor Gelfand et al. (1996) found any intervention effects on the cognitive functioning of offspring of depressed mothers; in contrast, Lyons-Ruth et al. (1990) found significant treatment effects for a home-visiting intervention among offspring of depressed mothers. Eighteen-month-old toddlers of depressed mothers who had not taken part in the preventive intervention obtained Mental Development Index (MDI) scores on the Bayley Scales of Infant Development that were 10 points lower than those toddlers whose mother participated in the intervention.

In our intervention for toddler offspring of mothers with MDD, we also examined the impact of TPP on the course of cognitive development in toddlers from middle-SES backgrounds whose mothers had experienced MDD prior to the child's age of 18 months. During the toddler period, the emergence of self-awareness and the development of symbolic representation are central issues (Cicchetti & Schneider-Rosen, 1986). Through facilitating communication and expressiveness between mother and child and optimizing the emotional quality of the mother-child relationships, the TPP intervention enhanced children's resolution of the competent developmental tasks of infancy and toddlerhood. Competent development during toddlerhood results in a positive emerging self in which children are more autonomous, free to explore and engage their environment, and more likely to have greater facility in the expression of their internal experience (Cicchetti & Toth, 1995).

At baseline, the DI, DC, and NC groups did not differ on the Bayley MDI. At the postintervention follow-up, a decline in IQ was found in the DC group, whereas the DI and NC groups continued to be equivalent, with higher Wechsler Preschool and primary Scale of Intelligence-Revised (WPPSI-R, 1989) Full-Scale and Verbal IQs than in the DC group. The worst outcome was found among the DC children whose mother had experienced subsequent depressive episodes. In contrast, among children of depressed mothers in the DI groups, no differences in cognitive development were observed for those children of mothers in the intervention who did or did not have subsequent depressive episodes between baseline and age 3. Thus, TPP contributed to children's making normative cognitive advances, even when mothers continued to struggle with recurrent depression. Conversely, children in the DC group were more delayed when their mother experienced recurrent depressive episodes. Specifically, among children whose mother had subsequent depressive episodes, there was nearly a

15-point difference in Verbal IQ favoring children in the intervention group (Cicchetti et al., 2000).

Taken in tandem, the efficacy of the TPP intervention in fostering attachment security, positive representational models, and normative cognitive development, even in the presence of ongoing maternal depression, underscores the criticality of providing prevention interventions for children of depressed mothers. The fact that more difficulties emerged over time among the offspring of mothers with subsequent depressive episodes further highlights the need for intervening preventively in the lives of these children. Without intervention, it is highly likely that the young offspring of mothers with MDD in the DI group, as appears to be the case with the youngsters in the DC group, would develop a depressive-typic organization that forebodes later maladaptation and possible depressive illness. It is important to note that the provision of TPP did not result in a reduction of maternal depression. Although not a surprising outcome, given the effects of recurrent depressive episodes on child development, further attention needs to be directed toward effectively treating MDD in mothers.

CONCLUSION AND FUTURE PERSPECTIVE

A central objective of this chapter has been to illustrate the essential role that a developmental psychopathology perspective can play in bridging the worlds of basic research and clinical practice. We invoked a number of the principles of developmental psychopathology to guide the research conducted in our laboratory on maltreated children and the offspring of mothers with MDD. We chose to focus on the research we carried out with infants, toddlers, and preschoolers from these high-risk conditions as exemplars of how research findings could be utilized to conduct and implement preventive interventions. Guided by an organizational perspective on development that informed the discoveries of our basic research, we demonstrated the efficacy of several randomized clinical trials with maltreated infants, toddlers, and preschoolers, as well as with the infant and toddler offspring of mothers with MDD.

The experimental nature of randomized clinical trials provides an unprecedented opportunity to make causal inferences in the field. Independent variables manipulated in prevention trials may be several steps removed from underlying etiologic factors because such trials are primarily concerned with alleviating suffering and

promoting competence. Nonetheless, careful research design and assiduous measurement of ancillary process variables through which intervention effects may occur can shed light on the theory-driven mechanisms underlying healthy and pathological outcomes (Cicchetti & Hinshaw, 2002; Kraemer, Stice, Kazdin, Offord, & Kupfer, 2001).

Recent initiatives at the National Institute of Mental Health, wherein funding decisions are tied to the real-world applications of research findings and to research capable of reducing the burden of mental illness, certainly will increasingly encourage investigators to devise and conduct investigations that break down the dualisms that exist between basic research and clinical intervention. In a report of the National Advisory Mental Health Council (2000, p. v) entitled *Translating Behavioral Science into Action*, the workgroup concluded that “too few researchers are attempting to bridge across basic, clinical, and services research, and not enough are working with colleagues in related allied disciplines to move research advances out of the laboratory and into clinical care, service delivery, and policy making.” In this report, “translational research is defined as research designed to address how basic behavioral processes inform the diagnosis, prevention, treatment, and delivery of services for mental illness and, conversely, how knowledge of mental illness increases our understanding of basic behavioral processes” (p. iii). This formulation of translational research is in direct accord with principles of developmental psychopathology—namely, the reciprocal interplay between basic and applied research and between normal and atypical development (Cicchetti & Toth, 1998b).

In recent years, developmental psychopathologists have advocated a multiple-levels-of-analysis approach to the investigation of maladaptation and psychopathology (Cicchetti & Blender, 2004; Cicchetti & Dawson, 2002). Thus, the examination of multiple systems, domains, and levels of the ecology on the same individuals is thought to eventuate in a more complete depiction of individual patterns of adaptation and maladaptation. We believe it is essential that this multiple-levels-of-analysis approach be adopted by scientists who are conducting randomized controlled clinical preventive intervention trials. For example, the inclusion of molecular genetic methods (e.g., sequencing DNA and utilizing functional polymorphisms to examine gene \times environment interactions), neuroimaging techniques (e.g., to investigate brain structure and function, pre- and postintervention), and stress-reactivity

paradigms (e.g., to ascertain whether neurobiological stress systems are modifiable as a result of treatment), in conjunction with psychological outcomes, will enhance the understanding of the impact of interventions on brain-behavior relations (see, e.g., Caspi et al., 2002, 2003; Cicchetti & Posner, 2005; Fishbein, 2000; Goldapple et al., 2004). Similarly, the incorporation of biological measures into the research armamentaria of researchers investigating pathways to competence in the presence of significant adversity, as well as the translation of this integrative research into resilience-promoting interventions that assess biological, psychological, and ecological variables, will contribute to greatly reducing the schisms that exist between research and practice (Cicchetti, 2003; Curtis & Cicchetti, 2003; Luthar & Cicchetti, 2000).

Given the substantial monetary investment in supporting both basic research with relevance to the understanding and treatment of mental illness and in randomized prevention and treatment trials, it is of paramount importance that the knowledge gained from such endeavors be transported into real-world contexts. Researchers must be advocates, not only for the scientific dissemination of knowledge, but also for reaching policymakers and clinicians who may lack the understanding or resources needed to provide interventions that have been found to be efficacious. It would be naive to suggest that impediments to implementing evidence-supported treatments in nonresearch settings do not exist. However, although efforts to traverse the path from the university laboratory to the clinical world may cause apprehension, avoidance, and resistance, such a journey must not be eschewed. Rather, as a field we need to embrace the diversity among us, equally welcoming potentially elucidating contributions from basic researchers and frontline professionals. Such collaborative endeavors and active efforts to improve the conduct and utilization of research and the scientific base of practice will benefit researchers, practitioners, policymakers, and, most important, children and families in need of support and treatment.

Ensuring the well-being of at-risk children through supportive assistance to their families is a powerful idea that has driven a substantial amount of early intervention research and program development activity. Since the early 1970s, a diverse set of interventions has been developed to help families promote positive child outcomes. Programs vary in the substantive focus of assistance to families, from parenting and child-rearing responsibilities, to family connections with community services, to job skills. Intervention methods may include home visiting, group sessions at a program center, and/or case management, sometimes provided in a concurrent or sequential arrangement with a center-based

I am grateful to Carolyn Pape Cowan, Philip A. Cowan, and Joan E. Grusec for thoughtful reviews of an earlier draft of this chapter; to Karen E. Diamond, K. Ann Renninger, and Irving E. Sigel for helping me shape the chapter's focus; and to James S. Bates for gathering material and reviewing successive drafts.

early childhood program. Staff who work directly with families may be professionals or paraprofessionals.

In spite of varied program efforts, the expectation that intervention with families will enable children to succeed in life has yet to be fully realized. Some interventions have produced short- and long-term positive effects; many other interventions have yielded weak effects, sometimes on a small number of outcomes, or no effects.

Reasons for the overall mixed picture of results have received limited attention in the scholarly literature. Reviews of early intervention research have tended to juxtapose direct work with the child versus the family in an attempt to identify the most beneficial approach. The problem with this analysis strategy is that it ignores issues of quality in intervention design, implementation, and evaluation. Discerning what seems to work and not work in approaches to families in early interventions requires respectful attention to variations in intervention design. Considerations of quality also necessitate a careful look at common problems in intervention re-

search: simplistic or poorly conceptualized program models, mismatches between program approach and population circumstances, inadequate implementation of a program model, and faulty research designs, including inappropriate and/or insensitive measures.

An increasingly common conclusion of analyses of the early intervention literature is that researchers need to look more carefully into the “black box” of programs to determine the process by which interventions contribute, or fall short of contributing, to improvements in children’s well-being (e.g., Brooks-Gunn, Berlin, & Fuligni, 2000; Gomby, Culross, & Behrman, 1999; National Research Council and Institute of Medicine, 2000). Accordingly, a closer examination of research on the role of families in early interventions holds promise of identifying factors and patterns that warrant attention in program design decisions and in future intervention research.

CHAPTER PURPOSE AND ORGANIZATION

The purpose of this chapter is to identify potentially critical characteristics of effective approaches to families in interventions aimed at enhancing the well-being of at-risk children from birth to 5 years of age. To this end, the chapter examines variations in the design of interventions with regard to programmatic elements of support to families (e.g., staffing, intensity) and different combinations of program content and participant roles. It also describes conceptual and empirical influences on program design and identifies needed directions in research aimed at discerning what works in the relation of families to early childhood interventions.

A premise of the chapter is that a major decision in the design and delivery of early childhood interventions is how much and what type of programmatic room to make for families. The issue is not a dichotomous matter of whether early interventions should include provisions for families. Even early interventions that seek to compensate for deficiencies in family functioning by providing a year-round, full-day educational program for young children include modest voluntary options for connecting with families. The current sociopolitical climate—particularly values underlying parental rights and respect for family cultures and traditions—ensures that, at a minimum, interventions will give rhetorical if not nominal attention to families.

Consistent with purposes of this volume, an assumption of the chapter is that readers have an interest in the

application of research to pressing societal problems. Most of the chapter is organized by program variables, and attention is given to issues in translating research to practice and in conducting intervention research.

After defining key terms and the literature included in this chapter, I describe in general terms how conceptualizations of families and empirical knowledge from developmental and intervention researches have shaped the development of family interventions. A goal of this section is to provide an orientation to substantive bases of intervention approaches to families. At the same time, the section acknowledges the limitations of the extant research literature and provides a case description of the process of applying conceptualizations of families and research knowledge to the development of practice guidelines for a federally sponsored family intervention program.

The chapter then moves to a major section on elements of program support to families with young children. The section is organized around seven areas requiring decisions in the design and implementation of family interventions. The variables examined here include leading candidates for indicators of quality in interventions with families. If the field eventually is successful in a search for what works in early intervention, the list of attributes of effective interventions with families likely will include some of the factors described here. This section partly addresses the chapter’s secondary interest in the translation of research to practice. It is organized by program variables and draws on developmental and intervention research literatures in an attempt to demonstrate the benefits of using findings from both types of investigations.

The section on elements of program support to families is followed by an examination of five basic designs of family interventions in early childhood. The designs are defined by the program participant status of parents (i.e., adjunct, supplementary, primary) and by the scope of program goals and content focused on family functioning (i.e., child- versus broad-focused). These two dimensions represent dominant perspectives on how best to achieve better outcomes for children at risk. Illustrative interventions are described in each of the five basic program designs, with attention to program content and methods, effects, and whether and how parent or family factors contribute to child outcomes.

The chapter’s concluding section identifies needed directions in family intervention program development

and research. Themes of this section emphasize intervention responsiveness to family circumstances and use of rigorous research methods in an incremental manner to determine effective intervention elements.

DEFINITIONAL AND LITERATURE PARAMETERS

Early intervention refers to *a broad array of activities designed to enhance a young child's development* (Ramey & Ramey, 1998, p. 110). These activities typically are provided through programs of early education and care, services aimed at promoting positive parenting and/or family functioning, and individualized developmental or therapeutic services. Individual programs provide activities in one or more of these areas through center- and/or home-based delivery systems.

There are two main literatures on early intervention, defined by population group: children considered to be at risk of developmental delay or academic difficulty, generally due to family economic or educational status, and children with identified disabilities or developmental delays. Programs serving the at-risk group tend to emphasize the prevention of negative outcomes, whereas interventions serving children with identified disabilities or delays typically are viewed as remediation or treatment programs (Ramey & Ramey, 1998).

Although the two literatures on early intervention are seldom combined, in practice the program and population boundaries are blurred. For example, early intervention for young children with identified disabilities and developmental delays supported by the federal Individuals with Disabilities Education Act may, at state discretion, provide supports to children judged to be at risk (e.g., multiproblem family). Head Start, conceived as a program for children at risk due to poverty, requires that a minimum of 10% of children have identified disabilities but does not impose a low-income requirement as a program eligibility criterion for children with disabilities. Families with children receiving early intervention services do not fall neatly into two groups. One recent study of state early intervention services for children with identified disabilities and developmental delays found that families of children with developmental delay had a median annual gross income just above the poverty level (Diamond & Kontos, 2004).

This chapter focuses primarily on early intervention for children deemed to be at risk of developmental delay

or academic difficulty. The risk indicators here generally include family socioeconomic status, adolescent parenthood, and premature and low birthweight status. In a modest step toward bridging the two early intervention literatures, the chapter also draws on research on early intervention for children with identified disabilities or developmental delays. Certainly there are issues unique to poverty and to disabilities that deserve careful attention in designing and understanding early intervention, and caution is needed with generalizations. At the same time, consideration of commonalities and differences in findings across the two literatures provides a stronger empirical base for contemplating advances in intervention design and delivery.

Because the parent-child dyad is of special interest to work with families in early intervention, the chapter gives specific attention to *parenting*. I use an adaptation of Bornstein's (2000) definition of parenting, particularly *direct effects on children of experiences that parents provide, including parents' beliefs and behaviors, and indirect effects which take place through parents' relationships with each other, the daily routines and objects (e.g., books) available in the home environment, and their connections to extrafamilial support systems*.

Due to space limitations, the chapter is based on early intervention research conducted in the United States. The international literature offers a rich comparative perspective on early childhood intervention (Boocock & Larner, 1998), including research on several family interventions similar to programs examined in the United States (e.g., Westheimer, 2003) and follow-up studies of intervention effects such as a recent set of longitudinal investigations sponsored by the Bernard van Leer Foundation (www.bernardvanleer.org).

INFLUENCES ON THE ROLE OF FAMILIES IN EARLY CHILDHOOD INTERVENTIONS

Approaches to families in early childhood interventions in the United States have been shaped by conceptualizations of families and the findings of research on interventions and on children's development in diverse family contexts. Each of these domains of influence is described here. To illustrate the contribution of these influences to intervention work with families, the section ends with a case description of the process through which a content framework was developed for the par-

enting education component of the federal Even Start Family Literacy Program.

Conceptualizations of Families

The form, substance, and process of approaches to family interventions may be traced to powerful ideas about family contributions to children's development, the contexts of family functioning, and family resourcefulness. Origins of these ideas include theory and research as well as sociopolitical developments, particularly growing population diversity in the United States, the Civil Rights movement, and the War on Poverty. Influential constructs are the object of critical commentary and periodic refinement, and, as noted in the following discussion, each of the prevalent perspectives on families is in transition as intervention programs yield information on the experiences of putting ideas into practice, scholars question the empirical base of prevailing assumptions, and social policies such as welfare reform shape family life.

Families as Developmental Contexts

Central to the early intervention field is the idea that families are a significant context of early development. For decades the notion that "families matter" has been bolstered by theories and scientific evidence pointing to the lasting impact of families on children's development and by research on the formative quality of the early years.

Results of research linking family variables to child outcomes do not necessarily lead to rationales for interventions aimed at changing and supporting families. Some scholars have concluded from the family effects literature that early intervention should compensate for, and seek to reduce, family deficiencies by placing the child in a high-quality early childhood program for most of the child's waking hours, preferably as early in life as possible. In extrapolations based on results of a longitudinal study of family language interactions and children's intellectual outcomes, for example, Hart and Risley (1995) estimated that children in families receiving welfare would need 41 hours per week of language-rich, out-of-home experiences per week from birth to equal the language experiences of children in average working-class families.

In contrast, other researchers have inferred from the family effects literature that a potentially more power-

ful and efficient way to improve child outcomes is to support family capacity to promote the healthy development of children. Early childhood interventions that include complementary or exclusive work with families are assumed to produce more powerful effects through enduring changes in parenting and other family processes than interventions that give minimal or no substantive attention to parents and other family members. An influential report by Bronfenbrenner (1974, p. 300) on effects of early intervention bolstered this argument with the conclusion that "without family involvement, intervention is likely to be unsuccessful, and what few effects are achieved are likely to disappear once the intervention is discontinued." This conclusion was based largely on findings of several intervention studies (e.g., Radin, 1972) indicating that parent participation in the intervention helped to sustain IQ gains after the program ended. Hence, the report reinforced the expectation of continuing support for improved child outcomes through enduring changes in families.

The merits of child- and family-oriented programs have long been debated in the early intervention literature (e.g., Zigler & Berman, 1983) and today remain an active area of empirical investigation (e.g., Barnett, Young, & Schweinhart, 1998; Reynolds, Ou, & Topitzes, 2004). At the core of this main feature of intervention design are theoretical differences in whether the primary locus of forces regulating developmental change is internal or external to the child or a product of interaction between internal and external forces (P. A. Cowan, Powell, & Cowan, 1998). Although treatments of this topic often dichotomize the issue as child-versus parent-focused intervention, in reality programs differ in the amount and type of attention given to parents. All theories of child development have assumed that laypersons need expert guidance in the rearing of young children (Kessen, 1979), and parent education has been viewed as a part of early childhood programs since the establishment of nursery schools in the United States in the early 1900s (D. R. Powell & Diamond, 1995). A major distinction across programs, then, is the extent to which intervention with the family is considered integral to achieving sustained positive effects on the child.

The magnitude of family effects on children—overstated at times in research, policy, and early intervention arenas—has been challenged vigorously since the mid-1990s (Rowe, 1994), notably in Harris's (1995,

1998) argument that parents have little or no influence on their children's outcomes. Her position has received considerable academic attention (e.g., Collins, Maccoby, Steinberg, Hetherington, & Bornstein, 2000; Okagaki & Luster, 2005), and it remains to be seen whether a "parents don't matter" perspective ultimately will influence early intervention approaches to families. For the short term, criticisms of the family effects literature have increased research interest in family interventions because interventions with parents are the best means available to social scientists for testing the magnitude of family effects on children (P. A. Cowan & Cowan, 2002), including Harris's (2002) argument that changes in child behavior via intervention in the home environment will not transfer to changes in a child's behavior at school or in other settings that do not involve the parent.

Families in Context

Since the mid-1970s, the early intervention field has been influenced by the idea that families are embedded in an interconnected system of formal and informal resources at neighborhood and community levels that vary dramatically in the provision of supports for individual and family well-being. Intervenors often communicate the essence of the developmental literature on contextualism by citing the African proverb "It takes a whole village to raise a child." The prominence of this idea has been advanced in part by societal interest in the consequences of a rapidly changing social landscape characterized by increases in single-parent households, mothers working outside the home, and the racial, ethnic, and linguistic diversity of families.

A major contribution of ecological perspectives to the early intervention field is increased awareness of population differences. *A priori* assumptions cannot be made that characteristics identified in one or several groups exist or function in the same way in another group (Lerner, 1998), and interventions found to be effective or ineffective with one population or context may have a different pattern of results with a different population or context. The notion that a particular program model or strategy can work with any family or parent has been replaced by questions about appropriate ways to achieve program responsiveness to family circumstances (D. R. Powell, 2005).

Theory and research on the ecology of human development also has expanded the content boundaries of intervention interest in family functioning. The popularity

of the "whole village" statement represents a broadening, and sometimes abandonment, of program models that assume the primary task with families is to provide information on child development and parenting. In addition to or in lieu of parenting education, interventions increasingly seek to strengthen a family's connections with its larger environment as a means of improving family support of positive child outcomes. One of four goals of the federal Early Head Start Program, for example, is community development, including improvements in child care quality, community collaboration, and the integration of supportive services to families (Love et al., 2002). Programs also may attempt to facilitate use of social support provided through informal sources such as family, friends, and neighbors (Dunst, 2000).

Many interventions targeted at low-income families take special interest in parents' economic self-sufficiency skills as a pathway to improved family functioning and child outcomes. To this end, programs provide services aimed at strengthening parents' employment-related skills as well as child development services that may include early childhood programs, parenting education, and preventive health care. Interventions adhering to this approach, commonly called two-generation programs (Smith & Zaslow, 1995), are congruent with welfare reform policies that require labor force participation and with changes in norms regarding women's roles in society.

Family interventions have encountered challenges in translating broad constructs about family contexts to the level of program design and implementation. A critical and unresolved matter is determining specific variables that can be efficiently and effectively targeted in myriad interrelated and powerful influences on the daily functioning of families living in poverty and other high-risk conditions. In recognition of the absence of a magic bullet, program designers have embraced the concept of comprehensive services to families but struggled with the availability, integration, and quality of existing services provided by different agencies operating under different categorical funding streams and assumptions about how best to support families (e.g., St. Pierre, Layzer, & Barnes, 1998). There is a risk of minimal or diffused focus on the child in social support interventions (Dunst, 2000) and limited clarity on how to substantively combine child- and family-oriented services (Mahoney et al., 1999). The field also has had to grapple with some naive expectations of the rapidity and ease by which education and employment-related services for

parents contribute to improved child outcomes (e.g., teach parents to read so they can read to their children).

Families as Resourceful

A third idea with growing influence on early intervention is that family strengths should be marshaled toward the optimal development of children and parents. The strengths-based concept is supported by scholarly work on the flow of social support in natural helping systems (Cohen, Underwood, & Gottlieb, 2000), the benefits of building on strengths in efforts to promote individual and family well-being (Trivette, Dunst, & Deal, 1997), and growing interest in the promotion of positive development in contrast to the customary focus on the treatment and prevention of negative outcomes (Lerner, Fisher, & Weinberg, 2000; Pollard & Rosenberg, 2003).

The “build on family strengths” idea is in part a backlash against early intervention assumptions and practices that emphasize family deficits. The early 1960s origins of intervention programs for children from low-income families were based on a view of limitations in family child-rearing practices, particularly in the area of language use with children, as the primary cause of low-income children’s school failures. A high level of optimism about the plasticity of human development during this era led to the expectation that early education programs could provide children with school readiness experiences missing in their home, thereby moving children to a more productive developmental trajectory in life. According to this view, readiness for school resides in the child, and inadequate mothering is an indirect cause of school failure. Early interventions built on these premises were deemed to be blatant forms of institutional racism (Baratz & Baratz, 1970), and policies and practices that imposed middle-class European American values and practices on other populations were harshly criticized (Laosa, 1983).

These criticisms plus the press of the Civil Rights movement and the War on Poverty led to an erosion of support for the deficit perspective beginning in the late 1960s. Significant in this paradigm change was seminal research such as Labov’s (1970) work on African American dialect and Heath’s (1983) study of language use in low-income communities and the success of teachers in building on cultural differences among children. There was prompt abandonment of the term “deficits” in the scholarly literature and an emphasis on “differences” in depictions of family and community language systems

(Vernon-Feagans, 1996) and in descriptions of child-rearing practices (Yando, Seitz, & Zigler, 1979).

Legislative actions in the 1960s and 1970s supported the principle that families have resources to contribute to intervention programs. The call for “maximum feasible participation” of families in programs supported by the Economic Opportunity Act of 1964 functioned as an impetus for Head Start’s eventual decisions on how to work with families (e.g., 51% of local policy council members are parents), and federal legislation included provisions for parental rights in decisions about a child’s educational placement and treatment plan. This occurred in the context of larger concerns about rapidly increasing professional involvement in functions and decisions historically handled by the family (Lasch, 1977), ethical concerns about professional manipulation of parents in intervention programs (Hess, 1980; Sigel, 1983), and whether the scientific base of child development was sufficiently rigorous and definitive to warrant professional edicts about how to rear young children (Cochran & Woolever, 1983), particularly in racial and ethnic minority families.

Current professional standards for early intervention reflect a view of families as resourceful contributors to program decisions and actions. The emphasis is on partnerships that promote family capacities and ensure shared decision making with program staff rather than view parents as helpmates in implementing program-determined agendas (D. R. Powell, 2001). Early intervention work with families is to focus on promotion (versus treatment), individuals exercising existing capabilities and developing new competencies (versus professionals solving problems for people), defining practice from a broad range of community resources (versus mostly or exclusively professional services), and programs as agents of families, responsive to family desires and concerns (versus professionals as experts who determine clients’ needs; Dunst & Trivette, 1997).

Evidence suggests there is a gap between principles and practice in the implementation of standards regarding program relationships with families. Studies point to limited attention to family outcomes and supports in individualized family service plans (e.g., McWilliam et al., 1998), for example. The emphasis on family resourcefulness has triggered clarifications of the roles of professionals in early interventions (Buysse & Wesley, 1993) and reconsiderations of professional preparation for working with families (McBride & Brotherson, 1997; D. R. Powell, 2000) as programs seek ways to

carry out a strengths-based approach. This situation in the early intervention field reflects conditions in a broader movement toward the promotion of child well-being wherein there is an upsurge of interest in policies and programs that promote positive outcomes, but considerable conceptual, methodological, and empirical work is needed (Moore & Keyes, 2003).

Empirical Knowledge

Prominent ideas about families provide intervention designers and staff with a common point of reference for work with families and an accessible language for communicating with policymakers and the lay public about intervention goals and practices. By themselves, however, big ideas generally offer insufficient guidance for fine-tuning the design and implementation of an intervention. Sound bite representations of basic constructs (e.g., “families matter”) may foster simplistic program assumptions and actions (e.g., “when the family is okay, the child is okay”). To add essential details, program designers and staff have long turned to professional knowledge or clinical judgment derived from accumulated experiences with a population and intervention modality (Shonkoff, 2000). To a lesser extent, they also have turned to empirical research as a source of information on family intervention design and implementation. The use of education and social science to inform practice is a complex and poorly understood topic (Shonkoff, 2000; Sigel, 1998), and family interventions in early childhood are no exception to a general pattern of limited or missing connections between research and design and implementation of education and human services.

Expansion of the early intervention field has occurred along several paths with regard to the role of empirical knowledge. One is the classical research and program development strategy wherein an intervention model is tested in a single or multiple sites and replicated in additional sites only after outcome data offer promise of positive effects. Another path is implementation of a program on a large-scale basis without the benefit of results from rigorous study of smaller-scale programs to guide staged or incremental expansion of the model (Yoshikawa, Rosman, & Hsueh, 2002).

With a few striking exceptions, our knowledge of causal relations regarding the role of families in early interventions is too limited to support widespread expansion and replication of most program models. Although the use of random assignment is growing in intervention

research, investigations designed to identify what works in early interventions—that is, studies with the greatest potential to inform program design and implementation decisions—generally have not used experimental designs. For instance, within-group comparisons are commonly used to determine whether intervention effects vary by population characteristics, sometimes in a post hoc search for *any* intervention effects (D. R. Powell, 2005). Moreover, randomized trials in intervention research commonly examine the effectiveness of a treatment variable that is actually a composite of many variables (e.g., curriculum, intensity, staffing), usually organized in a complex manner. In D. T. Campbell’s (1986) proposed renaming of *internal validity* with *local molar causal validity*, the word *molar* represented this multivariate quality of interventions. Results of experimental study of an intervention that, in essence, is an intervention package leave to speculation the identification of important elements of an intervention. Thus, interveners who adopt some but not all of an intervention run the risk of omitting a key attribute of the program package (Shadish, Cook, & Campbell, 2002).

Our understanding of family contributions to children’s development is also limited. Most of what is known about child-family context relations is derived from correlational studies. Because children cannot be randomly assigned to different environmental conditions, researchers have depended, sometimes brilliantly (e.g., effects of the Great Depression; Elder, 1974), on naturally occurring variations to examine links between child and environment. Self-selection is among the serious problems of this approach.

Further, growing interest in the role of context in child development and early intervention has accentuated issues in generalizing the results of developmental and intervention research. Three factors underlie this problem. One is the shallow level of empirical science on the diverse populations increasingly served by programs. Context and diversity have been addressed in theoretical work to a greater extent than in research, and existing research on group differences is often limited by insufficient attention to individual differences within groups and by overlaps among race, ethnicity, culture, and socioeconomic status (Garcia Coll & Magnuson, 2000). A second factor is that, as noted earlier, evidence pointing to population-specific links between child-rearing patterns and child outcomes raises questions about the need for population-specific intervention content. A small but impressive set of early intervention

models have had the opportunity to address external validity questions through consecutive randomized trials with different populations and contexts (Kitzman et al., 2000; Olds, Henderson, Chamberlin, & Tatelbaum, 1986; Olds et al., 2002) or implementation with a sufficient number of ethnically diverse families to permit analyses by population group (Reid, Webster-Stratton, & Beauchaine, 2001). A third factor is disagreements both in developmental and intervention research literatures regarding the extent to which universal knowledge is possible. Relativistic arguments that all developmental processes are culturally dependent (e.g., Shweder, 1993) or that interventions cannot be objectively defined (e.g., Olson, 2003) essentially imply that each intervention needs to invent itself.

An obvious consequence of this state of developmental and intervention research is that empirical science cannot be used to significantly help interventions act on some currently prominent ideas on how to work with families. One example is the growing interest in fathers. Research on father-child relationships across different contexts has matured in the past 2 decades (Lamb, 2003), but intervention research has not kept pace with increases in the range of programs and program components targeted at fathers (Mincy & Pouncy, 2002). Another example is the emphasis on family systems. References to families and to family systems dominate descriptions of early intervention understandings of children's developmental contexts, but family systems research is an emerging topic in the developmental sciences. The empirical literature on family effects is primarily about parenting and parent-child interactions and relationships (Parke & Buriel, 1998). Not surprisingly, most "family-oriented" program practices are a variant of parenting education generally aimed at mothers. A less obvious consequence of research limitations is that ethical problems arise when interveners fill data voids with information or advice to families that transcends the limits of empirical science or overstate the effectiveness of an intervention to participants and policymakers (P. A. Cowan et al., 1998).

Future generations of intervention programs may have the benefit of more and better information on causal relations in child-family interactions and intervention processes. Currently, there is strong emphasis on internal validity in experimental research. Influential reports recommend greater use of rigorous intervention studies to improve child outcomes (e.g., National Research Council, 2002; National Research Council and

Institute of Medicine, 2000), for example, and the federal government is shaping the dissemination of findings from research on replicable interventions within a "best practices" framework (e.g., the What Works Clearinghouse established by the Institute of Education Science).

More and better research data on context and diversity eventually may provide an empirical basis for determining what type of population-specific content is needed in interventions with particular populations. In time, a more robust database also may help shift the focus of existing debates about the utility of generalizations. A major task in generating a culturally sensitive approach to the study of child development is to strike a balance between cultural relativism and absolute universalism (Parke, 2004). In the absence of adequate research knowledge, a strategy of forming relationships with families that enable their idiosyncratic strengths to shape the intervention process is far superior to the risks of attempting to translate a limited database into intervention content (Brinker, 1992).

A certain level of local reinvention in the development of an intervention may be a necessary step as interveners actively learn the boundaries and details of their collective and individual work. Generalizations are broadband by definition and typically in need of fine-tuning in applications to particular contexts. Local data can play a complementary role here. For example, Neuman and her colleagues (Neuman, Hagedorn, Celano, & Daly, 1995) gathered data on African American adolescent mothers' beliefs about children's literacy development and used their findings, which emphasized within-group differences, to individualize the presentation of program content. As a complement to locally generated data and to the relatively small samples common to developmental research, national survey data on families and young children offer a potentially useful source of information to developers and implementers of intervention programs. One recent national survey, for example, found that nearly 80% of parents reported that grandparents lived within an hour's drive from their home, and 70% reported having many friends and relatives they can count on. These data appear to refute the typical portrayal of young families disconnected from family and friends due to geographic mobility (Halfon & McLearn, 2002).

A Case Illustration

In 1998, I was invited by the federal administrator responsible for the Even Start Family Literacy Program in

the U.S. Department of Education to develop guidance to local programs regarding the content and method of the parenting education component of the Even Start Program. The assignment was carried out in collaboration with Diane D'Angelo, a seasoned early childhood practitioner and senior staff member at the RMC Research Corporation, and resulted in a U.S. Department of Education publication (D. R. Powell & D'Angelo, 2000; see also D. R. Powell, 2004) widely distributed to Even Start Programs as well as numerous presentations at national and regional Even Start meetings. In essence, the assignment was an experiment in translating dominant conceptualizations of families and research on family literacy environments into concrete suggestions for programs on how to promote parenting that fosters early literacy development.

The Even Start Program was created as a demonstration program in 1988 through congressional action that called for the integration of early childhood, adult education, and parenting education into a program aimed at improving the literacy skills of all family members. Goals are to help parents become full partners in the education of their children, to assist children in reaching their full potential as learners, and to provide literacy training for their parents. Core services include early childhood education from birth to 8 years of age, adult education services that develop basic educational and literacy skills, parenting education, and joint parent-child activities focused on early literacy development. There is emphasis on programmatic integration of these core services, and families are expected to participate in all core services. To be eligible for program participation, a family must have an adult who is eligible for adult basic education and a child less than 8 years of age (St. Pierre & Swartz, 1995). The program was implemented in 76 sites in 1989, and by 1999 to 2000 had grown to more than 800 local projects.

Since the inception of Even Start, the parenting component has been a challenging aspect of the program for several reasons. One is that parenting education was defined in general terms in the legislation establishing Even Start, and programs have used a variety of commercial and locally developed curricula that generally focus on ages and stages of child development, often with little focused attention to early literacy development. Second, many Even Start Programs appeared to be staffing the parenting education component with individuals who had limited preparation for the role. In most

communities in the United States, the availability of qualified personnel to provide parenting education is severely restricted because there are few baccalaureate degree programs and certification programs in parenting education. In general, the field of parenting education is less well developed than the fields of adult education and early childhood education. There are no commonly accepted standards for parenting education; in contrast, there are highly regarded benchmarks of appropriate practice in early childhood education and in adult education. Third, across a range of programs, there have been reports of resistance from some parents to participate in parenting education (e.g., it is seen by some as a distraction from work toward the general equivalency diploma). An early national evaluation of Even Start indicated that the parenting education component was not one of the main appeals for participation. Although the anticipated results of the guidance on how the Even Start Program might improve its work with parents—a federal publication and series of conference presentations—could not be expected to significantly change this situation, the development of a conceptual framework on the role of parents in fostering children's literacy was viewed as an essential foundation for improving the Even Start parenting education component.

The guidance to programs was developed through a review of research literatures on family contributions to young children's early literacy development and early school success and on methods of parenting education; extensive consultation with family literacy program practitioners; visits to 12 local Even Start Programs for the purpose of observing promising practices in parenting education that might serve as illustrations to other programs; and feedback on early drafts of the guidance document provided by local Even Start Program staff, state coordinators of Even Start Programs, researchers familiar with the Even Start Program, and U.S. Department of Education officials.

Our first direct exposure to the challenges of finding common ground involving research-based guidance on family practices regarding early literacy and the diversity of prevailing approaches to parenting education in Even Start occurred in early consultations with practitioners about a goal statement for the parenting education component. We proposed a goal statement focused on children's literacy outcomes, in view of the larger literacy goals of the Even Start Family Literacy Program. This was well received by some practitioners but

deemed to be too narrow by others who viewed the parenting education component as appropriately addressing a wide range of content, including self-esteem, the “empowerment” of parents, and coping with the difficult contexts of poverty. The compromise was a goal statement fully focused on children’s literacy outcomes and content that embraces a range of topics coupled with suggestions that programs “begin where parents are” by initially engaging parents around content that seems most appropriate to their current circumstance (e.g., moved to a safer neighborhood) and eventually moving toward sustained focus on family practices that directly support children’s literacy development. The goal statement is as follows: “The overall goal of parenting education in Even Start Family Literacy Programs is to strengthen parents’ support of their young children’s literacy development and early school success” (D. R. Powell & D’Angelo, 2000, p. 5). The content is organized into five domains:

1. Engage in language-rich parent-child interactions.
2. Provide supports for literacy in the family.
3. Hold appropriate expectations of child’s learning and development.
4. Actively embrace the parenting role.
5. Form and maintain connections with community and other resources.

This compromise position initially was of concern to practitioners who wanted a report focused on a small set of specific family practices. Some Even Start Programs, for instance, promote the primary message “Read to your child,” and their representatives to the consultation process wanted the guidance document to focus exclusively on this message. Our description of studies indicating that shared book reading accounted for about 8% of the variance in children’s early reading abilities (e.g., Scarborough & Dobrich, 1994) often was met with disbelief. Further, our argument that research suggests there is not a silver bullet for school readiness, that many studies use composite measures of family literacy environment that make it impossible to identify specific practices or environmental conditions, and that other practices, including *how* to read with young children, should be emphasized in a guidance document typically was met with the response that program staff and parents may become confused with information on

too many family correlates of early literacy development. For these programs, content in the domain of “form and maintain connections with community and other resources” appeared to be viewed as social work, not parenting education. Further, our document did not communicate key practices through acronyms or key words found in some other research-based recommendations for parenting practices (e.g., Borkowski, Ramey, & Stile, 2002).

The literature review work also encountered the persistent issues of causality and generalizability noted in the prior section of this chapter. Our numerous consultations with practitioners made clear that prospective users of the program guidance work desired clear language about effects of family environments and parenting practices on children’s literacy outcomes. Practitioners noted, for instance, the extensive trade book literature on “10 steps to a brighter child” and indicated that, to ensure use of the guidance document, we would need to offer assurances that specific family conditions “produce” early school success, as commonly found in mass circulation periodicals and books. Our final report attempted to accommodate this situation through text that reflected the correlational nature of existing studies but a one-page summary chart that used a sentence-completion format beginning with the stem, “Parents strengthen their children’s literacy development and school-related competence when they . . .” (D. R. Powell & D’Angelo, 2000, p. 6). Although confined to one page, the chart entailed more sentence-completion bullets (17 in the five aforementioned domains) than some practitioners preferred, as noted earlier.

The generalizability issues we encountered in our work stemmed primarily from the limited amount of research on low-income and ethnic minority populations—the Even Start target population—regarding family factors associated with children’s literacy outcomes. Most of the research on family literacy environments focuses on parents (typically mothers), not family variables, in middle-class European American populations. Although research on parenting seems compatible with the goal of developing guidance for a parenting education component, it would be far preferable to speak to family factors in a program that seeks to serve the entire family.

Responses to these issues in the field of family literacy programs illustrate possible implications for the content of work with families in early interventions. By

design, family literacy programs typically serve families with adult members who have limited levels of education and income and often are English-language learners relatively new to the United States.

The fact that the extant research literature on family contributions to children's literacy development generally does not represent populations that family interventions typically serve has generated a range of responses in the family literacy program field (D. R. Powell, Okagaki, & Bojczyk, 2004). At one end of a continuum are rationales for sharing with lower-income, ethnic minority families what we know from research on how primarily middle-class European American families successfully support children's early reading success. At the approximate midpoint are programs that seek to learn about and accommodate the interests and preferences of culturally diverse parents, while promoting practices known to foster children's literacy development in middle-class European American families. At the other end are programs organized exclusively around and within the sociocultural contexts of participants. The family support field has many historical and contemporary examples of programs that assume "the most valid and useful knowledge about the rearing of children is lodged among the people . . . rather than in the heads of college professors, trained professionals, or the books written by so-called experts" (Cochran & Woolever, 1983, p. 229). Clearly, this is a field with strikingly different perspectives on family resourcefulness.

In our consultations for development of the Even Start guide, practitioners who saw value in sharing results of existing research saw no difficulty with our plan to develop a conceptual framework based on the extant literature. For those adhering to a sociocultural perspective on family literacy, however, there was a high level of concern about a guide based heavily on research involving middle-class populations. There was specific criticism of the design and results of the aforementioned Hart and Risley (1995) study, which appeared to command a high level of receptive attention in the Department of Education at the time of our work. Some practitioners took issue with the Hart and Risley comparisons of professional, working-class, and welfare families, arguing that the language environments of low-income families had distinctive qualities not appreciated by mainstream society and that schools and other institutions needed to accommodate diverse family culture rather than expect families to change their interaction styles to accommodate schools. This is a familiar argument, of course, yet the final draft of the guide endorsed a perspective that all parties involved in

the schooling enterprise, including schools and families, share joint responsibility for children's learning. Further, the guidance document's emphasis on responsiveness to cultural diversity addressed specific program practices that, based on our visits to program sites, might facilitate fuller participation of adults from diverse families in program services. For instance, we found that in many programs, the preschool component's curriculum emphasis on "follow the child's lead" in teaching practices was also carried out in the parent-child interaction time component of the program. Yet, our observations suggested that in programs strongly adhering to this approach, some parents (e.g., Latinas) appeared to view the concept as a foreign idea, apparently preferring that adults, not children, take the lead in directing the learning interaction. In contrast, programs subscribing to a more adult-led approach seemed to have a higher level of parent participation during the parent-child literacy interaction time. Our report's suggestion that programs remain flexible and responsive in their approaches to the adult-child interaction time, because not all parent populations appear to see value in the "follow the child's lead" philosophy, was controversial among practitioners expressing support for a child-centered curriculum and opposition to adult-directed learning experiences.

In many ways, development of the guidance document was a goodness-of-fit journey that entailed negotiated understandings of how programs make use of the strengths and limitations of existing research and work with what families bring to program settings. The consultation process and site visits introduced us to numerous program assumptions, often unspoken yet fully evident in program services, and our greatest challenges occurred when our understanding of the extant research literature conflicted with prevailing program ideas and practices. Because research is far from definitive in this arena, we found it appropriate and useful to organize and communicate research results through a focus on general principles and illustrative practices rather than prescriptions for practice. Perhaps the most important contribution of the guidance document is clarity on outcome (children's literacy development).

ELEMENTS OF PROGRAMMATIC SUPPORT TO FAMILIES

The design and implementation of family interventions require decisions in the following seven areas: content,

participants, delivery format, intensity, staffing, targeting and recruiting families, and host agency supports for program implementation. Each of these areas may be viewed as a program lever for supporting family contributions to children's growth and development.

In this section, research on families and child development and on early intervention work with families is reviewed selectively in each of the seven program design and implementation areas to highlight options in determining the substance and form of program connections with families. The focus of many early childhood intervention studies was broadened in the mid-1980s to include questions about "what works" and "what works for whom," in addition to customary attention to program effects (Guralnick, 1997; Korfsmacher, 2001; D. R. Powell, 2005). The current yield of searches for what works in early interventions is promising but insufficiently robust to offer a list of indicators of quality in intervention work with families. Accordingly, the treatment of the seven program design and implementation areas does not offer a summary of best practices.

The family and child development studies noted briefly and selectively emphasize research trends worthy of consideration in intervention design decisions. It is well beyond the scope of this chapter to summarize the family and child development research literature relevant to the specific populations and developmental domains that particular interventions address.

Distinctions between basic and applied research are increasingly blurred, if not artificial, and intervention research has considerable potential to contribute to our understanding of person-context relations in child development (P. A. Cowan & Cowan, 2002; Lerner, 1998). An intent of organizing this section by key attributes of interventions versus by type of research literatures is to demonstrate the utility of building on coordinated use of developmental and intervention researches to formulate decisions about program design and implementation aimed at improving children's well-being.

Content

A common answer to the question of what information to share with families is to use an early childhood classroom curriculum as the content base of work with families. For programs where children participate in an early childhood classroom, a presumed advantage of this strategy is curriculum continuity: Classroom activities and experiences are extended to and reinforced in the home.

A potential limitation of this arrangement is that the program does not engage a family on its own terms. That is, content may not build on unique contributions of families to children's development, including parents' goals for their children. Research on educational outcomes has long recognized the distinctive influences of families and schools on children's educational attainment (e.g., Coleman et al., 1966), and qualitative differences between parenting and teaching have been set forth theoretically (Katz, 1980). In this vein, a premise of some interventions is that learning at home is often incidental to other ongoing activities (Neuman, 1999) and that suggestions for new parent and child behaviors need to be woven into daily family routines. For interventions seeking to develop or tailor content around family research literature, the four domains of knowledge described next offer implications for program content decisions.

Early Development in Context

A starting point for decisions about the content of work with families in early intervention programs is research on family processes associated with children's development. This literature offers a broad domain of possible content for early intervention work with families, but historically interventions have narrowed their interest in families to parenting. A result is program messages about the importance of parent responsiveness, monitoring, mentoring, and modeling (Borkowski et al., 2002). Parenting is only one dimension of family processes, and, although it is an appropriate way for interveners to think about and connect with families, intervention attention to parenting may be more appropriately situated in the dynamic network of factors that affect children's development.

Research on structural dimensions of families (e.g., one-parent households) and child development has been of interest to interventions in terms of understanding how variables such as household composition might moderate program effects (e.g., Cole, Kitzman, Olds, & Sidora, 1998), but in general, family configuration has been viewed as an ethically inappropriate target of change in early interventions. Currently, this stance is being challenged by prominent initiatives and calls for the promotion of marriage (e.g., Waite & Gallagher, 2000) in federal policies and in social programs such as Head Start.

Research on racial, ethnic, and cultural contexts of family processes and child development is crucial to decisions about the content of early intervention work with

families because family child-rearing beliefs and practices are embedded in these contexts (McLoyd, 1998) and because families served by early intervention increasingly represent backgrounds other than European American, although intervention staff often are European American. There is a growing literature on the child-rearing practices and concerns of different population groups, including African American, Latino, Native American, and Asian American (e.g., Parke & Buriel, 1998) and some evidence to suggest that links between parenting practices and child outcomes differ by population group. For example, mothers' reported use of harsh physical discipline has been found to be associated with a higher frequency of children's externalizing behavior problems in school for European American children but not for African American children (Deater-Deckard, Dodge, Bates, & Pettit, 1996), and ethnic group differences have been found in the relation of parents' expectations and beliefs to children's school achievement (Okagaki & Frensch, 1998).

Economic resources and parent education level are similarly influential contextual variables that often are confounded with race and ethnicity. Studies of socioeconomic status (SES) and child development outcomes are especially helpful to decisions about intervention design when results shed light on causal mechanisms by which SES influences family processes and children's outcomes (Duncan, Brooks-Gunn, Yeung, & Smith, 1998; Lerner, 2003) and when attention is given to within-group differences such as cumulative effects of stress when living in poverty (e.g., Evans, 2004; McLoyd, 1998).

At a minimum, research on population group differences in family processes and child development can be used in a due diligence effort to inform intervention staff *in general terms* about the population it seeks to serve. This is a first and critical step toward developing the cross-cultural competence of interveners (Hanson, 1992; Yutrzenka, 1995). Essential understandings here include traditional child-rearing values and practices as well as collective historical experiences such as the Native American boarding school movement (Harjo, 1993). Research on acculturation and assimilation experiences, including bicultural adaptation, is especially useful to interventions such as family literacy programs serving populations that are new to the United States and/or to mainstream systems. In addition to generating a population profile, research findings suggestive of population-

specific links between child-rearing practices and child outcomes imply a need for population-specific content in interventions with families. There has been movement in this direction in the parenting education field for African American and Latino families, but methodological limitations of existing evaluations limit our understanding of the effectiveness of these efforts (Cheng Gorman & Balter, 1997).

Family child-rearing processes are also influenced by person variables such as maternal depression (e.g., Embry & Dawson, 2002) and child temperament (e.g., Kochanska, 1997). Research on effects of a child disability on families suggests that there is increased risk of divorce and financial pressures, and indirect negative consequences for siblings (e.g., Hogan & Msall, 2002). Studies of the role of person variables in family processes, particularly bidirectional influences, can be used to inform intervention content that helps family members appropriately respond to the person characteristics of concern. Interventions that formulate goals and content around parent variables such as depression need to decide whether changes in the targeted variable provide a direct pathway to improved child outcomes or desired changes in the targeted parent variable are the first of several steps toward improved child outcomes (e.g., first improve relationship skills, then increase child-rearing knowledge and skills; Booth, Mitchell, Barnard, & Spieker, 1989).

Relationships as Developmental Contexts

One clear trend in child development research is the focus on interpersonal relationships as developmental contexts. Bowlby's (1969) attachment theory offers a substantive foundation of this orientation, and corresponding research now transcends the social-emotional domain generally pursued in attachment studies. For example, in a study of mother-child joint book reading, Bus and van IJzendoorn (1988) found that securely attached dyads paid more attention to reading instruction and engaged in more proto-reading, there was less need to discipline, and children were less distracted than in anxiously attached dyads. A relationships perspective on early development and learning suggests that the content of interventions with families should be framed within dyadic and other family relationships. Guidance on how to read with young children, for example, should account for the interpersonal context in which the reading takes place.

Early intervention work with families typically deals with the mother-child dyad, often independent of a family system that likely includes many other subsystems, including father-child, child-sibling, marital/partner, sibling-parent, and extended kith and kin systems. Theoretical models of linkages among family subsystems (e.g., Luster & Okagaki, 1993; Parke & Buriel, 1998) and of a family systems approach to parenting interventions (C. P. Cowan et al., 1985; P. A. Cowan et al., 1998) have been developed. However, other than research on the direct and indirect relationships of the marital/partner subsystem quality to child outcomes (e.g., Cummings, Goeke-Morey, & Graham, 2002), studies to date neither specify the pathways through which different family subsystems exert their influence (Parke & Buriel, 1998) nor clarify the relative weight of parent-child relationships versus other family relationships in relation to child outcomes (Parke & O'Neil, 1997). Thus, currently there is a limited empirical basis for early interventions to generate specific content that recognizes the embeddedness of the child and parent-child relationships within a system of family influences.

Individual and Family Support Systems

Another program content decision stemming from ecological perspectives on child and family development is how early interventions address social supports for family members, including a parent's life course goals such as additional schooling or employment. Generally, intervention actions aimed at improving family support systems are viewed as requisite to improved individual or family functioning so that focused work eventually can be pursued with child development content.

Intervention attention to individual and family support systems can require considerable staff time and energy (e.g., enrolling a parent in an adult education program most likely will require arrangements for transportation and child care) and is a major undertaking with families living in high-stress circumstances. Home visitors often report that a family's pressing life circumstances take precedence over a program's child development content; for example, "If a mother isn't making it financially, and she's just had a fight with her boyfriend, and he's just split, there ain't no way I can just say to her, 'okay, let's you and I go play a game with the child'" (Mindick, 1986, p. 83).

Interventions run the risk of having no impact on child outcomes if pressing family matters dominate program

work with families. An early example of this point is the Child and Family Resource Program, a family-oriented early intervention that gave minimal attention to parenting and child development content with parents in part because family crises occupied the joint agenda of intervener and family. The intervention improved some aspects of adult functioning but had no effects on child outcomes (Travers, Irwin, & Nauta, 1981; Travers, Nauta, & Irwin, 1982). There appears to be no intervention research evidence to support the idea that improvements in the provision of social supports is a direct pathway to improved child outcomes. A meta-analysis of 88 preventive interventions focused on enhancing parental sensitivity and infant attachment found that interventions with a clear-cut behavioral focus on parental sensitivity were more effective than interventions with a broader content focus that included attention to social support and parents' mental representations as well as parental sensitivity (Bakermans-Kranenburg, van IJzendoorn, & Juffer, 2003).

A major content decision in this domain is the specific focus of attempts to improve supports for individual and family functioning. One option is a mediator role, such as case management aimed at strengthening links with informal and formal resources. The intervener's work here entails referral to needed services and, in some cases, active involvement in ensuring that services are accessed (e.g., driving a family member to a clinic appointment) and are responsive to a family's circumstance (e.g., finding an agency staff person who speaks the family's language). A concurrent or alternative option is to train parents in skills related to effective development and use of support resources (e.g., problem-solving skills; Wasik, Bryant, Lyons, Sparling, & Ramey, 1997).

Family Members' Views of Their Situation

Because early intervention programs generally focus on proximal processes involving the child and family, and not distal contexts, research that increases our understanding of how families make sense of, navigate, and help shape their ecological niches can be especially useful. Studies that link family child-rearing practices to prevailing understandings and beliefs within different types of families may be particularly useful in helping interveners anticipate how to approach the introduction of a program or given topic to families. Parents and other primary caregivers are not blank slates. They filter, edit,

and process program information in relation to existing constructs, goals, pressing issues (Goodnow, 2000; D. R. Powell, 1988), and perhaps the views of one or more influential others who may not be visibly involved in the intervention.

The ways family members act on their perceptions of the larger environment are one route by which context influences child rearing. Interventions that focus on content independent of family members' ideas about the world they and their children live in may "take us only along part of the road" toward improved child outcomes (Goodnow, 2000, p. 441). For example, research on strategies used by families to buffer their children from violence in a high-risk African American neighborhood illustrates how mothers' danger management efforts (e.g., monitoring, cautionary warnings, in-home learning, resource brokering) serve as intervening processes that mediate effects of community conditions on family functioning and outcomes (Jarrett & Jefferson, 2003, 2004).

Participants

There is a limited but growing body of research to inform program decisions about what members of a family or household should be encouraged to participate in a family intervention. An early experimental study on this topic regarding adult family members, conducted with well-educated European Americans to determine the effectiveness of newborn interventions, employed the Brazeltown Neonatal Behavioral Assessment Scale as a tool for influencing parental behavior. The study found short-term positive effects on mothers and fathers who jointly participated in the intervention (versus mother participating without the baby's father) and who were highly engaged in the intervention (Belsky, 1986). With higher-risk populations, household composition (i.e., whether a new mother lives alone or with her partner or the baby's grandmother; Cole et al., 1998) and mothers' perceived quality of her partner's support (i.e., communicate clearly, express affection, low levels of hostility; Heinicke et al., 1998) have been found to moderate intervention outcomes. A meta-analysis of interventions aimed at improving either parental sensitivity or infant attachment or both found that interventions involving fathers were more effective than interventions focusing on mothers only, but the analysis included a small number of interventions targeting fathers (Bakermans-Kranenburg et al., 2003). More generally, it appears that effects of

planned variation in the joint participation of parent and significant other(s) in an intervention have not been examined in higher-risk populations.

The growing research literature on fathers and child development, coupled with societal concern about the limits or absence of father contributions to child rearing and other family functions, has accelerated intervention attention to fathers, as noted earlier. Many families involved in family interventions differ from the modal family type that developmentalists have examined in father-child relationship studies (Marsiglio, Amato, Day, & Lamb, 2000). Intervenors face challenges of determining which fathers to involve in a program when more than one man plays a fathering role in a child's life (e.g., nonresident biological father, a resident stepfather, a grandfather or other male relative; Roggman, Fitzgerald, Bradley, & Raikes, 2002). Program staff also need to recognize the benefits and problems of adapting methods that work with mothers in approaches to fathers (Roggman et al., 2002), a nuance perhaps connected to the finding that mature programs are more likely than newer programs to involve fathers (Raikes, Summers, & Roggman, 2005). The gatekeeping role of women in nonresident fathers' and stepfathers' relationships with their children also needs attention in program designs and actions (Raikes et al., 2005).

A major implication and challenge of viewing relationships as developmental contexts is to establish productive connections with the important relationship systems in a family. The customary practice is for intervention staff to develop separate relationships with each member of a family dyad or triad. Certainly the intervener's relationship with the parent or primary caregiver, typically the priority relationship in interventions, is valuable in its own right and a point of access to the family. But what may be more important is how the intervener manages his or her relationship to the parent-child relationship (Emde & Robinson, 2000) and to the partner relationship (C. P. Cowan, Cowan, & Heming, 2005).

Format

Discussion groups and home visits have rich histories of use in early childhood interventions that reflect different assumptions about how best to facilitate growth and change in families, specifically the peer learning and support presumed to exist in discussion groups and the tailoring to family circumstances afforded in home vis-

its (Bryant & Wasik, 2004). An early quasi-experimental study found that long-term peer discussion groups produced stronger effects on maternal child-rearing attitudes than home visits (Slaughter, 1983), and a meta-analysis of 665 studies of 260 family support programs, 98% of which offered parenting education, found that parent groups produced stronger effects on child outcomes than home visiting (Layzer, Goodson, Bernstein, & Price, 2001). The average effect sizes for parent groups as the primary method of delivering education were .54 when targeted to children at biological risk and .27 when used with nontargeted populations, compared to average effect sizes for home visiting of .36 when targeted to children at biological risk and .09 when used with nontargeted populations. Perhaps program effectiveness increases when the unique strengths of home- and group-based methods are maximized sequentially or concurrently. A 17-site study of the Early Head Start Program found that a combination of center-based and home-based methods yielded a stronger pattern of effects on children's language and social-emotional development and on parents' behavior and participation in self-sufficiency activities (i.e., job training) than center-based or home-based strategies alone (Love et al., 2002).

High expectations of positive results of home visiting were prominently reduced in 1999 when a widely distributed David and Lucile Packard Foundation publication on results of evaluations of six nationally visible home visiting models recommended that policymakers and practitioners maintain modest expectations of home visiting and consider including home visiting as one of a range of services offered to families with young children (Gomby et al., 1999).

Decisions about the use of groups and/or home visits need to recognize that these are delivery systems, not programs, and existing studies of groups and home visits do not control for other important program features (e.g., content, pedagogical approach, frequency, child presence) that program designers need to consider in concert with program delivery methods.

Intensity

A prevailing assumption in the early childhood intervention field is that more is better, and lackluster findings of early intervention work with families are often attributed to insufficient levels of program intensity. Intensity has four dimensions: the frequency of contact with a fam-

ily; the length or duration of an intervention; the point at which an intervention begins working with a family, generally defined by child age (timing); and the extent to which participants are actively engaged in a program.

Frequency

Experimental research on the relation of frequency of intervention contact with families to child outcomes is exceptionally limited (for a review, see D. R. Powell, 2005). Within-group analyses of dose-response relationships in early childhood interventions involving parents typically find that higher levels of participation are associated with stronger program effects (e.g., Ramey et al., 1992). The chief problem of dose-response correlational analyses is the lack of control for population characteristics. Research by C. Powell and Grantham-McGregor (1989) in Jamaica apparently is the only published investigation that systematically varied levels of program frequency. However, this two-study contribution is limited because random assignment to different frequencies of home visiting (twice a month, once a month, control condition) was by neighborhood area (not family) in Study 1. In Study 2, families in a different sample were randomly assigned to either weekly home visits or a control condition. Results of separate analyses for Study 1 and Study 2 indicate that bimonthly visits had a small influence on children's developmental functioning and that there were significant developmental improvements in children in families receiving weekly home visits compared to children in the control group.

Duration

Research on the length of intervention work with families generally has the same population confounds as within-group analyses of the frequency of contact. An additional methodological problem in studies of intervention duration is the high rate of participant attrition. Among the families randomly assigned to the intervention group in one three-site study of a parent-oriented home visiting program, for example, 22% never began any visits and 35% received some visits but dropped out by the year 2 assessment. Attrition was so high in two of the three study sites that the evaluation of the planned 3-year program was discontinued at the end of the second year (Wagner, Spiker, & Linn, 2002). The Bakermans-Kranenburg et al. (2003) meta-analysis found that interventions with fewer than five sessions were as effective (effect size = .42) as interventions with 5 to 16 sessions (effect size = .38), but interventions with more than 16

sessions were less effective (effect size = .21) than interventions with a smaller number of sessions. Follow-up outcome data were not considered in this analysis.

Studies indicating that positive effects of preschool interventions on IQ fade over time (Barnett, 1995; Consortium for Longitudinal Studies, 1983) have led to interest in follow-up interventions in elementary school. Effects of a home-school intervention were examined in a randomized study of the Abecedarian Project, an early intervention program beginning in infancy (Ramey, Dorval, & Baker-Ward, 1983; the infancy/preschool phase of the Abecedarian Project is described in the section on Approaches to Families in Early Interventions). Participants in the infancy/preschool intervention were randomly assigned to a K-2 educational support program at kindergarten entry. This yielded three intervention groups: preschool and K-2 educational support intervention, early intervention only, and K-2 educational support intervention only; a control group was also added. The K-2 educational support intervention consisted of a home-school resource teacher for each child and the child's family. The teachers prepared an individualized set of home activities to supplement the school's basic curriculum in reading and math; they helped families secure such community services as decent housing or adult literacy classes, and they were advocates for the child and family within the school and community.

The K-2 educational support intervention by itself was not as effective as the preschool condition or the preschool plus K-2 educational support condition in increasing school performance, although it did increase parental involvement in their child's education. Follow-up research when children were 15 years old found that the preschool-only condition had a positive effect on grade retention, and both the preschool-only condition and the preschool plus K-2 educational support condition, but not the K-2 educational support-only condition, had positive effects on reading and math performance (Ramey, Ramey, Lanzi, & Cotton, 2002). Intervention effects on reading performance were particularly strong. The effect sizes for the preschool plus K-2 educational support condition and the preschool-only condition were .87 and .53, respectively, but was under .15 for the K-2 educational support-only condition and the control condition (Ramey et al., 2000). Interestingly, between 36% and 48% of children in the intervention conditions involving the K-2 educational support also were placed in special education, perhaps because the home-school resource teachers were special educators

who sought out special education services they believed would be helpful to a child (Ramey et al., 2002).

A follow-up assessment when study participants were 21 years of age found that the school-age intervention helped to maintain preschool benefits for reading, but the effects of the school-age component were weaker than those of the preschool program (Campbell, Ramey, Pungello, Sparling, & Johnson, 2002).

A study of the Abecedarian children's experiences in elementary school found that children had difficulty meeting teachers' expectations of a "middle-class way with words" and that teachers had difficulty responding to the distinctive nature of the Abecedarian children's incorrect answers to questions (Vernon-Feagans, 1996, p. 210). There is anecdotal evidence that public ridicule of individual performance and marginalized status contributed to a loss of interest in school (e.g., an older boy in the Abecedarian community told one of the Abecedarian kindergarteners, "See, Melvin, you stop likin to go to school when you get there"; Vernon-Feagans, 1996, p. 205). Abecedarian children were assigned to low-ability groups even when child ability data such as IQ scores (e.g., 130) indicated that a higher placement would be appropriate. Vernon-Feagans identified the Abecedarian children's low-income African American status as a factor in how school personnel viewed and accommodated nonmainstream children and argues for reforms that would enable schools to be ready for all children.

Timing

A companion to the "more is better" assumption in the early intervention field is the "earlier is better" perspective, driven largely by a view of the earliest years of life as a critical developmental period. Although this premise has been disputed in recent years (e.g., Bruer, 1999), there is scant intervention research to guide decisions about the timing of work with families. In the Bakermans-Kranenburg et al. (2003) meta-analysis of interventions focused on parental sensitivity and infant attachment security, interventions starting 6 months after birth or later were somewhat more effective (effect size = .44) than interventions starting prenatally or within the first 6 months of life (effect size = .28).

Level and Type of Engagement

Intervention methods vary in the extent to which they encourage an active level of participant engagement. For example, presumably, an intervention that includes guided discussion with a program participant about his

or her observed behavior is more intense than a didactic presentation of information that entails no tailoring of content to a participant or involvement of a participant in discussion of the content.

Research suggests that participants' active engagement of program content is predictive of outcomes. Liaw, Meisels, and Brooks-Gunn (1995) found that parent and child active experience in an intervention (i.e., parent's interest in the intervention activities during the home visit and child's mastery of tasks taught at the child development center) were stronger predictors of child IQ and quality of home environment scores at age 3 years than program exposure (i.e., number of contacts in home and child development center) and rate of participation (i.e., number of activities presented per visit to parent in the home or per day to the child at the center). A higher level of active experience on the part of both child and parent was more strongly associated with child IQ and home environment quality than a high level of active experience on the part of the child only or the parent only. In another intervention study, the rate at which a curriculum emphasizing adult-child interactions was implemented in home visits and in the child development center added significantly to the prediction of children's IQ scores at 3 years of age (Sparling et al., 1991). An implication of these findings is that interventions may need to give attention to staff practices (e.g., individualization of content) that are likely to support active engagement of an intervention.

Intervention staff often model desired parenting practices, although little is known about the effectiveness of this pedagogical strategy. One qualitative study of a home visiting program found that parents were not always aware that the home visitor was modeling appropriate practices for the parent (Hebbeler & Gerlach-Downie, 2002). Videotaped demonstrations of appropriate practices, found to be effective in parent training for families with conduct-problem children (Webster-Stratton, 1990; Webster-Stratton, Kolpacoff, & Hollinsworth, 1988), are a promising tool. Videotapes of recommended joint book reading practices were found to be more effective than live demonstrations of recommended practices, perhaps because mothers featured in the videotapes were more similar to the demographic characteristics of the intervention participants than the staff person conducting the live demonstration (Arnold, Lonigan, Whitehurst, & Epstein, 1994).

Constructive feedback to individuals based on observations of their parenting behaviors is another interven-

tion method for which there is limited evidence on effectiveness. Coaching adolescent mothers to use labeling, scaffolding, and contingent responsivity in literacy-focused social interactions with their preschool-age children is an illustration of this intervention method (Neuman & Gallagher, 1994). Some interventions videotape parent-child interaction for use in a guided discussion with the parent about parent and child behaviors. A meta-analysis of interventions focused on parental sensitivity and infant attachment security found that interventions with video feedback were more effective (effect size = .44) than interventions without this method (effect size = .31; Bakermans-Kranenburg et al., 2003).

There is some evidence to suggest that the quality of relationship between intervener and family is predictive of intervention outcomes. In an intervention involving nurses as home visitors, a positive relation between nurses' empathy (i.e., trust, understanding, acceptance) toward their client-mothers and the mothers' empathy toward their child was found for mothers with higher levels of psychological resources (e.g., emotional well-being; Korfmacher, Kitzman, & Olds, 1998). In a different intervention also involving nurses as home visitors, therapeutic relationships with mothers that included demonstrations of ways to handle family relationships and problems were found to be effective with mothers with limited social skills (Booth et al., 1989). A review of early family intervention studies in which the relationship between the family and the intervener was viewed as central to intervention outcomes points to positive intervention effects on maternal functioning and quality of family and community support (Heinicke & Ponce, 1999). Many of the interventions included in the Heinecke and Ponce review were represented in the Bakermans-Kranenburg et al. (2003) meta-analysis, which found that randomized interventions were effective in changing insensitive parenting (effect size = .33) and, to a lesser extent, infant attachment insecurity (effect size = .20). With few exceptions (e.g., Arnold et al., 1994), experimental designs have not been employed in research on different methods of working with parents or families.

Staffing

Paraprofessionals have been employed most commonly as staff responsible for direct work with families in early childhood interventions. They are generally selected on the basis of their existing ties to local residents

and their ability to establish a strong interpersonal relationship with program participants. Paraprofessionals are expected to provide a high level of personal credibility that aids in recruiting and retaining hard-to-reach families, facilitates parent acceptance of the program, and enhances their effectiveness as a role model for parents (D. R. Powell, 1993). Evaluations of some home-based (Wagner & Clayton, 1999) and group-based (Miller, 1988) interventions staffed by paraprofessionals have produced weak or no positive effects, but the studies do not make clear whether results were a function of the maturity of the program model or the abilities of paraprofessionals.

A randomized trial of a home visiting program model with first-time, low-income mothers in Denver addressed the question of whether paraprofessionals can produce positive results in a well-developed program found to be effective when delivered by professionals (Olds et al., 2002). Results indicated that, when trained in the Nurse-Family Partnership model (previously known as the Nurse Home Visiting Program), paraprofessionals produced small effects that rarely achieved statistical or clinical significance. Nurses produced significant effects on a wide range of maternal and child outcomes. For most outcomes on which either paraprofessionals or nurses produced significant effects, the paraprofessionals typically had effects that were about half the size of those produced by nurses.

Olds and his colleagues (2002) speculate that, from a family's perspective, nurses may have higher levels of legitimacy than paraprofessionals to address concerns about pregnancy complications, labor and delivery, and the care of newborns, and thus may have more power to engage parents and support adaptive behavior change. In their study, nurses spent more time focused on personal health and parenting issues, and paraprofessionals devoted more time to topics related to environmental health and safety. Mothers' ratings of the helping relationship did not differ between nurses and paraprofessionals (Korfmacher, O'Brien, Hiatt, & Olds, 1999). Generalization of the Olds et al. findings is limited to programs serving first-time, low-income mothers with a program model focused on health issues. The study leaves open the question of whether there would be different outcomes if paraprofessionals were trained and supported in a program model uniquely suited to their backgrounds and abilities (Korfmacher, 2001).

Reports from other home visiting interventions indicate that lay home visitors may have special difficulty systematically addressing parenting behaviors, finding

it easier to provide material support such as transportation to a clinic appointment, and may avoid discussing sensitive issues faced by families (e.g., adolescent pregnancy) that are also a part of the paraprofessional's life history (Musick & Stott, 2000). Also, a cost-benefit analysis indicates that the amount of training and professional supervision of paraprofessionals has a tendency to erase any economic benefit of employing paraprofessionals (Harkavy & Bond, 1992). This indirectly raises questions about how the quality of supervision of intervention staff contributes to overall program quality and effects.

Targeting and Recruiting Families

There is long-standing concern that the families most likely to benefit from an intervention program may be the least likely to participate. Problems of and strategies for recruiting hard-to-reach families are persistent topics in the field. Most reports identify personal contact as superior to flyers and other impersonal methods of contacting prospective participants. Few intervention studies have addressed the question of who accepts and who declines the invitation to participate (McCurdy & Daro, 2001). A multisite study of Hawaii's Healthy Start Program, a home visiting intervention that serves families identified through screening at birth as highly stressed and/or at risk for child abuse, found that of 897 families offered the possibility of program enrollment, 82% agreed to enroll. Initial willingness to participate was associated with the method of assessment (i.e., odds of accepting the program were twice as great for mothers assessed in person than by telephone), infant biologic risk (i.e., low birthweight, premature), overall score on a measure of family stress, and maternal age and education (i.e., adolescent mothers who had not finished high school were 2.5 times more likely to enroll than adult mothers with a high school education; Duggan et al., 2000).

Agreeing to participate is not to be confused with actually participating. In a multisite study of the Parents as Teachers program, for example, one in five families who initially agreed to enrollment did not subsequently participate in a home visit (Wagner, Spiker, Linn, Gerlach-Downie, & Hernandez, 2003). As noted earlier, attrition rates are typically high in interventions serving at-risk populations. In the model home visiting programs included in the Packard Foundation publication, 20% to 67% of families enrolled in the programs departed before the programs were scheduled to end (Gomby et al.,

1999), a pattern found in childhood intervention research spanning several decades. Whether there is differential attrition is largely unanswered.

Population characteristics have been found to predict level of program participation. Families in the Hawaii Healthy Start Program were more likely to have had at least 12 home visits in the 1st year if the father was violent, substance abusing, and at extremely high risk; if the mother did not use violence unilaterally as a means of dealing with conflict with her partner; and if the mother was not at extremely high risk (Duggan et al., 2000; Duggan et al., 1999). In contrast, a study of the Oregon Healthy Start Program found that mothers were significantly less likely to actively engage in home visits when living in a county that displayed poor community health (i.e., high infant death rate, low birthweight rate) or when isolated from immediate family and friendship networks (McGuigan, Katzev, & Pratt, 2003). A study of psychological characteristics of parents as predictors of patterns of participation in an Early Head Start Program found that mothers who entered the program with a lower sense of mastery, more difficult attitudes toward relationships, and more stressful life events were likely to be classified as superficially engaged in the program (i.e., high frequency of attendance but low engagement in terms of perceived levels of interest and attentiveness; Robinson et al., 2002).

With regard to program outcomes, results of a number of investigations suggest that higher-risk mothers and their children benefit more from early childhood interventions than lower-risk populations. The risk indicators examined in various studies include education level (Brooks-Gunn, Gross, Kraemer, Spiker, & Shapiro, 1997), mother's sense of control over her life (Olds et al., 1986), psychological resources (Olds, Henderson, et al., 1998), social skills (Booth et al., 1989), depression (Lyons-Ruth, Connell, Grunebaum, & Botein, 1990), and mental health risks (Baydar, Reid, & Webster-Stratton, 2003).

Studies indicating that early interventions with families are more effective with higher-risk than with lower-risk populations raise questions about the merits of targeting specific populations. Research on this topic is limited, although programs have pursued various strategies. One option is to use screening data to target higher-risk samples for a program (e.g., Duggan et al., 2000) or, within a universal program, to determine the level of needed services (Daro & Harding, 1999). The reliability and validity of screening tools is critical to these types of practices. Some argue speculatively that

when programs are offered to all parents (e.g., Head Start participants) in a nonstigmatizing manner, higher-risk parents in fact participate and that the inclusion of lower-risk parents in heterogeneous groups enhances program effects on higher-risk parents by providing positive parenting models (Baydar et al., 2003). Another option in a universal intervention is to enhance program supports for higher-risk families. For example, Robinson et al. (2002) studied parents' psychological characteristics of predictors of participation in Early Head Start, conducted as a collaboration between researchers and program staff. Findings led staff to strengthen attention to mental health factors in in-service staff trainings and to supplement the information gathering at the enrollment point with brief assessments of psychological characteristics of mothers that would provide anticipatory guidance to home visitors (e.g., use patience and persistence with a woman with many life stressors and a low sense of mastery who might express few signals of seeking a relationship but in fact may be in need of support).

Supports for Program Implementation

Developers of early interventions have long suggested that program delivery systems, including the host agency and community supports for the program, affect the quality of program implementation (e.g., Weikart, Bond, & McNeil, 1978). There is now a fledgling body of research on program implementation that holds promise of eventually offering guidance on conditions associated with successful implementation of an intervention. This information is particularly needed to inform decisions about taking model programs to scale.

Organizational cultures and capacities appear to shape the ways a host agency carries out an early intervention. A study of the implementation of the Early Head Start Program found that agency experiences in providing services to families and to infants and toddlers prior to becoming an Early Head Start Program were linked to the ease with which Early Head Start components were fully implemented. For example, staff in some agencies with experience in providing parent and family support programs initially resisted the Early Head Start focus on child development services (Kisker, Paulsell, Love, & Raikes, 2002). In a three-site study of the Hawaii Healthy Start Program, Duggan and her colleagues (1999, 2000) found significant differences across agencies in program implementation. The agency with the lowest family retention rate viewed the entire family more than the target child as its primary client,

and home visitors were likely to honor family wishes about program participation and focus on more receptive families. The two agencies with higher family retention rates reportedly expected that many at-risk families would be reluctant to participate in home visiting and regarded outreach to an isolated family, for instance, as more important than honoring a family's inclination to be left alone. Home visitors in these two agencies persisted in contacting families by telephone and in person, whereas staff in the agency with low retention rates were advised to send a letter to a reluctant family offering a final chance to participate.

APPROACHES TO FAMILIES IN EARLY INTERVENTION: FIVE BASIC PROGRAM DESIGNS

A premise of this chapter is that considerations of the merits of family interventions require a finer-grained examination of intervention components and processes than is generally provided in the literature. This section describes five basic program designs, defined by the parent's role (adjunct, supplementary, primary) and by whether intervention goals and content aimed at adult family members emphasize child rearing or a broader set of family functions that include child rearing as well as domains such as economic self-sufficiency and use of educational, human, and health services. Key distinctions across the five intervention designs are depicted in Table 14.1.

Participant role and program goals and content, essentially the *who* and *what* dimensions of intervention design, capture conceptual differences in program assumptions about how best to achieve better outcomes for children at risk. The approaches represent contrasting theories of change (Weiss, 1995) regarding pathways of influence or causal linkages within interventions.

In early interventions where the parent is in an adjunct or supplementary role in a program serving children directly, the hypothesized mechanism by which an intervention influences child well-being typically emphasizes strengthening the child's knowledge or skills, such as cognitive ability. This initial boost in ability is expected to expand into further abilities and corresponding outcomes, sometimes called a Matthew effect (e.g., Stanovich, 1986). With regard to the family in this arrangement, the child may be viewed as a mediator of change in parents' behaviors or cognitions (e.g., asking for storybooks to be read at home as at preschool). The

TABLE 14.1 Approaches to Families in Early Childhood Interventions: Five Basic Program Designs

Program Design	Targeted Participant		Targeted Family Function	
	Child	Parent	Child Rearing	Other ^a
Parent is adjunct to child program (e.g., Abecedarian Project)			X	
Parent is supplementary to child program (e.g., Perry Preschool Project)	X	X	X	
Parent is primary participant: child-focused content (e.g., Parents as Teachers)			X	X
Parent is primary participant: broad-focused content (e.g., Nurse-Family Partnership)			X	X
Parent and child are primary participants (e.g., Even Start Family Literacy)	X	X	X	X

^aFor example, family use of educational, human, and health services; parent job skills; parent problem-solving skills.

intervention also may supplement its direct work with the child by regularly conducting home visits or group meetings; these are hypothesized to add value to the child program by providing families with skills and encouragement to reinforce the child's gains during and after child participation in the program.

In interventions where the parent is the sole primary participant, the prevailing hypothesis is that direct, regular work with the parent(s) will lead to changes in parent behaviors, including parent-child interaction, which in turn will improve child outcomes that are sustained over time due to ongoing family support. The content of intervention with the parent may focus primarily on the child-rearing role or a broader set of family functions.

Hypothesized pathways are more complex in interventions where both parent and child are primary participants. The substance of direct work with the parent(s) may be a hypothesized link to both child and parent outcomes. Intervention aimed at improving a parent's problem-solving skills, for instance, may assume that improved problem-solving skills will enable parents to more effectively cope with daily situations and enhance overall parental well-being, which may directly

and perhaps indirectly increase the likelihood of positive parent-child relationships (Wasik, Bryant, Lyons, et al., 1997). The timing of intersections among pathways of influence is an important consideration because the focus of direct work with the parent(s) often is a prerequisite to positive influence on the child (e.g., teaching a parent to read so the parent can in turn help the child learn to read).

Although multiple paths of intervention effects are inherent in interventions that cast both parent and child as primary participants, note that more than one hypothesized mediator of intervention effects may be embraced in child-oriented and parent-oriented program designs. With few exceptions (e.g., Reynolds et al., 2004), most intervention research has examined one model of causal linkages, generally focused on child ability.

The discussion follows the order of intervention designs listed in Table 14.1, beginning with interventions in which the parent is adjunct or supplementary to a child program and ending with the most complicated of intervention designs, where both parent and child are primary participants and a range of family functions is addressed. Some preliminary hypotheses about program design are offered at the end of the section.

The interventions described in this section were selected for purposes of illustrating different combinations of program content and status of parent participants. The section does not offer an inclusive or exhaustive review of family interventions and thus does not provide conclusions about intervention effectiveness or design. Most, but not all, of these interventions were developed in the field of early childhood intervention. They were targeted at lower-income families and evaluated with an experimental or strong quasi-experimental research design, often in more than one research site.

Parent as Adjunct to Child Program

It is rare to find an early childhood intervention that does not include some programmatic attention to families because, as noted in this chapter's introduction, early childhood education has a tradition of viewing parents as partners in supporting a young child's development. There is considerable variation in how programs act on the partnership idea, however (D. R. Powell, 2001). Of interest here are early interventions that approach work with families as adjunct to the primary mission of working with the child. These child-focused programs typically provide occasional opportunities for parents to be involved in the program and encourage but do not require

parent participation. Program provisions for parent participation generally follow recommendations of the National Association for the Education of Young Children (NAEYC) for establishing reciprocal relationships with families, including frequent, two-way communication with children's parents; parent participation in decisions about their children's care and education; teacher respect for parents' child-rearing preferences and concerns; family involvement in assessing and planning for individual children; and program assistance in linking families to a range of community services (Bredekamp & Copple, 1997).

Program Approaches

The preschool phase of the Abecedarian Project, begun in 1972 at the Frank Porter Graham Child Development Center at the University of North Carolina, illustrates the ways supportive services may be offered to families in a child-centered intervention. The home-school educational support phase of the Abecedarian Project beginning in kindergarten was described previously. The project was designed to determine whether an educationally focused full-day child care program beginning in infancy could prevent nonorganically caused mild mental retardation in children from high-risk families (Ramey et al., 1983). Families were selected on the basis of scores on an index of factors indicative of risk for school failure. The families were mostly low-income and African American. They were matched on high-risk scores and maternal IQ, and then pair members were randomly assigned to either the intervention group or the control group. Four cohorts of approximately 28 children were selected for the study over a 5-year period (Ramey et al., 1983), resulting in an enrolled sample of 111 children (57 experimental, 54 control).

The center-based educational program for children was year-round (50 weeks), 5 days a week for up to 8 hours a day. Children began attending the center as young as 6 weeks of age; 98% of the children had begun by age 3 months. The program focused on skills that would enhance children's abilities to succeed in the public schools. Primary emphasis was on cognitive and language development. The program used the Learninggames curriculum for infants and toddlers, comprising more than 300 items in language, motor, social, and cognitive areas (Sparling & Lewis, 1979). Experiences were tailored to the developmental status of individual children, and teachers maintained a developmental chart for each child to help provide an appropriate match between child functioning and curriculum items. The curriculum beginning

at age 3 years emphasized active child functioning and independence with systematic exposure to science, math, and music (Ramey et al., 1983).

Program provisions for establishing and maintaining relationships with parents included many of the practices now recommended by NAEYC. There were regular parent-teacher conferences focused on the child's growth and development and scheduled group discussions on a range of topics related to family and child development. Vans transported children between home and the center, and, although "there was no formal parent involvement or home visiting component to the intervention," many of the center staff had strong ties to the African American community and families served by the program (Vernon-Feagans, 1996, p. 80). Project social workers also were available to provide direct and indirect assistance with housing, social services, and counseling on personal and family matters (Ramey & Ramey, 1992; Ramey et al., 2002). The social work services, also available to families in the control group (Ramey et al., 2002), were provided upon request (Ramey et al., 1983, p. 87). Published reports that provide the most information regarding Abecedarian effects on parents do not indicate the extent to which experimental and control group parents made use of these services, or how frequently experimental group parents participated in meetings and communications with teachers at the center (Ramey et al., 1983; Ramey & Ramey, 1992; Ramey et al., 2002).

Effects

Outcome data indicate that the Abecedarian intervention prevented intellectual decline during the preschool period (Ramey & Campbell, 1984). A subgroup analysis of 13 children of retarded mothers found that intervention effects were greatest for children of mothers with IQ below 70 (Martin, Ramey, & Ramey, 1990).

No differences between experimental and control group mothers were found in child-rearing attitudes when infants were 6 and 18 months of age, and in mothers' locus of control when infants were 3 months old (Ramey et al., 1983). When children were 20 months of age, analyses of videotaped mother-child interaction in a laboratory indicated that experimental group infants were communicating with their mothers at a significantly higher level than control group infants. Experimental group infants were equivalent to infants in a middle-class comparison sample (nonrandomized) in "requesting" behaviors (O'Connell & Farran, 1980 cited in Ramey et al., 1983). At 36 months of age, infants in the experimental

group were four times as likely to attempt to modify their mother's behavior (e.g., ask mother to watch their activity, read them a book) than control group infants, and mutual play activities involving mother and child lasted twice as long for mother-child dyads in the experimental group (Farran & Haskins, 1977 cited in Ramey et al., 1983). It appears, then, that children in the Abecedarian child development center presented different demand characteristics when interacting with their mother and thus may have affected the quality of mother-child interaction by their ability to bring out the best in caregivers (Ramey et al., 2002). There were no differences between experimental and control group families in the quality of the home environment at 54 months (Ramey et al., 1983).

A pattern of positive intervention effects on reading and math performance was found when children were assessed at 8 and 12 years of age (F. A. Campbell & Ramey, 1994, 1995). As reported earlier in this chapter, follow-up research when children were 15 years of age found that the preschool intervention had a positive effect on grade retention (Ramey et al., 2002). Also at the 15-year follow-up, 12% of children in the preschool-only group compared to 48% in the control group had been placed in special education during the 10 years they attended school (Ramey et al., 2000).

At 21 years of age, participants in the preschool intervention earned significantly higher scores on intellectual and academic measures, attained significantly more years of total education, were more likely to attend a 4-year college, and showed a reduction in teenage pregnancy compared to participants in the control group (Campbell et al., 2002). Preschool cognitive gains accounted for a substantial portion of intervention differences in the development of reading and math skills from age 3 to 21 years (Campbell, Pungello, Miller-Johnson, Burchinal, & Ramey, 2001).

Follow-up results suggest that the early childhood program enabled mothers to continue their education. Experimental group mothers had significantly higher education levels (11.9 years) than control group mothers (10.3 years) when their children were 54 months of age despite the fact that the levels of education were comparable (10.30 for experimental and 10.12 for control) at the time of their child's birth (Ramey, 1980). Also, more control group mothers were unemployed or engaged in unskilled employment than experimental mothers, and experimental group mothers held more semiskilled or skilled jobs than control group mothers (Ramey et al., 1983). Adolescent parents seemed to benefit the most. At the time of

kindergarten entry, 46% of teenage mothers in the intervention group had graduated from high school and obtained postsecondary training compared to 13% in the control group (F. A. Campbell, Breitmayer, & Ramey, 1986). This pattern continued at follow-up. When children were 15 years of age, 80% of teenage mothers whose children had participated in the preschool intervention compared to 28% of comparable control mothers had attained a postsecondary education. Rates of employment were highest (92%) for teenage mothers in the experimental group and lowest (66%) for teenage mothers in the control group (Ramey et al., 2000).

Parent as Supplementary to Child Program

Early interventions that view parents as supplementary participants require or expect regular involvement in program provisions for parents. This level of frequency is in contrast to occasional opportunities for parent participation characterized by the adjunct role. Regular, supplemental work with parents is expected to add value to intervention effects achieved through direct work with the child. Child-rearing issues typically are the focus of work with parents, although, in keeping with NAEYC standards (Bredekamp & Copple, 1997), it is common for programs to also facilitate access to health, education, and social services when needed, generally through referrals. In this type of program design, a distinction across interventions is whether the content of work with parents primarily addresses a single child-rearing domain (e.g., cognitive development) or multiple child-rearing domains. Each of these two content approaches is discussed next, beginning with interventions that address multiple child-rearing domains in work with parents.

Multiple Child-Rearing Domains

The Perry Preschool Project, launched in 1962 in Ypsilanti, Michigan, is arguably the best-known investigation of the effects of early childhood education on low-income children. The experimental study has gained visibility in policy and early childhood practitioner circles for its follow-up findings regarding real-world variables (e.g., income, criminal behavior, home ownership) at age 27 years (Schweinhart, Barnes, Weikart, Barnett, & Epstein, 1993) and 40 years (Schweinhart et al., 2005) and for its cost-benefit analyses (e.g., Barnett, 1996).

Less well-known is the targeted focus on parents in the Perry Preschool Project: Mothers received weekly

home visits lasting about 90 minutes from their child's preschool teacher aimed at involving mothers in providing educational support at home and extending school activities on an individual basis. For each home visit, teachers offered materials (e.g., puppets, clay, art materials) that were conducive to involving the mother and were tailored to areas where a child might need extra work. Informal discussions with the mother about child-rearing practices and the child's preparation for school were viewed as an important part of each home visit. There also were periodic group meetings with content planned in collaboration with parents (mostly mothers) and focused on child-rearing practices (Weikart, Rogers, Adcock, & McClelland, 1971).

The Chicago Child-Parent Center Program represents a second illustration of an early childhood program design in which parents are important supplementary participants. This large-scale program provides educational services to economically disadvantaged children and their parents from preschool to early elementary school, ages 3 through 9 years. It was established in 1967 through funding from the federal Elementary and Secondary Education Act of 1965 (Title 1). The half-day preschool and half-day or full-day kindergarten classrooms emphasize language arts and math through relatively structured experiences offered in a range of settings (e.g., large group, small group, individualized activities).

The parent involvement program in the Chicago Child-Parent Centers is more intensive than what was offered in the Perry Preschool Project. Parent involvement in the Chicago program is expected to promote children's school readiness and school adjustment via enhanced parent-child interactions, parent and child participation in school, and social support among parents. During preschool and kindergarten years, parents were required to participate at least one-half day per week, although average participation rates were lower. Parent participation was expected but not required in the primary grades. A parent room, located adjacent to the children's preschool and kindergarten classrooms and staffed by a full-time parent resource teacher, was a core part of the intervention's work with parents. Parent room activities include participation in parent reading groups, craft projects, and workshops on child development. Other avenues for parent involvement included classroom volunteering, home visits, participation in high school coursework, and parent-teacher conferences and other school meetings.

A full-time staff person responsible for outreach services to families, including referral to health and social service agencies, is located at each center. The outreach worker meets with each family at the beginning of the year and additional visits occur as needed (Reynolds, 2000). Compared to nonparticipants, participants in the Perry Preschool Project experimental group at age 27 years had significantly higher monthly earnings, rates of home ownership, and level of schooling completed, and significantly lower percentages receiving social services at some time in the previous 10 years and fewer arrests (Schweinhart et al., 1993). At age 40 years, adults who had participated in the preschool program had higher earnings, were more likely to hold a job, had committed fewer crimes, and were more likely to have graduated from high school than adults who did not participate in a preschool program (Schweinhart et al., in press).

Long-term effects of the Chicago Child-Parent Centers were examined with a quasi-experimental design involving 1,539 children who participated in the intervention in 1983 to 1989: an intervention group that received the services from ages 3 through 9 years, as described earlier, and a comparison group of children who participated in alternative full-day kindergartens. Results indicated that children who participated in the preschool intervention for 1 or 2 years had a higher rate of high school completion, more years of completed education, and lower rates of school dropout by age 20 years, and lower rates of juvenile arrest, violent arrests, grade retention, and special education placement by age 18 years. The largest gains in educational attainment occurred for boys in the intervention (Reynolds, Temple, Robertson, & Mann, 2001).

Did these interventions have an influence on parents? To what extent did parents mediate intervention effects on children? Follow-up data in the Perry Preschool Project when children were in fourth grade suggested that the experimental mothers had more developmentally supportive child-rearing attitudes but not behaviors than control mothers (Weikart et al., 1978). At age 15 years, more experimental group mothers than control group mothers were satisfied with their child's school performance, and experimental group mothers had higher educational aspirations for their child than control group mothers (Schweinhart & Weikart, 1980). Data were not collected from parents in follow-up studies when study participants were 19, 27, and 40 years of age. In the Chicago Child-Parent Program, parent data were collected when children were 10

to 12 years of age. Parents of program children were more likely than parents of children in the comparison group to have higher educational expectations for their children, higher rates of satisfaction with their children's education, and higher levels of involvement in school activities (Reynolds, 2000).

Perry Preschool Study researchers have consistently emphasized children's intellectual performance in causal models of how preschool participation influences subsequent outcomes, including adult functioning (Barnett et al., 1998; Schweinhart et al., 1993, in press). In models designed to explain preschool program effects at 27 years (Barnett et al., 1998; Schweinhart et al., 1993) and 40 years (Schweinhart et al., in press), preschool experience directly improves early childhood intellectual performance, the gateway to all subsequent intervention effects. Family variables are not included in the models except in relation to entry-level socioeconomic status predictors of intellectual performance. Analyses conducted when children were in fourth grade indicated that the home environment was a more powerful predictor of achievement and school success in the control group than in the experimental group, prompting the investigators to suggest that the intervention reduced the effects of the home environment on the acquisition of academic skills (Weikart et al., 1978).

The limited attention to intervention effects on parents in the Perry Preschool analyses leaves open important questions about the contribution of parents to children's outcomes (Zigler & Seitz, 1993). In a secondary analysis of the Perry Preschool data that combined experimental and control groups, there was a mixed pattern of links between family variables and children's subsequent achievement. For example, maternal involvement in kindergarten was predictive of children's competence and adjustment in kindergarten. However, for male youth during adolescence, there was a negative relationship between how often parents contacted teachers on their own and level of education attained by the child, perhaps because contact with the school was due to concern about student performance. Mothers who were identified by their child as role models at the 27-year follow-up were significantly more involved in their child's school at kindergarten than mothers who were not selected by their children as role models. Children's cognitive competence and academic motivation in kindergarten were more strongly predictive of subsequent achievement and educational attainment (Luster & McAdoo, 1996).

Reynolds et al. (2004) analyzed different mechanisms or pathways through which the Chicago Child-Parent Centers had long-term effects on educational attainment by age 20 and juvenile delinquency by age 18. They found that the primary mediators of effects for both outcomes were literacy skills in kindergarten and avoidance of grade retention (cognitive advantage), parent involvement in elementary school (when children were between 8 and 12 years of age) and avoidance of child maltreatment (family support), and attendance in high-quality elementary schools and lower number of school moves (school support). The model accounted for 58% of preschool links with school completion and 79% of preschool links with juvenile arrest.

Single Child-Rearing Domain

Research on two interventions related to different aspects of child functioning illustrates the benefits of focused attention to a specific domain of child development through educational work with parents and enhanced teacher practices in existing preschool classrooms. The studies also offer indirect evidence regarding the merits of intervention with parents alone versus intervention with parents in combination with curriculum enhancements in a center-based early childhood program.

The first study deals with preventive interventions focused on child conduct problems. In a study involving Head Start Programs, Webster-Stratton (1998) found that a short-term training program offered to all parents (regardless of whether their child had behavior problems) contributed to significant improvements in parenting interactions with children, reductions in children's negative behaviors, and increases in prosocial behaviors for children of parents who participated in the training program compared to children of comparison group parents. There were no significant intervention effects on children's negative behaviors at school, however.

Webster-Stratton and her colleagues (Webster-Stratton, Reid, & Hammond, 2001) hypothesized that an intervention involving parent training combined with in-depth parallel training for teachers in classroom management skills would result in reduced conduct problems and greater social competence at both school and home. In a study involving 14 Head Start centers (36 classes) that were randomly assigned to either an experimental condition or a control condition, a 12-week parent training program offered to all parents and delivered through weekly parent group meetings was combined with 6 monthly 1-day workshops (i.e., 36 hours of training) for

teachers in classrooms in the intervention condition. Parent training topics included playing with your child, using praise and encouragement to bring out the best in your child, effective limit setting, and handling misbehavior. Parents viewed videotapes of modeled parenting skills and engaged in a focused group discussion after viewing each 2-minute vignette. The teacher training workshop topics included strengthening student social skills, using incentives to motivate students with behavior problems, and handling misbehavior using effective limit setting, ignoring, time-out, and other strategies. Teachers watched and discussed videotapes of other classroom teachers.

Following the 12-session weekly parent program, experimental mothers had significantly lower negative parenting and significantly higher positive parenting scores than control mothers. Experimental children showed significantly fewer conduct problems at school than control children, and children of mothers who attended six or more intervention sessions showed significantly fewer conduct problems at home than children in the control group. At the end of training, experimental teachers exhibited significantly better classroom management skills than control teachers. Experimental effects were maintained 1 year later for parents who attended more than six parent group trainings (Webster-Stratton et al., 2001).

A comparison of the Webster-Stratton (1998) and Webster-Stratton et al. (2001) findings indirectly suggests that if behavior is to be changed in a particular setting (i.e., home, school), intervention focused on the targeted behavior is needed within the setting of interest. Intervention with parents contributed to changes in children's behaviors at home but not in the Head Start classrooms, whereas intervention both with teachers and parents led to changes in children's behaviors both at home and at school.

Children's early reading abilities are the focus of the second example of an intervention involving concurrent training of parents and teachers. The intervention is the dialogic reading program developed by Whitehurst and colleagues (Whitehurst, Arnold, et al., 1994; Whitehurst, Epstein, et al., 1994; Whitehurst et al., 1988). This program promotes the child's active participation in adult-child shared book reading by shifting the adult's typical role of storyteller to the role of active listener, asking questions, adding information, and prompting the child to increase the sophistication of descriptions of material in the picture book.

In a study of the effects of dialogic reading with low-income children, Whitehurst, Arnold, et al. (1994) randomly assigned children attending publicly subsidized child care centers to one of two intervention conditions or a control condition. In one intervention condition, children were read to by their parents at home and by their child care teachers in small groups of no more than five children. In the second intervention condition, children were read to by their child care teachers in the small group format. A videotape training method (Arnold et al., 1994) was used to train teachers and parents in dialogic reading. Children in both intervention groups experienced significant increases in oral language skills compared to children in the control group at the end of the 6-week intervention, and these gains were maintained on a 6-month follow-up assessment. Children who were read to by both teachers and parents had larger gains than children who were read to by teachers only (Whitehurst, Arnold, et al., 1994).

In a subsequent investigation, Lonigan and Whitehurst (1998) extended the design of the Whitehurst, Arnold, et al. (1994) study by adding a third intervention group where only parents read to their children using the dialogic reading approach. The intent of the Lonigan and Whitehurst experiment was to determine the relative effectiveness of parents versus teachers in implementing dialogic reading. Four child care centers serving mainly families eligible for subsidized child care participated in the study; children were randomly assigned to one of the four study conditions, and teachers and parents in the respective intervention conditions participated in videotape training in dialogic reading methods as carried out in the Whitehurst, Arnold, et al. study. Results of the Lonigan and Whitehurst investigation indicated that at the end of the 6-week intervention, each of the intervention conditions had a significant effect on oral language skills; effects were largest in the two intervention conditions involving home reading. The investigators speculate that a one-on-one reading context provided by parents may be more conducive to a child's active participation in shared reading than the group format most commonly used in classrooms.

Parent as Primary Participant

As noted in the introduction to this chapter, the idea that families are central to achieving meaningful change in children's outcomes has led many designers of early intervention programs to view work with par-

ents in adjunct or supplementary roles in child-focused interventions to be an insufficient influence on families. A better program design, some argue, is to support families through intensive intervention with the parent. Two types of parent-focused interventions are considered next, one with a content emphasis on family child-rearing environments and one with a content emphasis on a broader range of family functions.

Child-Focused Content

Early childhood intervention via parenting education and support has been an active part of the early intervention field since the 1960s. Early efforts in this area include the Florida Parent Education Infant and Toddler Program (Gordon, Guinagh, & Jester, 1977), the Mother-Child Home Program (Levenstein, 1977, 1988), and the Early Training Project (Klaus & Gray, 1968). Later interventions targeted adolescent mothers (e.g., Field, Widmayer, Greenberg, & Stoller, 1982; Osofsky, Culp, & Ware, 1988) and parents of children with disabilities (e.g., Brassell & Dunst, 1978). There also is a rich tradition of family interventions that seek to change antisocial behavior in children through behavioral parent training (e.g., Serketich & Dumas, 1996).

Program Approaches. The Parents as Teachers (PAT) Program is one prominent model representative of this tradition. It was founded in 1981 as the New Parents as Teachers Program by Mildred Winter (Vartuli & Winter, 1989), with program content originally based on Burton White's (White & Watts, 1973) research on early childhood development. PAT is a core element of Edward Zigler's (Zigler, Finn-Stevenson, & Hall, 2002) School of the 21st Century model. A major program component is home visits conducted with the parent (usually the mother) to share age-appropriate activities and child development information aimed at strengthening the quality of mother-child interaction and the home learning environment. There also are periodic group meetings of parents, developmental screenings, and referrals to community services. School readiness is a major program goal.

Effects. The PAT Program has been subjected to a series of randomized trials with low-income populations. A three-site study conducted in geographically dispersed urban areas with a total sample of 665 children and their families found few statistically significant effects on parenting and child development at the

end of 2 years in the program (child's 2nd birthday). There were only three statistically significant differences among 28 measures of parent outcomes: a higher frequency of telling stories, saying nursery rhymes, and singing with the child among very low-income intervention group parents compared to very low-income control group parents, and a higher frequency of parents' happiness in caring for their child and acceptance of their child's behavior among the more moderate-income intervention families compared to their control group counterparts. There were no statistically significant effects on child outcomes (Wagner et al., 2002).

In separate randomized trials of the PAT Program with primarily Latino parents in northern California and with adolescent parents in southern California, there were small and inconsistent positive effects on parent knowledge, attitudes, and behavior, and no gains in child development or health when experimental and control groups were compared overall. Subgroup analyses in the northern California site indicated that children in primarily Spanish-speaking Latino families benefited more than either non-Latino or English-speaking Latino families; there were significant child gains in cognitive, communication, social, and self-help development but not a corresponding consistent pattern of positive intervention effects on mothers. Also, subgroup analyses in the southern California site indicated that families receiving both PAT services and comprehensive case management services designed to help mothers improve their life course benefited most (Wagner & Clayton, 1999). Attrition was high and the frequency of home visits was well below the intended monthly contact in each of the PAT studies.

A qualitative study focused on why the PAT Program was not more effective in the two California randomized trials found that home visitors emphasized their social support role and generally did not discuss parenting behaviors that appeared to be in need of change or improvement, even though program goals emphasized both confidence building and focus on parenting behaviors. Mothers viewed the time the home visitor spent interacting with their child as a direct intervention (a "vitamin") that would enhance the child's development, whereas the home visitors saw the same interaction as modeling for the parent (Hebbeler & Gerlach-Downie, 2002).

Implementation issues aside, it is useful to ponder whether a different method (groups) and content (social development) are critical variables here. Recall from the previous section that Webster-Stratton's (1998) group-

based intervention with parents regarding children's Conduct Disorder yielded positive effects on parents and children's behaviors at home.

Broad-Focused Content

Since the 1970s, reviewers of the early intervention research literature have argued that parenting education programs aimed at low-income families are likely to yield few or no positive outcomes because they are not equipped to address parents' primary concerns, namely, major sources of stress faced by parents living in poverty (e.g., Chilman, 1973; St. Pierre & Layzer, 1998). Results of the PAT Program in southern California suggest that there are benefits in providing parents with concrete assistance with personal and family life issues combined with support for improvements in parenting knowledge and skills. In an intervention condition that combined the PAT Program with case management for adolescent mothers, experimental group participants were more accepting of their children's behavior, children experienced significant gains of 1 or 2 months in cognitive development, and there were significantly fewer opened cases of child abuse or neglect compared to control group participants. There were no intervention effects on a range of other outcome variables, however (Wagner & Clayton, 1999). Described next are approaches and results of other parent-oriented interventions that have attempted to support parent and family functioning as an avenue to improved child outcomes.

Program Approaches. A case management approach to family support via home visiting was examined in the Comprehensive Child Development Project (CCDP), a 21-site randomized experiment that began in 1989. The project's name is misleading, as the initiative did not provide services directly to children other than developmental screening (Goodson, Layzer, St. Pierre, Bernstein, & Lopez, 2000; see also Gilliam, Ripple, Zigler, & Leiter, 2000). The project was mandated by federal law to serve infants and young children from low-income families who, "because of environmental, health, or other factors, need intensive and comprehensive supportive services to enhance their development" (Goodson et al., 2000, p. 10).

The CCDP was an ambitious intervention designed to work with two or more generations of a family and to involve all family members on a broad range of issues (St. Pierre, Layzer, Goodson, & Bernstein, 1997).

The model of hypothesized CCDP effects speaks to the complexity of the program. The model included five domains of short-term parent/family effects (physical health, mental health, parenting, steps to economic self-sufficiency, employment and income), two domains of short-term child effects (physical health, developmental), plus long-term child effects in four areas (improved school success, reduced special education placement, reduced retention in grade, reduced teen pregnancy) and long-term parent effects on economic self-sufficiency (St. Pierre et al., 1997). Improved parenting knowledge and skills and economic self-sufficiency were the two main hypothesized indirect pathways to improved child well-being, and participation in high-quality programs of early education and care was the primary hypothesized direct pathway to better child outcomes (Goodson et al., 2000).

The CCDP provided case management, parenting education for the mother or primary caregiver, arrangements for developmentally appropriate early childhood education experiences for all children, and developmental screening. Case management was central to the CCDP because without case managers, the CCDP families would have been no different from other low-income families in their community who had access to existing services (Goodson et al., 2000; St. Pierre et al., 1997). Family case managers developed service plans with families based on an assessment of needs (e.g., housing, domestic violence) and identification of goals and necessary actions, and helped families carry out their plans, including referral to health and mental health services and specialists. Referrals also were made to education-related services such as adult literacy education and job training and placement. Emphasis in the case management work was on coordination of services for a family; case managers referred families to services (i.e., provided mother with contact information for a program) and also engaged in brokering of services (i.e., worked with a non-CCDP program on behalf of a CCDP family and followed up to ensure that the family received needed services; St. Pierre et al., 1997). Case managers, usually paraprofessionals, were families' main point of contact with the program, although other CCDP specialists (e.g., health and mental health coordinators, staff responsible for male involvement in the program) interacted with families on an as-needed basis.

When children were between birth and 3 years of age, most early childhood education was delivered through home visits by early childhood specialists. The focus was on educating parents about child development and

parenting skills. Parenting education also was provided through group sessions and printed materials. For older children, program staff linked families to Head Start or high-quality child care. Families were expected to participate for 5 years, beginning during the mother's pregnancy or during the target child's 1st year.

The Nurse-Family Partnership (NFP; previously known as the Nurse Home Visiting Program) also illustrates an intervention approach focused on parents and their contexts. The program seeks to improve (a) the outcomes of pregnancy, (b) quality of caregiving (and related child health and developmental outcomes), and (c) maternal life course development. Nurse home visitors provide information on child development, particularly how to promote sensitive and responsive caregiving (e.g., understanding and responding to infant nonverbal cues, crying behavior, colic). They also attempt to enhance parents' informal social support networks and use of community services, including health and human services that can reduce situational stressors encountered by low-income families. First-time mothers are recruited for the intervention during pregnancy and encouraged to remain in the program through their child's 2nd birthday. Pregnancy and the early years of a child's life are targeted because it is a time when parents are learning the parental role (Olds, Kitzman, Cole, & Robinson, 1997).

The program views the relationship between the nurse home visitor and the mother and other family members beginning during pregnancy as a therapeutic alliance that provides a model to mothers of care and support. An assumption is that this alliance challenges negative views a mother may have of herself as undeserving of attention and care. The intervention also seeks to promote self-efficacy by helping participants set small achievable goals for behavioral change that, if accomplished, would strengthen confidence in dealing with similar situations in the future. The program gives particular attention to women's progressive mastery of their roles as parents and as adults "responsible for their own health and economic self-sufficiency" (Olds, Kitzman, et al., 1997, p. 12).

Effects. Evaluation of the 21 sites of the CCDP, involving a sample of 4,410 families for 5 years, found no statistically significant intervention effects on child outcomes (cognitive, social-emotional, health) or parent outcomes (parenting, family economic self-sufficiency, maternal life course) compared to a control group. Accordingly, there was no empirical support for the two hy-

pothesized indirect pathways (parenting behavior and family economic status) to improved child well-being. Results do not support the hypothesized direct pathway of participation in high-quality programs of early education and care to improved child outcomes. Significantly more CCDP children than control children were enrolled in center-based programs, and program children spent more hours than control children in center-based programs, but overall, the amount of exposure was modest (an average of 2 to 3 hours a day) and data are not available on whether the center-based programs enrolling CCDP children were of higher quality than programs enrolling control group children (Goodson et al., 2000; St. Pierre et al., 1997).

The NFP has been tested in three successive randomized trials. The original trial with predominantly European Americans conducted between 1978 and 1980 in semirural Elmira, New York, found that the intervention reduced rates of child abuse and neglect, maternal welfare dependence, closely spaced successive pregnancies, and maternal criminal behavior related to use of alcohol and other drugs (Olds, Eckenrode, et al., 1997; Olds et al., 1986). Positive intervention effects were concentrated on poor, unmarried adolescents, a subgroup at greatest risk of inappropriate caregiving. Intervention mothers in this high-risk subgroup were significantly less likely to punish and restrict their children, and provided their children with a larger number of appropriate play materials as measured by the Home Observation for Measurement of the Environment (HOME; Caldwell & Bradley, 1984) scale than their counterparts in the comparison group when children were 22 months of age. There were trends when children were 12 and 24 months of age for intervention children to have higher developmental quotients than babies of counterparts in the comparison condition (Olds et al., 1986). A 15-year follow-up of adolescents born to low-income women who received the nurse home visits during pregnancy and postnatally and who were unmarried found fewer instances of running away, fewer arrests, fewer convictions and violations of probation, fewer lifetime sex partners, and fewer days having consumed alcohol in the prior 6 months than youth in the comparison group. Parents who participated in the intervention reported that their children had fewer behavioral problems related to use of alcohol and other drugs, but there were no program effects on other behavioral problems (Olds, Henderson, et al., 1998).

In a subsequent randomized trial conducted with primarily African American women in Memphis, Ten-

nessee, in the early 1990s, nurse-visited mothers held fewer child-rearing beliefs associated with child abuse and neglect, including belief in physical punishment and unrealistic expectations for infants, and had higher quality home environments as measured by the HOME inventory than comparison group mothers when their children were 24 months of age. There was no intervention effect on maternal teaching behavior, child's use of well-child care, immunization status, the child's mental development, or parent report of child behavior problems. Children born to mothers with limited psychological resources were observed to be more responsive to their mother and to communicate their needs more clearly than children of low-resource mothers in the comparison group. At 24 months, nurse-visited mothers reported having fewer second pregnancies and higher levels of perceived mastery than mothers in the comparison group (Kitzman, Cole, Yoos, & Olds, 1997). A 3-year follow-up of the Memphis trial found that intervention mothers had fewer subsequent pregnancies and fewer months of welfare and food stamp use, but the results were smaller in magnitude than those achieved in the Elmira trial (Kitzman et al., 2000).

In the most recent trial, conducted in Denver, Colorado, in the mid-1990s, nurse-visited infants at 6 months of age were less likely to exhibit emotional vulnerability in response to fear stimuli. At 21 months, nurse-visited children born to women with low psychological resources were less likely to exhibit language delays, and at 24 months they exhibited superior mental development compared to counterpart children in the comparison group. There were no intervention effects on women's educational achievement or use of welfare or children's behavior problems (Olds et al., 2002).

Child and Parent as Primary Participants

One of the typical responses to findings of modest or no effects of parent-focused interventions is the argument that early childhood intervention is more effective when it entails direct, intensive work with both parent and child than with the parent alone.

Research-based interventions that work directly with the child and the parent and provide supports for a range of family functions span nearly 4 decades. Initial efforts, launched in the late 1960s and in 1970, include Head Start's Parent-Child Center Program (Lazar et al., 1970), the Parent-Child Development Center (Andrews et al., 1982), the Yale Child Welfare Project (Provence, Naylor, & Patterson, 1977), and the Syracuse Family

Development Research Program (Lally, Mangione, & Honig, 1988). These early interventions, like their contemporary counterparts, differ on theoretical and programmatic dimensions (e.g., whether direct services to parent and to child are offered concurrently or sequentially), but they share a clear goal of improving a range of parent outcomes, including maternal depression, sense of mastery, problem-solving and life management skills, and abilities related to economic self-sufficiency.

Research on the initial wave of interventions in this area yielded positive, albeit modest, program effects on parents and children and provided a basis for further development and testing of program models. For example, a three-site, experimental study of the Parent-Child Development Center (PCDC) Program found that children achieved superior Stanford-Binet scores at the time of program graduation (36 months of age), and program mothers scored significantly higher than control group mothers on dimensions of positive maternal behavior. The PCDC children maintained their IQ gains 1 year after leaving the program (Andrews et al., 1982) but not beyond (Bridgeman, Blumenthal, & Andrews, 1981). A 10-year follow-up study of the Yale Child Welfare Project, which provided families with pediatric care, social work, child care, and psychological services in an individualized manner by a four-person team of professionals, found positive program effects on intervention children's school attendance and boys' use of special school services, but no program effects on children's IQ scores. Program mothers were more likely to be self-supporting, have more formal education, and have smaller family size than mothers who had not been in the program (Seitz, Rosenbaum, & Apfel, 1985). A later follow-up study found positive program effects on intervention children's siblings' school attendance and performance (Seitz & Apfel, 1994). Reduced rates of juvenile delinquency, better school performance, and more positive child and parental attitudes toward self and the environment (i.e., problem-solving orientation) were found for intervention girls but not boys in junior high school in a 10-year follow-up study of the Syracuse Family Development Research Program (Lally et al., 1988). The positive effects of these interventions provided a basis for further development and testing of other program models.

Interventions that seek to improve parent and family functioning differ in the amount of emphasis on the parent's employment skills. The early set of interventions in this area tended to provide referrals to programs providing adult literacy and job training on an as-needed or

as-requested basis. Partly in response to welfare reform, more recent child and family interventions include training directly related to economic self-sufficiency as an integral part of service provisions. Illustrations of these contrasting approaches and their effects are described next.

Program Approaches

The Infant Health and Development Program (IHDP) was an eight-site randomized study of a 3-year intervention with low birthweight, premature infants that included three components: home visits through age 3 years, weekly in the 1st year and biweekly in the 2nd and 3rd years; child participation in child development centers beginning at age 1 year through age 3 years for a full day, 50 weeks a year; and parent group meetings every other month during the 2nd and 3rd years. IHDP was launched in 1985.

The home visits promoted knowledge and skill development in child health and development, using the Partners for Learning curriculum for age-appropriate games and activities that foster cognitive, language, and social development (Sparling & Lewis, 1995), and in problem-solving skills, using the Parent Problem Solving Program designed to help parents learn effective ways of coping with stress related to parenting and other life events (Wasik, Bryant, Lyons, et al., 1997). Activities from the Partners for Learning curriculum also were used in the child development center (Ramey, Sparling, Bryant, & Wasik, 1997). Home visitor selection and training included major attention to basic clinical skills (i.e., observing, listening, questioning, probing, prompting, supporting) that would enable visitors to develop an empathic, trusting relationship with parents and other family members (Wasik, Bryant, Lyons, et al., 1997).

The problem-solving curriculum was based on the assumption that daily situations encountered by parents are often complex and demanding, and that problem-solving skills can enhance overall parental well-being and increase the likelihood of positive parent-child relationships. The curriculum views problem solving as a cognitive-behavioral process that includes both thinking and action components. Seven steps are emphasized: problem definition, goal selection, generation of solutions, consideration of consequences, decision making, implementation, and evaluation. Home visitors gave explicit attention to each of these steps in guided discussions with parents and used a booklet and three visual aids as reminders of key words in the problem-solving process: a "Stop" card that includes the

words Stop, Think, Act, and Check; and a "Think" card that includes key questions corresponding to the problem-solving steps (What is the problem? What do I want? What can I do? What will happen if? What is my decision? Wasik, Bryant, Lyons, et al., 1997).

The Even Start Family Literacy Program is illustrative of the trend to include job-related training in two-generation interventions. It was described earlier in this chapter in the case illustration.

Effects

In the IHDP study, 985 infants were randomly assigned to either intervention (home visitors, child development center, parent group meetings) or follow-up conditions in each of the eight research sites through a computer-driven process that gave consideration to such key factors as birthweight, gender, maternal education, maternal race, and primary language in the home. Both intervention group and follow-up group infants received medical, developmental, and social assessments, with referral to pediatric care and other services as needed. At 3 years of age, the end of the intervention, intervention children had significantly higher intelligence test scores and receptive vocabulary test scores and lower scores on a parental measure of reported behavior problems than children in the follow-up group. Benefits were more pronounced among heavier low-birthweight than in lighter low-birthweight infants (IHDP, 1990). Child outcomes were positively associated with frequency of family participation in the intervention (Ramey et al., 1992). When children were 5 years of age, there were no significant overall differences in IQ score, receptive vocabulary, or reported behavior problems, but heavier low-birthweight children in the intervention had higher IQ scores, verbal IQ scores, and receptive vocabulary scores than their counterparts in the follow-up group (Brooks-Gunn et al., 1994). At 8 years of age, there were modest intervention effects on cognitive and academic skills of heavier low-birthweight children (McCarton et al., 1997).

There were no intervention effects on the home environment, as measured by the HOME inventory, at 12 months, but at 36 months the home environments of intervention families were higher than follow-up families in total HOME scores, suggesting that the impact of the intervention may be cumulative. At 36 months, there were intervention effects on the learning stimulation, modeling, variety of experience, and acceptance subscales, aspects of the home environment emphasized in the Partners for Learning curriculum (Bradley et al.,

1994). The intervention effect on children's IQ scores at 3 years of age was much greater for children from lower-quality homes, as measured by the HOME inventory. As noted earlier, there were no overall intervention effects on child IQ at 5 and 8 years of age (control group children caught up with treatment group children at age 8 years), and the IQ difference between children from higher- and lower-quality home environments, as measured when children were 3 years of age, declined with child age (Bradley, Burchinal, & Casey, 2001).

Analysis of videotaped mother-child interaction at the child's 30-month clinic visit found small positive effects of the intervention on maternal interactive behavior but not on a rating summarizing maternal affective behavior. A rating of dyadic quality of the mother-child interactions showed that intervention mothers and their children were more synchronous, exhibiting greater cooperation and harmony, than follow-up mother-child dyads, and intervention children were rated as significantly more persistent and goal-directed and more attentive, involved, and enthusiastic while working on a challenging problem-solving task in the presence of the child's mother (Spiker, Ferguson, & Brooks-Gunn, 1993).

Intervention mothers scored higher than follow-up group mothers on a self-report measure of problem-solving skills, but there were no differences between intervention and follow-up group mothers on a measure of coping with health and daily living at 36 months (Wasik, Bryant, Sparling, & Ramey, 1997) and on measures of knowledge or concepts of child development at 12, 24, or 36 months (Banasich, Brooks-Gunn, Spiker, & Black, 1997).

The IHDP intervention reduced maternal distress (depression and anxiety) when children were 1 and 3 years of age, especially for women with less than high school education, but maternal distress did not moderate or mediate intervention effects on child outcomes. IHDP effects on maternal distress at 1 year were likely a result of the home visits because child development center and parent group meetings were not offered during the 1st year. Life events moderated the influence of the intervention on children's test scores; the intervention was more effective for children whose mother had fewer life events (Klebanov, Brooks-Gunn, & McCormick, 2001).

Even Start has been evaluated in three national evaluations beginning in 1989. The third and most recent evaluation, conducted from 1997/1998 through 2000/2001, included an experimental design study to test program effectiveness in 18 sites involving about 460 families who

were randomly assigned to either Even Start or a control group (St. Pierre et al., 2003). Results indicated that Even Start Program children and parents did not gain more than control group children and parents, about one-third of whom received early childhood education or adult education through non-Even Start services. Even Start families participated in a small amount of program services relative to their apparent needs and program goals. There was some evaluation evidence to suggest that Even Start early childhood classrooms, though of good quality overall, gave insufficient attention to language acquisition and reasoning skills.

Preliminary Hypotheses about Program Design

Although it is impossible to move toward conclusions about the design of family interventions from a review of programs selected for illustrative purposes only, the patterns of findings across these different approaches to families point to some preliminary hypotheses about central features of program design.

It appears unlikely that the child serves as a mediator of early childhood program effects on family interactions when parents are assigned an adjunct role in an intensive early childhood program. Because interventions targeted to parents living in high-risk circumstances are complicated and difficult enterprises, there is great appeal in the notion that direct work with the child can trigger changes in patterns of interaction within a family, thereby reducing the need to work with parents to achieve positive change in parent-child interactions. Years ago, Lazar (1983) proposed a pattern of "stimulation stimulating," wherein a child comes home from preschool with skills and interests that place new demands on family interactions (i.e., child requests to be read to) and prompt parents to praise the child's accomplishments and to raise their achievement expectations and encouragement of the child to do well in school. Although the Abecedarian findings suggest that experimental group children presented different demand characteristics when interacting with their mother, there is no subsequent evidence to suggest that these behaviors led to changes in family interactions. This is not surprising theoretically. Family systems theory indicates that homeostatic features of families maintain the stability of their patterns of interaction (Minuchin, 1985, 2002).

More generally, it seems that placement of parents in an adjunct role in an intensive early childhood program

is unlikely to impact parents' child-rearing competence. This is an important hypothesis to investigate because the provisions for program connections with parents in the Abecedarian project mirror the widely used NAEYC guidelines for appropriate practice in early childhood programs.

Increasing the frequency of focused program exchanges with parents—represented in the program design where parents assume a supplementary role in an early childhood program—may increase the likelihood of program impact on parenting competence and child outcomes if the content is focused on a single child-rearing domain that is also a curriculum enhancement in the early childhood program. Results of the dialogic reading program (Whitehurst, Arnold, et al., 1994) and the child conduct program (Webster-Stratton et al., 2001) demonstrate the promise of a dual home-and-school focus on well-defined content.

Programs that embrace a broad area of content have greater opportunity than more narrowly focused programs to employ the social work principle "Begin where clients are." The flexibility and, one hopes, the resourcefulness to focus on a range of issues do not necessarily ensure that the program worker will eventually engage parents in child-related topics once other matters have been addressed. The ability to weave child and parent content into a conversation dominated by a parent's legitimate concerns about other pressing personal or family circumstances requires keen clinical skills that may be more readily possessed by professionals than paraprofessionals. A relationship with one staff person also may help parents focus on parent and child issues. For example, in the CCDP, the separation of child development and parenting information (provided by a bachelor's-level staff person in most sites) from case management work (carried out by a paraprofessional) may have seemed artificial to parents and may have suppressed in-depth discussion of child and parenting concerns in the context of other family matters. One striking difference between the CCDP and the NFP is the focus on the nurse-mother-family relationships, parent development, and connections with informal social support networks in NFP and on referral to and brokering with formal services in CCDP. In view of NFP effects on child and parent outcomes, particularly for parents at greatest risk, a relationship-based approach to intervention in the context of informal and formal systems of family support may be central to promoting child and parent well-being.

Program assistance with parents' job-related skills is unlikely to have immediate positive effects on parenting and child outcomes. Parental workplace experiences may increase the value parents place on their child's education, and characteristics of parents' jobs (e.g., autonomy, problem solving) have been found to be significant predictors of child outcomes, such as reduced child behavior problems (Cooksey, Menaghan, & Jekielek, 1997) and early reading ability (Parcel & Menaghan, 1994). Yet, the path to major change in education and employment is slow and uncertain for educationally disadvantaged parents living in poverty (Wilson, Ellwood, & Brooks-Gunn, 1995), and low-pay, low-complexity work for mothers attempting to leave welfare may result in negative child outcomes (Menaghan & Parcel, 1995). Thus, it seems unrealistic to expect that associations found between parenting practices and child outcomes in substantively more complex employment will be realized in a timely manner for low-income young children typically targeted for early intervention.

NEEDED DIRECTIONS IN APPROACHES TO FAMILIES IN EARLY CHILDHOOD INTERVENTIONS

Needed directions in research and program development are set forth below. In both areas, emphasis is given to focusing on the components and processes of interventions with families.

Research

Since the 1960s, the early intervention field has been driven by research on program models that span a range of assumptions about how to improve the outcomes of children at risk. Current funding streams, policies, and practices have been greatly influenced by the design and evaluation results of prominent models. At the same time, the early intervention field is composed mostly of state- and locally developed efforts that may be inspired by but seldom are full replications or adoptions of existing models (Ramey & Ramey, 1998). Moreover, there is a history of model interventions being watered down in the process of taking programs to scale as policymakers trade quantity for quality in stretching program resources (Schorr & Schorr, 1988). One proposed solution to this problem is for developers of model programs to emphasize essential elements of the model (Olds, O'Brien, Racine, Glazner, & Kitzman, 1998). A persua-

sive case for specific model components is difficult to make when research on program models examines an intervention package rather than individual program elements, as noted earlier in this chapter. Too, adaptation to local circumstances is expected practice in the development of new programs or adoption of an existing program model (Yoshikawa et al., 2002). Research on potentially critical elements of intervention programs, then, holds promise of providing guidance to program implementers, particularly when a set of studies can be used to formulate indicators of program quality in work with families.

Rigorous research methods, particularly experimental designs, are essential to searches for critical elements of effective interventions. Within-group comparison analyses are the dominant design of existing research on potentially critical elements of early interventions. An example is the dosage-response relationship. The chief problem with correlational methods is that causality cannot be established. Strong positive correlations between indices of program participation and program outcomes are difficult to interpret, for example, because preintervention population differences may be related to participant-outcome relationships. Needed, then, are experimental studies that systematically vary a program element. Especially informative are between-group comparison studies that entail an enhancement or adaptation of a particular program, found to be effective in prior investigations, to determine whether there are more effective program designs. Movement in this direction requires resources as well as maturity in research-based development of intervention models that currently is limited to a relatively small set of early childhood interventions. Examples include planned variation in the use of videotapes versus in-person staff to demonstrate effective joint book reading strategies with preschool children (Arnold et al., 1994) and in the use of professional nurses versus paraprofessionals to deliver a home visiting program (Olds et al., 2002). Also illustrative of this approach is a federally funded Even Start study, known as the Classroom Literacy Interventions and Outcomes study, initiated in 2003 to assess the relative effectiveness of different family literacy curricula in promoting language and literacy outcomes for children and their parents (St. Pierre, Ricciuti, & Tao, 2004).

In addition to stronger research designs, the investigation of family interventions needs sophisticated measurement approaches and sufficient resources for data collection with a population that often is difficult

to track and engage. The customary sample attrition rates alone present multiple challenges for data collection and analyses (McCall & Green, 2004) and interpretation of results (Wagner et al., 2002). Observational methods need to be central to the measurement of program outcomes (particularly among adults) and program processes. Existing studies suggest that the conceptualization and measurement of program processes need to move beyond frequency of program contact with participants (D. R. Powell et al., 2004). Further, the status of program implementation research needs to be elevated through use of rigorous methods to assess treatment fidelity and through contributions to our understanding of links between program variables and participant outcomes.

Especially needed are theoretically driven research designs for examining the mediator and moderator roles of family factors in early intervention processes. Much of the existing research has a post hoc, exploratory quality and, though investigators are to be commended for maximizing the yield of studies originally intended to examine child outcomes with minimal attention to process variables, the results are typically elusive. The early intervention field would benefit from greater use of an incremental, research-based approach to program development. Gradual improvements in the design of a program model based in part on results of repeated experimental study have not been the norm of program development in early intervention (Yoshikawa et al., 2002), yet the more effective interventions have followed this pattern. For example, the content and methods of the NFP were revised after each of three consecutive randomized trials that, as noted earlier, also produced important data on how well the model worked with different populations and in semirural and urban settings. Specifically, the intervention's parent-infant curricula were broadened to promote sensitive and responsive caregiving through refinements and expansions that incorporated activities from other interventions (Olds, Kitzman, et al., 1997). This incremental approach to program development is in contrast with the early intervention field's modal pattern of taking programs to scale without a well-researched model program to provide a solid base of guidance for program design and implementation decisions. Head Start is a classic example of the rapid launching of a program (Zigler & Muenchow, 1992). The quick program rollout pattern has continued with, for example, the 23-site Comprehensive Child Development Program, based partly on the Beethoven Project in Chicago, which had a

history of program implementation problems, and with the Even Start Family Literacy Program, initially implemented in 76 sites and based loosely on a program model (the Parent and Child Education Program in Kentucky; Heberle, 1992) that has not been subjected to a credible experimental study.

A potential limitation of an incremental approach to program development is that the societal context initially giving shape to a program model may shift while the program is in development, rendering the program model incompatible with contemporary circumstances. An example is the Parent-Child Development Center Program. The PCDC research and program development plan was experimental, rigorous, and long term with replications, but some of the intervention's basic assumptions about the target population (e.g., stay-at-home mothers available for frequent, daytime participation at a program center) proved to be problematic while the program was undergoing a randomized outcome study and contributed to premature termination of the larger project. The program was conceived prior to serious national economic troubles, including inflation, and the growth of the women's movement in the 1970s. The PCDC emphasized motherhood and child-rearing skills, but program participants increasingly were interested in other roles, including potential wage earner, and not solely interested in their role as an agent for enhancing their child's development. Many program participants entered or reentered the labor force for personal as well as financial reasons (Andrews et al., 1982).

Program Development

A challenge facing any social intervention is responsiveness to the daily realities of the target population. Interventions aimed at families living in poverty and high-risk conditions have long struggled with this task (e.g., Chilman, 1973). Today, most parents living in poverty are engaged in school, job training, or employment. In the broader population, families with young children increasingly face difficult decisions about use of time for family and work, with employment patterns suggesting, for example, that employed mothers of preschoolers in dual-earner families work about 9 more hours a week than they would prefer and fathers' work hours increasing as the number of children rises (Jacobs & Gerson, 2004). Parent employment is negatively correlated with level of parent participation in Head Start (e.g., Castro, Bryant, Peisner-Feinberg, & Skinner, 2004), and growing numbers of parents are un-

available for participation in time-intensive intervention programs crafted in an earlier era.

The limited availability of many parents for program participation provides a pragmatic basis for dismissing the idea of working with parents and primary caregivers. However, early interventions that programmatically disconnect children from their families reduce the potential of enhancing children's well-being by ignoring a major context of early development. Nonfamilial child care does not reduce the influence of parents on children's behavior and development (e.g., National Institute of Child Health and Human Development Early Child Care Research Network, 1998), and family factors continue to be among the predictors of young children's outcomes when children participate in intensive classroom-based early interventions (Burchinal, Campbell, Bryant, Wasik, & Ramey, 1997).

Contemporary family conditions heighten interest in family program designs that work with parents in conjunction with an early childhood program. A common configuration is for parents to assume an adjunct role in relation to their child's center-based program. A potentially significant limitation of the adjunct role is that it does not appear to lead to improvements in parents' child-rearing competence, as noted in the previous section.

Of greater promise is the program design characterized by a supplementary role for parents, particularly when well-defined program content is shared with parents in a concentrated time period and also emphasized in the early childhood curriculum. The examples in the previous section were curriculum enhancements of existing preschool programs that involved both parent and teacher in focused training aimed at improving children's early reading skills (Whitehurst, Arnold, et al., 1994) and behavior conduct (Webster-Stratton et al., 2001). Efficiency is one of many appeals of these approaches. Work with parents was frequent but within a relatively brief time frame and presumably focused on content of keen interest to parents. Because some studies of early childhood programs have found weak or no effects of an add-on educational component for parents (e.g., Boyce, White, & Kerr, 1993), an important future direction is to identify characteristics of effective approaches. Also needed is follow-up research on the sustainability of short-term effects achieved by these content-specific approaches as well as on the extent to which parents (and teachers) continue to engage in practices promoted by the intervention.

Family interventions aimed at helping parents improve their educational and vocational aspirations while

also providing an early childhood program—the "parent and child as primary participants" design described in the previous section—appear on the surface to be responsive to the needs of many low-income families, but considerable program development work is needed to refine the potential of this approach. It is not clear that the current organization of most two-generation programs address in sufficient detail the range of problems experienced by program participants living in poverty. Individual program components may be of insufficient intensity (St. Pierre et al., 1998). One task is to achieve balanced, high-quality attention to both parent and child in two-generation interventions. Anecdotal information from the Even Start Program suggests there is a tendency for some programs to focus on one set of outcomes at the exclusion of others, for example, viewing the preschool component as a custodial arrangement staffed by minimally trained individuals and aimed at freeing parents for participation in parenting or job training classes. The mission of the sponsoring agency (i.e., early childhood or adult education) and the outcomes by which programs are assessed (i.e., children's school readiness or adult GED completion rates) may contribute to imbalances. A related task is to provide quality services in each of the components. For example, most adult education programs are replications of poor high school settings in which most Even Start participants initially failed (St. Pierre et al., 1998).

Important program development work needs to be carried out with program content. The previous section on intervention design suggests that program goals and content are linked to participant outcomes. Intervention programs have a valuable role to play in testing hypotheses offered in developmental literatures (see section on "Elements of Programmatic Support to Families"). Father contributions to family functioning are an example of an area in pressing need of further development. Systematic refinement and assessment of program goals and content require some boundaries. The family functions that interventions seek to support or change—that is, the goals and content of a program—represent many different variables that expand in number and diversity as interventions broaden their reach. The substantive offerings of an intervention also need to be thoughtfully calibrated with target population interests and circumstances. For example, Farran (2000) has speculated that the problem-solving skills curriculum used with parents in the Infant Health and Development Project may have been more frustrating than helpful to parents attempting to cope with poverty-related problems that often are

fairly intractable (e.g., inadequate housing, poor health, lack of transportation, little money).

Intervention methods also need thoughtful program development attention. For example, Gomby and colleagues (1999, p. 17) have suggested that home visiting program attrition rates may reflect family views of "a most unusual approach to service delivery. There are very few occasions in America in which a nonfamily member regularly visits the home to persuade someone to change his or her behavior." As suggested in previous sections of this chapter, interventions have a long way to go in applying family systems theory to practices with participants (i.e., working with relationship systems, not individuals per se) and in examining the effects of different pedagogical approaches, particularly strategies that encourage active participant engagement.

The long-neglected area of program implementation needs to be a high priority of program designers. The extant literature contains potent hints of some serious problems in carrying out program plans. Because staffing arrangements appear to be a linchpin in intervention programs, the early intervention field would benefit from future work that refines and transcends the paraprofessional versus professional debate to examine specific skills and background characteristics of effective intervention staff as well as approaches to staff supervision.

Family interventions operate at the intersection of profound sociopolitical changes affecting families, growing societal concern about children's outcomes, a limited base of pertinent empirical science, and often unrealistic expectations of what programs can accomplish. It is difficult to overstate the complexities of research and practice in this terrain. It is equally difficult to overemphasize the opportunities to contribute to an understanding of how the hopes and actions of families can be marshaled on behalf of their children's futures.

CHAPTER 15

School-Based Social and Emotional Learning Programs

JEFFREY S. KRESS and MAURICE J. ELIAS

THE COMPLEX, LONGITUDINAL NATURE OF SCHOOL-BASED SOCIAL-EMOTIONAL LEARNING INTERVENTIONS	595
DEVELOPMENTAL ARENAS IN SOCIAL-EMOTIONAL LEARNING PROGRAM IMPLEMENTATION	597
Developmental Arena 1: Program Implementation	597
Developmental Arena 2: The Program Implementers	600
Developmental Arena 3: The Social-Emotional Learning Intervention	601
Developmental Arena 4: The Consultant	602

From the late 1990s schools have been inundated with well-intentioned prevention and promotion programs that address such diverse issues as bullying, HIV/AIDS, alcohol, careers, character, civics, conflict resolution, delinquency, dropout, family life, health, morals, multiculturalism, pregnancy, service learning, truancy, and violence.

At the same time, the year 2002 marked the passage of the No Child Left Behind (NCLB) legislation, which placed a strong emphasis on test scores as the most important and tangible outcome of educational achievement. School funding was tied to progress in test performance, and educators quickly found themselves faced with a dilemma. The needs that had generated the proliferation of prevention-related programs had not abated. However, their accountability structure changed in ways that seemed incompatible with the continuation of those programs.

Signs of this dilemma were evident over a decade ago (Elias, 1995, pp.12–13):

The continuing undercurrent of emphasis on basic academic skills is probably driven more by economic and workplace forces—both domestic and international—than by a genuine concern with the well-being of our nation's

children and youth. For if the latter were the case, compelling statements about the inextricable bond linking personal, social, affective, and cognitive development would be more in the forefront. Arguments have been made that “Placing an overlay of strong academic demands on the current educational climate is likely to result in few increases in learning and instead exacerbate current stress-related problems and lead to further alienation among our student population.” (Elias, 1989, pp. 393–394)

What was previously described as an undercurrent has now become a rip tide, and the stress-related sequelae of trying to meet the academic and psychological demands of students in the schools are drowning both students and teachers alike. Efforts to redress these problems by returning attention to the bond across developmental areas have not been absent during this time, but they have undergone both conceptual and practical reformulations. Concomitantly, our understanding of what is required to implement these efforts—most specifically, what is being demanded of those who are expert consultants to implement interventions in schools—has become more sophisticated.

How have schools attempted to respond to growing demands to implement effective educational approaches

that promote academic success, enhance health, and prevent problem behaviors? Unfortunately, many child advocates, educational policymakers, and researchers, despite their good intentions, have proposed fragmented initiatives to address problems without an adequate understanding of the mission, priorities, and culture of schools (Sarason, 1996).

For a number of reasons, these uncoordinated efforts often fail to live up to their potential. Typically, they are introduced as a series of short-term, fragmented program initiatives. They are not sufficiently linked to the central mission of schools or to the issues for which teachers and other school personnel are held accountable, which is primarily academic performance. Rarely is there adequate staff development and support for program implementation. Programs that are insufficiently coordinated, monitored, evaluated, and improved over time have reduced impact on student behavior.

Even before the crisis precipitated by the NCLB legislation, concern for the disappointing performance of many prevention and health promotion efforts spurred a 1994 meeting hosted by the Fetzer Institute. Attendees included school-based prevention researchers, educators, and child advocates who were involved in diverse educational efforts to enhance children's positive development, including social competence promotion, emotional intelligence, drug education, violence prevention, sex education, health promotion, character education, service learning, civic education, school reform, and school-family-community partnerships. The Fetzer group first introduced the term *social and emotional learning* (SEL) as a conceptual framework to address both the needs of young people and the fragmentation that typically characterizes the response of schools to those needs (Elias et al., 1997). They believed that, unlike the many "categorical" prevention programs that targeted specific problems, SEL programming could address underlying causes of problem behavior while supporting academic achievement. A new organization, the Collaborative for Academic, Social, and Emotional Learning (CASEL), also emerged from this meeting with the goal of establishing high-quality, evidence-based SEL as an essential part of preschool through high school education (see www.CASEL.org).

Social and emotional learning skills have had several competing conceptualizations, including those of Bar-On (Bar-On & Parker, 2000), Mayer and Salovey (1993), Goleman (1995), and CASEL (Elias, 2003). Of these, CASEL's has been most focused on children and

has served as the guide for virtually all school-based SEL interventions. Hence, we will concern ourselves with CASEL's view of SEL skills. (See Ciarrochi, Forgas, & Mayer, 2001, for an overview of theoretical perspectives.)

The skills of social-emotional learning are presented in Table 15.1. CASEL (2003) posits five interrelated skill areas: self-awareness, social awareness, self-management and organization, responsible problem solving, and relationship management. Within each area, there are specific competencies supported by research and practice as essential for effective social-emotional functioning. The list does not purport to be comprehensive; rather, it is drawn from research and practice and is intended to guide intervention. Further, the conceptualization of the skills is that they are important at all developmental levels; what changes is the level of cognitive-emotional complexity with which they are applied, as well as the situations in which they will be used. Hence, Table 15.1 provides a framework for looking at the skills from the perspective of childhood and beyond. (See Elias et al., 1997, for versions appropriate to other stages of child development.)

The fact that SEL has been part of the popular literature is significant. People reading about it from all walks of life, from various professions, as psychologists, educators, members of the business community, and parents, can share this term (Goleman, 1995). Similarly, SEL and emotional intelligence found their way into psychology, education, business, and other professional journals and in over 30 languages. This has created a base of interest and involvement that far eclipsed prior work in social competence promotion, even though the long history of research and conceptualization in that area clearly provided the foundation from which SEL and emotional intelligence could spring (Consortium on the School-Based Promotion of Social Competence, 1994).

However, SEL also had "value added" as a concept. First, it placed a strong emphasis on such dimensions as emotion and spirituality (Kessler, 2000). Second, it was based in advances in brain research (Brandt, 2003). Third, SEL became tied to factors that were being studied in education and related fields as mediators of academic performance, that is, the emotional state of children, their cognitive capacity to learn, and their style of learning. Just as the education field seemed to be focusing on "back to basics" in terms of both skills and learning approaches, the SEL field was uncovering

TABLE 15.1 Social-Emotional Learning Skills

<i>Self-Awareness</i>
Recognizing and naming one's emotions
Understanding the reasons and circumstances for feeling as one does
Recognizing and naming others' emotions
Recognizing strengths in, and mobilizing positive feelings about, self, school, family, and support networks
Knowing one's needs and values
Perceiving oneself accurately
Believing in personal efficacy
Having a sense of spirituality
<i>Social Awareness</i>
Appreciating diversity
Showing respect to others
Listening carefully and accurately
Increasing empathy and sensitivity to others' feelings
Understanding others' perspectives, points of view, and feelings
<i>Self-Management and Organization</i>
Verbalizing and coping with anxiety, anger, and depression
Controlling impulses, aggression, and self-destructive, antisocial behavior
Managing personal and interpersonal stress
Focusing on tasks at hand
Setting short- and long-term goals
Planning thoughtfully and thoroughly
Modifying performance in light of feedback
Mobilizing positive motivation
Activating hope and optimism
Working toward optimal performance states
<i>Responsible Decision Making</i>
Analyzing situations perceptively and identifying problems clearly
Exercising social decision-making and problem-solving skills
Responding constructively and in a problem-solving manner to interpersonal obstacles
Engaging in self-evaluation and reflection
Conducting oneself with personal, moral, and ethical responsibility
<i>Relationship Management</i>
Managing emotions in relationships, harmonizing diverse feelings and viewpoints
Showing sensitivity to social-emotional cues
Expressing emotions effectively
Communicating clearly
Engaging others in social situations
Building relationships
Working cooperatively
Exercising assertiveness, leadership, and persuasion
Managing conflict, negotiation, refusal
Providing, seeking help

reasons why genuine learning required attention to other factors (Zins, Weissberg, Wang, & Walberg, 2004).

Yet another trend was operating in the late 1990s and early 2000s that is relevant to understanding SEL, its emergence, and why action research in that field has generated such unique insights. Both in the therapeutic field and in education, there was a push for evidence-based interventions. Those who were funding services (managed care companies and federal and state government for the former; federal, state, and local government for the latter) were concerned about accountability. Were children receiving services that were cost-effective? Could they be delivered in prescriptive ways, to ensure fidelity and maximize efficiency? Thus came the push for manualized therapeutic interventions and scripted school reform plans and related interventions. And with these circumscribed interventions came the need for accountability and the gold standard of research: randomized clinical trials.

Randomized clinical trials work best for discrete, time-limited, low-complexity interventions (Elias, 1997). This led to an ascendance of the short-term, focused "program" as the unit of intervention and study, along with the illusion/deception that programs were simple to implement in a controlled, replicable, and consistent manner. Outcomes research focused on the efficacy of such programs as implemented in "model" sites. For example, the American Psychological Association's *14 Ounces of Prevention* (Price, Cowen, Lorion, & Ramos-McKay, 1988) and the 1997 publication *Primary Prevention Works* (Albee & Gullotta, 1997) contain program descriptions and outcome data for SEL programs that address a range of populations across the life span. In the chapter in the latter volume on the Social Decision Making/Social Problem Solving program, which is the focus of this chapter, data were reviewed showing the efficacy of the program in terms of (a) improving teachers' abilities in facilitating students' social decision making and problem solving and (b) improving the social decision-making and problem-solving skills of students. Positive outcomes such as these further boosted interest in the field.

As the field matured, it became evident that there were significant issues to consider in terms not only of the structure of a program, but also of the process by which a program is implemented in a setting. Gager and Elias (1997) showed clearly that so-called model programs were variable in their success, and that their outcomes were related most strongly to implementation

considerations. That is, a model program could be carried out successfully and unsuccessfully in almost equal measure. (It should be noted that an essentially asymmetric relationship is suggested by the research, in that sound program design is a necessary but not sufficient condition for positive outcomes, whereas poor program design is highly unlikely to lead to positive outcomes, regardless of implementation.) This was not a reflection on the programs, but showed that the implementation process could no longer be neglected from a research, intervention, or conceptualization point of view. Social-emotional factors in the environment of the program, including its ecological context, had a strong influence on the effectiveness and impact of the program.

THE COMPLEX, LONGITUDINAL NATURE OF SCHOOL-BASED SOCIAL-EMOTIONAL LEARNING INTERVENTIONS

It is beneficial to provide a developmentally appropriate combination of formal, curriculum-based instruction with ongoing informal and infused opportunities to develop social and emotional skills from preschool through high school. (Elias et al., 1997, p. 33)

It has become widely accepted among researchers and those deeply involved with the SEL field that learning social and emotional skills is similar to learning other academic skills. That is, the effect of initial learning is enhanced over time to address the increasingly complex situations children face regarding academics, social relationships, citizenship, and health. This outcome is best accomplished through effective classroom instruction; student engagement in positive activities in and out of the classroom; and broad student, parent, and community involvement in program planning, implementation, and evaluation (CASEL, 2003; Weissberg & Greenberg, 1998). Ideally, planned, ongoing, systematic, and coordinated SEL instruction should begin in preschool and continue through high school.

Social and emotional learning programs also take many forms, but several generalities can be drawn about them. To begin with, a definition of SEL is provided by CASEL (2003, p. 8):

Social and emotional learning (SEL) is the process of developing fundamental social and emotional competencies in children. SEL programming is based on the understanding that (1) the best learning emerges from supportive and

challenging relationships, and (2) many different kinds of factors are caused by the same risk factors.

The specifics of how these relationships are formed and how the risk factors are addressed will vary from program to program. Recent years have seen the proliferation of SEL-enhancing programs and efforts. In an effort to help educators navigate among and decide between various programs and to effectively incorporate these into their practice, reviews of effectiveness research (e.g., CASEL, 2003) have been conducted and guidelines established for what constitutes effective programming (e.g., Elias et al., 1997). For example, Elias et al. delineate the scope of SEL programmatic efforts in the first of their 39 “Guidelines for Educators”:

Educators at all levels need explicit plans to help students become knowledgeable, responsible, and caring. Efforts are needed to build and reinforce skills in four major domains of SEL:

1. Life skills and social competencies.
2. Health promotion and problem prevention skills.
3. Coping skills and social support for transitions and crises.
4. Positive, contributory service. (pp. 21–22)

Successful programmatic approaches include a combination of direct instruction in social and emotional skills as well as opportunities to practice these skills in a variety of situations. Direct instruction involves introducing students to the basic components of complex social and emotional skills. Students practice the use of these skills, and receive guided feedback from the teacher. Teachers may establish prompts for use as cues by students to put the behaviors to use. A basic example can be drawn from the Social Decision Making/Social Problem Solving Program (SDM/SPS; Elias & Bruene-Butler, 2005a, 2005b, 2005c) that is discussed in depth later in this chapter. This curriculum includes instruction in communication skills. In this unit, students learn the prompt “Listening Position,” which includes the following behavioral components: (a) Sit or stand straight, (b) face the speaker, (c) look at the speaker. These three components are modeled by the teacher and practiced by the students as the teacher provides feedback on their efforts. The teacher may use a practice activity, such as asking the students to use Listening Position during a game that involves paying auditory attention (e.g., “Clap your hands when you hear me say a certain word”). Again, the teacher provides feedback.

In addition to this type of direct instruction, SEL skills are best taught when infused throughout the school day and in all aspects of a student's experience. To continue with the earlier example, teachers can find opportunities for students to role-play listening skills as part of a discussion about literature or history. A science teacher may reinforce listening skills as part of a lesson on the five senses. A principal, in calling an assembly to order, may use the same "Listening Position" prompt that students learned in their classrooms. Finally, efforts can be made to engage parents in the process by orienting them to the skills and prompts and helping them understand how best to coach their children.

As suggested by these examples, a comprehensively implemented approach to SEL transcends work by individual teachers in individual classes. In addition to the type of curriculum-based work described earlier, J. Cohen (1999, p. 13) points out that SEL can be addressed in less formal, "noncurriculum-based" ways in which educators "discover ways of being further attuned to SEL and how best to incorporate it into all they do at school," thereby "integrating a set of principles and practices with work that is taking place in the classroom." Further, Cohen points out that there are SEL initiatives targeting students at risk. Further, Cohen discusses a dimension of SEL specifically focusing on the educators themselves and the SEL competencies and experiences of those working in the school. Building on Cohen's rubric, we suggest two further related areas in which SEL can be manifested in a school. First, we can think about *systemic SEL*, or SEL initiatives that transcend the classroom and have to do with school policies (such as discipline) and governance (e.g., how students can have meaningful input into the functioning of the school community). Second, we see the importance of *administrative SEL*, or the ability of the administrator to draw on the principles of SEL in his or her interactions with staff and students and in bringing new programs or initiatives to the school.

Numerous successful, multiyear, multicomponent, school-based interventions promote positive academic, social, emotional, and health behavior. Examples include the following:

- Creating coordinated, caring communities of learners and enhancement of school and classroom climate through a combination of class meetings, peer leadership, family involvement, and whole-school community building activities (Battistich, Schaps, Watson, & Solomon, 1996; Solomon, Battistich, Watson, Schaps, & Lewis, 2000). This takes place by having an entire

school staff come together to discuss the potential program and agree that they support the values and procedures that are encompassed by the program and are prepared to implement it over time.

- Strengthening teacher instructional practices and increasing family involvement (Hawkins, Catalano, Kosterman, Abbott, & Hill, 1999). Teachers are taught how to create opportunities for children to bond with one another and participate in and support the creation of school norms; parents are similarly engaged in supporting school norms and in learning skills of nonviolent conflict resolution and anger management with their children.
- Establishing smaller units within schools and building trust among school staff, families, and students, thereby increasing student access, guidance, and support from school staff and other students (Felner et al., 1997). Specifically, students entering middle and high school do so in their own wings of buildings and share classes mostly with students in their own grade to increase camaraderie and mutual support; advisories also provide all students with regular problem-solving opportunities.
- Developing effective classroom-based SEL instructional programs that extend into all facets of the school environments, as well as family and/or community, to enhance students' social-emotional competence and health (Conduct Problems Prevention Research Group, 1999; Elias, Gara, Schuyler, Branden-Muller, & Sayette, 1991; Errecart et al., 1991; Greenberg & Kusché, 1998; Perry, 1999; Shure & Spivack, 1988). The skills imparted in such programs are reinforced by being explicitly used in physical education classes, in hallways, on the school bus, as part of service learning experiences, and for family problem solving. Invoking the skills outside the curriculum and instructional context serves to reinforce and generalize the use of those skills.

Despite the availability of evidence-based programs of varying degrees of complexity, many schools still do not use them (Ennett et al., 2003; Gottfredson & Gottfredson, 2001; Hallfors & Godette, 2002). For example, Ennett et al. surveyed educators from a national sample of public and private schools and found that only 14% use interactive teaching strategies and effective content in delivering substance use prevention programming. Hallfors and Godette's survey results from 81 Safe and Drug-Free School district coordina-

tors across 11 states indicated that 59% had selected a research-based curriculum for implementation, but only 19% reported that their schools were implementing these programs with fidelity. This issue is of equal if not greater importance than generating new and more accurate curricula; the level of practice would be enhanced greatly if even current knowledge was implemented to a greater degree.

The history and trajectory of development of the field of SEL provides insights into what we believe is one of the deep, structural issues maintaining the gap between knowledge and practice. Since the emergence of the SEL field, there has been a reconceptualization of what is needed to be an effective action researcher and practitioner. The field first moved from an emphasis on short-term, discrete programs, to a realization that multicomponent, multilevel, multiyear interventions, linked to the goals and fabric of the organizations for which they are intended, are essential for successful, enduring outcomes (Weissberg & Elias, 1993). Accompanying this view is an evolving understanding of the skills needed to implement such efforts effectively (Elias, 1997). Social and emotional learning, character education, service learning, prevention, and related school-based programs and activities are highly operator-dependent. That is, their success is not linked to some automated technology, but rather to actions carried out by human beings interacting with multiple others across situations over time. Even when such interactions are scripted, there is great potential variation, and the moment-to-moment decisions made by the human operators of an intervention, in ecological relationship to all those around them, greatly influence the ultimate outcomes.

For schools to successfully bring in comprehensive approaches to SEL in enduring and effective ways, they will need consultants who can negotiate a complex, interactive, ecological-developmental process. The remainder of the chapter focuses on a pragmatic-theoretical guide for consultants and researchers working to implement SEL in a variety of contexts.

DEVELOPMENTAL ARENAS IN SOCIAL-EMOTIONAL LEARNING PROGRAM IMPLEMENTATION

As our contribution to the greater likelihood that interactive, ecological-developmental processes will

be well-handled, we want to elucidate the developmental nexus within which effective SEL takes place. The centerpiece of our ecological considerations is the consultant and the path that he or she takes to being able to master, or at least address, the evolving complexity of interventions. An additional level of analysis is a set of developmental processes in the host settings that must ultimately be in alignment if SEL is to take root in a school and be a positive influence on children.

Developmental Arena 1: Program Implementation

Finding trends in the changing trajectories of individuals is a difficult endeavor due to the large number of variables that may influence the pathways. Examining the change trajectory of an organization, itself made up of multiple individuals undergoing their own processes of change within the ecology of the setting, yields a literature “that is diverse and often unwieldy” (Commins & Elias, 1991, p. 207). Efforts to summarize the process of program implementation within an organization are necessarily summative generalizations of the efforts of multiple individuals within the organization. A temporal cross section of the setting at a given point in time may reveal individuals whose level of implementation does not correspond to the overall level of implementation within the organization. New teachers come on board and need to be brought up to speed. Veteran teachers differ in terms of their own motivation to implement the program. Individual differences in creativity or drive for innovation will impact the degree to which one adheres to or makes changes to the program being implemented.

However, even with the multitude of factors impacting the process (many of which are discussed later in this chapter), there are trends that emerge as implementation of a new program unfolds in a setting. Novick, Kress, and Elias (2002), basing their work on Hord et al. (1987), summarize these trends by looking at the general levels of use of interventions by individuals within a setting (Table 15.2).

The earliest stage, though technically one of nonuse, is important in forming the foundation of future implementation efforts. All implementation efforts have a “prehistory” (Sarason, 1972) of past experiences with innovation in a setting, of beliefs, values, and experiences held by individuals within a setting, and of the culture of the school

TABLE 15.2 Levels of Use and Concern

Level of Use	Staff Members at This Level	Level of Concern	Staff Members at This Level	Adult Learners at This Level Need
Nonuse	Have little or no knowledge, no involvement, and no actions to help them become involved.	Awareness	May be concerned about the consequences of SEL deficits, but not about SEL programming or implementation.	To gain an understanding of the program rationale, the contextual supports/incentive supports for implementation, and skills needed for implementation.
Orientation	Are acquiring information about SEL and its value orientation and what it will require to carry out the innovation.	Informational	Would like to know more about SEL and how to promote it.	Introductory information about specific program goals, requirements, and time lines.
Preparation	Are preparing to use a new SEL idea or process.	Personal	Are considering using (or not using) SEL and are grappling with the impact that this decision will have on their work and on themselves.	Concrete information on what the innovation will look like, what materials they will use, and how to prepare themselves to take the first steps in getting started.
Mechanical use	Focus on short-term, day-to-day use, mastering the specific tasks and techniques they must carry out.	Management	Are concerned about their ability to handle the logistics of the program implementation.	Support and troubleshooting for implementation (e.g., observing other teachers, additional consultation/supervision, e-mail contact with experts, peer-group meetings to share and learn).
Routine	Have established use of the innovation; regular patterns of implementation predominate and few changes are made in ongoing use.	Consequences (I)	Wonder about the impact that their efforts are having on their students.	Praise and recognition for what they are doing; assistance in making implementation easier or better and assessing outcomes.
Refinement	Fine-tune SEL efforts based on feedback from consumers/clients and from their own experience.	Consequences (II)	Consider how to maximize program effectiveness and improve delivery.	Support and reinforcement for innovation while maintaining the core aspects of the plan.
Integration	Begin to step back and look at the big picture of the SEL work they are doing; they focus on how to combine their own efforts with those of colleagues.	Collaboration	Recognize that impact can be maximized by coordinating efforts with others and continuity over time.	Support for naturally occurring interactions and collaborations; planned contexts in which cooperation can occur.
Renewal	Reevaluate practice in light of factors such as changes in population, student needs, staffing patterns, freshness/relevance of materials.	Refocusing	Begin to supplement and enhance the intervention based on their own experience.	Opportunities for staff to share and discuss desirable, coordinated changes in the school's SEL efforts.

Source: Based on *Taking Charge of Change*, by S. M. Hord, W. L. Rutherford, L. Huling-Austin, and G. E. Hall, 1987, Alexandria, VA: Association for Supervision and Curriculum Development; and *Building Learning Communities with Character: How to Integrate Academic, Social and Emotional Learning*, by B. Novick, J. S. Kress, and M. J. Elias, 2002, Alexandria, VA: Association for Supervision and Curriculum Development.

in terms of such areas as staff collaboration and morale.¹ Does the school have a history of revolving-door innovations that might impact how seriously staff regard yet another new program? Do staff tend to work together

proactively to address concerns in the school, or does individual griping predominate? The answers to such questions will impact the trajectory of any programmatic efforts in a setting.

Early use stages are introductions or initiations of a new program into a setting, corresponding to the orientation, preparation, and mechanical use levels in Table 15.2. The goals and rationale of a program are introduced, and implementers are oriented to why such a program is important to the life of the school. Initiation progresses to include planning to take, and then actually embarking on, the first steps in implementing the pro-

¹The prehistory also involves the process by which the innovation was brought to the setting. Who initiated the effort: was it top-down from the principal, grassroots from the teachers, or some combination of the two? What program options were explored? These factors are important, but because they precede the onset of programming, they will not be a focus of this chapter.

gram. For SEL programming, introduction and initiation is a time when implementers consider the importance of SEL skills, the difficulties with deficits in such skills, and basic tenets of best practices for promoting SEL skills. Further, they are learning the nuts and bolts of implementing the specific program being brought to the school (e.g., Are there lessons to learn? Materials to use?) and planning how to incorporate new activities into existing class structures (e.g., When will the lessons be delivered?).

Once a degree of implementation mastery is achieved through repeated mechanical use, initiation gives way to regularity of programming efforts within a school. Such a routine level of use involves fairly consistent patterns of programming with few changes being made. As implementers gain increased fluency with the program and begin to notice subtleties such as differential impact on various students (e.g., based on gender, developmental level, special needs classification) and their own implementation style (e.g., comfort or lack thereof with various programmatic aspects), they may attempt to refine their efforts in light of their experiences and observations.

As staff members become regular users, the program moves toward institutionalization within a setting. The program becomes part of the standard operating procedure of a setting. A visitor would be unable to distinguish the institutionalized program from any other long-standing initiative. Many of the functions once performed by an outside consultant are now owned by the institution (Kress, Cimring, & Elias, 1997). New roles might be created to maintain the program, and the values and goals of the program may be reflected in the rituals and ceremonies of the school.

The institutionalization phase, like the routine use phase before it, is not static. Just as routine use is marked by refinement, institutionalization is marked by integration and renewal. The former term refers to the growing realization by implementers that their individual efforts will be enhanced to the extent to which they support one another and their efforts are carried through over time. The focus of programmatic efforts shifts from isolated classrooms to coordination among faculty members at and across grade levels and/or disciplines. As the overall quality and consistency of implementation continues to progress, implementers will be interested in renewing their efforts in light of contextually based changes. Student populations change, staff turnover occurs, new mandates are mandated, and new materials materialize. Programmatic response to such

changes can be seen in a Piagetian light: Changes may be “assimilated” into existing program structures, or the program “accommodates” to new realities.

A curriculum-based and problem-solving oriented program such as Interpersonal Cognitive Problem Solving (ICPS) (Shure & Spivack, 1988), Open Circle (Seigle, 2001), and SDM/SPS (Elias & Bruene-Butler, 2005a, 2005b, 2005c) is typically introduced in a half-day awareness workshop that shows staff the framework of the program, the key skills, and the problem-solving steps that are embodied in their lessons. Preparation involves another level of training, for at least an entire day, in which specific curriculum materials are presented to staff. What follows next is mechanical use, whereby teachers typically follow the curriculum lessons pretty much as presented in the curriculum but are not overly concerned if they miss an occasional lesson. There is not much flexibility and little spontaneous use of the curriculum in noninstructional time. Use is considered routine once there is an understanding of the importance of regular use if the program is to have an impact on students. Refinement is the next logical level; this is where problem-solving procedures might be modified to make them more clearly remembered or applied by particular students, or whole-class activities are recast into small groups (or vice versa) in an attempt to have a greater impact on students who do not seem to be grasping the skills based on standard presentation. Integration occurs when problem-solving skills are applied not only to social situations, but to academics, such as literature and social studies, and to the discipline system in the form of problem-solving worksheets to help students think through rule infractions and plan better ways to handle troubling situations when they occur in the future. Finally, after perhaps 2 to 3 years, these programs can be at the renewal level of use as the need to modify procedures and supplement materials is evaluated in light of the impact of the curriculum. For example, procedures from the Responsive Classroom program (www.responsiveclassroom.org) that focus on morning meetings, establishing rules, and building a positive sense of community often provide a valuable adjunct to Open Circle and SDM/SPS; self-control techniques from Second Step (www.cfc.org) have been used to bolster readiness skills for problem solving in ICPS. These modifications then go through their own levels of use process, albeit usually at a much quicker pace than shown by the original curriculum.

These trends can be considered developmental in that earlier stages of implementation are seen as enabling

later stages to occur. As in individual developmental theories, not all stages are achieved at the same speed (nor by all the implementers in any given setting at the same time), nor will any given setting (or its individual implementers) make their way fully to the “last” stage. Finally, there is a cyclical nature to the process, as modifications that are made during later phases might need to be initiated in a process similar to introducing a new program.

Developmental Arena 2: The Program Implementers

The stage-wise progress of implementing programmatic change on a systemic level has parallels in terms of learning, behavioral change, and innovation adaptation on the part of the implementers of any SEL program. This progression can be framed in terms of Prochaska and DiClemente’s (1984) transtheoretical model of behavior change (cf. Edwards, Jumper-Thuman, Plested, Oetting, & Swanson, 2000). In their model, individual readiness is described as an underlying factor in moving through stages of change, beginning with limited awareness of the problem and lack of motivation to change, and progressing through increases in both. With regard to SEL programming, various adult learning needs may emerge as implementers move from initial exposure to the intervention to preliminary inroads in its use to eventual regular usage.

Novick et al. (2002) have discussed a progression of levels of concern, or adult learner-implementer needs, based on Hord, Rutherford, Huling-Austin, and Hall (1987), that emerge as implementers move through the process of implementing an SEL program. As summarized in Table 15.2, these concerns and needs correspond to the levels of use discussed previously. In summary, these levels begin at a limited awareness of the issue of SEL and low motivation to implement SEL programming. As staff become more aware of the importance of SEL, and their own role in addressing SEL skills, basic “how to” issues come to the fore. Once implementers have achieved a degree of mastery of the basics of implementation, needs begin to focus on improving, supporting, and innovating practice.

These levels of concern point out the interplay between the progress of program implementation and implementers’ needs to have certain concerns addressed. A consultant must be aware of the particular concerns at any given time and be ready to help see that they are addressed. At some levels, for example, at the informa-

tion level, learners’ needs may be filled by a direct intervention on the part of the consultant (in this case, providing more information). Other levels, for example, collaboration, may require a more systemic approach to create the kind of learning communities that would meet some implementers’ concerns.

Factors Impacting Initiation into the Implementation Process

Embedded in this discussion is an understanding that the developmental needs of the adult learner-implementers are sensitive to social and emotional factors. At the early levels of concern, for example, beliefs and attitudes will be important in the progression toward initial steps of implementation. Specifically, the beliefs and attitudes held by the implementers regarding the origins of social and emotional skills and the best way to build such skills will impact the degree of motivation to implement any SEL program. Incompatibility between the consultant’s and implementers’ framing of a target problem can result in the latter group rejecting the program being promoted by the former (Everhart & Wandersman, 2000). Teachers who believe that social and emotional skills are part of a student’s immutable genetic makeup will be unlikely to show support for a program based on a social learning model of social and emotional skill development.

Perceptions regarding the importance of deficits in SEL skills and one’s responsibility for addressing them may have an impact on implementation, as well. For example, in a study of an antibullying program, degree of implementation was predicted by perceptions held by teachers regarding the extent of bullying behaviors in their school and teachers’ assessment of the importance of their role in stemming the problem (Kallestad & Olweus, 2003). Thorsen-Spano (1996) found that elementary school teachers with a favorable attitude toward conflict resolution report a higher level of implementation of a conflict resolution program in their class than do those who report a less favorable attitude. Teachers who do not see SEL skills as a problem (and therefore, “If it ain’t broke, don’t fix it”), or who see them as a concern but not their concern (“SEL is for the parents/school psychologist/and so on to deal with, not me”) will be unlikely to embrace an SEL program. A consultant must work to gauge the attitudes and feelings of the implementers both around the social-emotional climate of the school and about the implementation as it unfolds (Novick et al., 2002).

Factors Impacting Movement toward Regular Use

Implementers must possess a sense of their own ability to successfully carry out an SEL program. That is, a teacher might believe in the premise of the SEL program but have concerns about how he or she will handle factors such as classroom management during program sessions or finding time to implement an additional initiative (e.g., Ghaith & Yaghi, 1997). Such concerns can derail the efforts of the implementer to progress toward regular program use. Although teachers will enter the implementation process with a level of implementation self-efficacy, this factor will also be sensitive to iatrogenic effects. The relative success or failure of initial implementation efforts will have an impact on willingness to regularize programming. As such, Elias et al. (1997) have stressed the importance of “small wins” early on in creating positive momentum.

Growth in skill development will be enhanced by the extent to which individual efforts are given an opportunity to intersect with the efforts of others who are also involved in the process, thereby creating a community of learner-implementers. Such efforts “can enhance relationships, facilitate contextually relevant modifications, and foster understanding of the role of school culture in program implementation” (Nastasi, 2002, p. 222).

Factors Important during Institutionalization

Finally, in considering the development of the implementers *qua* implementers, it is important to keep in mind parallel developmental processes. Program implementation may be related to an educator’s experience level. For example, following a staff development program on cooperative learning, experience was negatively correlated with reported attitudes toward implementation (Ghaith & Yaghi, 1997). Also, as discussed by Everhart and Wandersman (2000), adults in an Eriksonian “generativity” stage may find it more exciting to modify the existing program or to try something new than to maintain implementation as is. Staff turnover ensures that any ongoing implementation cohort includes both those experienced with as well as new to any intervention. As such, a consultant must be careful not to generalize regarding the implementation-developmental level of any group of consultees. Newly hired teachers likely being at a less advanced level of concern (after all, they may enter the school with little or no familiarity with the SEL program being used). Further, teachers new to a set-

ting have these concerns play out in a social and emotional context different from that of the cohort with whom the innovation was introduced (Elias, Zins, Greenberg, Graczyk, & Weissberg, 2003). When first introduced to a program, implementers often have a cohort of colearners who are facing the same excitement, anxieties, and so on related to the program, and can support one another through the process. A new teacher, already needing to gain entry to a new workplace, may be the only one, or one of an isolated few, going through these initial awkward baby steps.

Developmental Arena 3: The Social-Emotional Learning Intervention

Another factor that operates in interplay with others in developmental progression is the nature of the intervention. At its inception, an intervention should be limited, tangible, and scripted. This allows it to incorporate complexity but not require full understanding on the part of implementers to carry it out. As long as its principles and procedures are clearly laid out in training and follow-up materials in ways that allow emulation, the implementer will be able to get a feel for what it is like to carry it out. As in the sensorimotor period of infancy, learning occurs without being accompanied by full understanding. Also, the intervention is not experienced as a flow or systematic sequence, but as a set of discrete events. Yet, operational knowledge sufficient to manage in the world in a rudimentary way is present.

From Discrete Intervention to Establishing a Flow

Feedback during this initial period of use is followed by the intervention being carried out for a full year or cycle (e.g., some interventions are designed for a set period of weeks or months, others go for a full academic year). It is at this point that the flow of an intervention is established and those implementing it can make realistic and comprehensive preparations for carrying it out. Among these plans are how to connect the intervention to other programs and services in the school and other experiences that the child has either in preparation or follow-up to the intervention. For example, in SDM/SPS, a first year of teaching students problem-solving skills led to a decision to provide them with readiness skills in 1 to 2 prior years, and then application opportunities to allow integration of problem-solving skills into academic subject areas in subsequent years.

Integration in the Culture and Climate of Classrooms and Schools

These expansions also go through the process of development, as noted earlier. In addition, within the classroom, an SEL intervention becomes integrated with classroom management—it becomes the umbrella under which related efforts are organized. At this point, the integration might not be clearly visible as such; it has become part of the culture and climate of the class. In Heinz Werner's (1957) terminology, the process of differentiation and integration takes a decisive turn toward the latter.

Yet, the process is not over. Interventions that operate only at the classroom level are still limited in their impact on the student body. The next part of the development of an intervention involves its principles being extracted and applied into building-wide SEL/SPS efforts. This includes such important areas as the overall school climate and the discipline and positive recognition systems used. Among the components one is likely to see that denote this process are administrator training and the training of bus drivers and lunch aides in intervention-linked techniques. Other indicators are an SDM/SPS Lab, Keep Calm Force (a schoolwide, peer-led self-control and problem-solving program), bulletin boards denoting application of intervention principles to everyday interactions and situations and academic content areas, positive recognition systems, and emphases on positive citizenship in and out of the school. In other words, the intervention tends to expand and become more comprehensive.

A Spiraling Process of 3 to 5 Years

At the same time, it becomes a bit harder to bring new people on board into this process because of turnover, changes in the target populations, and changes in the development of the adult learners. Sarason (1996) and others (e.g., Elias, 1997) suggest that it takes 3 to 5 years to proceed from the inception of a pilot intervention to its spreading systematically within an entire school building. To understand this process most accurately, it is best to think of it as a developmental trajectory that is less linear and perhaps more like a spiral in nature.

Developmental Arena 4: The Consultant

There are two aspects of the development of consultants that are of particular relevance. First, consultants gain experience over time, and thus develop expertise and so-

phistication. However, there is a second aspect of development. Over time, consultants are called on to handle more and more advanced stages of the intervention process. Schools call on consultants at different stages in the process of bringing in programs. The stages are:

1. Awareness
2. Training to begin
3. Ongoing consultation/support
4. Leadership team/administrator training
5. Program evaluation (including implementation monitoring, consumer feedback)
6. Intervention development and expansion
7. Contextual integration

Each stage brings its own nuances and requires consultants to have certain knowledge, skills, and perspectives. What happens almost inevitably, especially to effective consultants, is that they are called on to shepherd an SEL program through its various stages in a particular school or district over time. Ready or not, the consultant will have to develop the understandings and skills needed to deal with what is in essence a transformational process. Complexities abound, however, in that consultants might be working at different stages of programs at the same time in different settings, and sometimes they are called in to work at different stages, rather than following the developmental progression of stages during a single consultation.

1. Awareness

At this stage, consultants have the task of introducing an SEL program to potential adopters. This is best understood as marketing the intervention. Typically, the consultant has a limited time period, from 45 minutes to 3 hours, to introduce the intervention to a group that can be homogeneous (from one grade level), heterogeneous (from all elementary grades, or even K-12), to a mix (from the same school, but all different grade levels). The recipients may well be informed about the intervention, but it is more likely that they will not be, other than knowing the title or topic of the presentation and perhaps a synopsis. Rare indeed is the situation in which staff members will read an article in advance of an awareness training. Thus, the mind-set of the consultant must be one of reducing complexity, eschewing comprehensiveness, and maximizing entertainment/engagement as part of the workshop/presentation experience.

2. *Training to Begin*

If an awareness session goes well, the consultant may be called on to conduct a training with staff to get them started with the intervention. Several pragmatic factors influence the specific nature of the training, such as when during the school year it takes place (e.g., fall, early in the calendar year, May/June, summer, just prior to the start of school), the length of time (2 hours, a full day), the number and nature of staff people attending, and the extent to which the training is voluntary or mandatory (no, it is not incongruous to refer to degrees of mandatory, or even voluntary, attendance). Because the agenda of the consultant is to encourage trainees to begin and persist, whereas the main focus of the trainees is simply to begin in a sound, comfortable, effective way, another concern is the plan and resource allocation to follow up the training. One need not be a veteran consultant to recognize the inherent difficulties of conducting trainings in May/June or early or midsummer. Again, the consultant must balance how much to present the full year-long context of the program versus focusing on a segment but going into it in sufficient depth to allow trainees to begin to implement with confidence. Even in a full-day training, unless the groups are highly homogeneous and well prepared, it is difficult for consultants to give trainees a good feel for how the intervention looks and feels over the course of a school year and also have time to impart the skills and practice needed so that initial implementation goes well. A further consideration is the definition of "begin." How far along in the program should the consultant focus the initial training? In preparing staff from a single grade level from 10 elementary schools in an urban district for a 2-hour workshop, one consultant decided to focus on the generic structure of the lessons and then the first two lessons (out of 22 planned for the school year). Given how long it took staff from 10 buildings to arrive at a single location, functional instructional time was closer to 75 minutes. (Note that the decision about whether to start on time but then have perhaps 50% of the trainees come in while the training is in progress, versus waiting, is a vexing one that beginning consultants often do not anticipate.) Even in a generally positive and receptive climate, completing the two-session focus was a challenge under these circumstances.

It is useful to point out some developmental considerations here. The consultant is being asked to coordinate cognition, emotion, and behavior between the groups of trainees and the tasks for which they are being prepared.

The ability of the consultant to do this effectively increases with experience, reflection, and supervision. Some issues, such as how to address late arrivals, can be thought through in advance with the proper guidance; so can the issue of how to deal with absentees.

Werner's (1957) principle of differentiation and integration is relevant here as well. To do an awareness training, the amount of differentiation the consultant deals with is minimal. Deciding on what to emphasize, the consultant then must think of how to integrate these disparate elements so that he or she can have an integrated approach and the trainees can perceive their experience in an integrative, rather than scattered or disconnected, way. During a training to begin (as would occur at initial stages of implementation), the consultant has more to differentiate, but still not the full context of a year-long program. Integration usually needs to take place around the concept of "What do I do on Monday, and then the next Monday?" assuming that the cognitions, emotions, and behavior of trainees must be coordinated around these primary concerns.

3. *Ongoing Consultation/Support*

If there is an agreement to continue working with the consultant after the initial training, the consultant's attention must turn to how to support staff in implementing the program. Various studies converge to suggest that this is a pivotal point in the process for both psychological and pragmatic reasons (Diebolt, Miller, Gensheimer, Mondschein, & Ohmart, 2000; Gager & Elias, 1997; Greenberg & Kusché, 1988). The latter is self-evident. People want to be successful and comfortable taking on new tasks and would like to have questions answered before and after the initial session and receive feedback or support in preparation for the next one. The former has to do with the question of the school administration's commitment to the program teachers are being asked to carry out. Teachers want to know that they are not being asked to invest their time in a fad, or in a 1-year, short-lived, tangential intervention. No amount of verbal assurance is a substitute for tangible support. The consultant, then, needs skills in providing supportive consultation and feedback (a skill set that is more interactive and differentiated than doing a frontal group training) and needs to have the ability and perspective to negotiate a system or framework for that consultation to take place. Often, external consultants are constrained in being able to have the time and flexibility to observe and meet with teachers over the course

of a school year. Therefore, some procedure for developing local expertise must be developed. (Note that experienced consultants will often want to create initial agreements that include not only the awareness and initial trainings, but also the work that the consultant will do to help develop and sustain a system of ongoing consultation, support, and training.) This brings the consultant into the arena of administrative consultation and requires an understanding of district goals and policies, procedures and practices for staff development, staff schedules, and supervisory practices and methods of compensation.

4. Leadership Team/Administrator Training

It is one thing to have the administration agree to allow some staff members to serve in supervisory/coaching roles, and another for the administration to take ownership of the direction and operation of the program. Setting up an SEL or program-based leadership team is another pivotal task for consultants. To do this effectively requires consultants to understand well the roles of school administrators, social workers, guidance counselors, school psychologists, health educators, and character education and substance abuse and violence/bullying prevention coordinators. Should there be student-family support staff or any position with responsibility as a liaison to parents and the community, that person's input is also important because one of the purviews of the leadership team is funding. Consultants must know these roles because roles that might be assigned must be congruent with existing duties and patterns of availability. Designing and implementing a training for this group requires that the consultant find a way to concisely convey the key elements of the program, its pedagogy, and the expected implementation time line and structure. In addition, attendees should be exposed to basic principles of supportive, constructive supervisory feedback to teachers. And there is yet another level of concern: The leadership team will assume responsibility for program planning and evaluation, and so training in this process and the tasks involved must be provided. As before, the consultant must deal with logistical constraints (such as number and length of sessions and expectations about attendance and absence) and the attitude of staff toward the program and its implementation (Gager & Elias, 1997).

What begins to happen at this stage is that consultants are being asked to switch cognitive, emotional, and behavior gears in an increasingly disparate context. It is one thing to work with multiple schools or districts within the same or adjacent stages; that provides great

variation and challenge for the consultant to keep straight. But it is another to shift back and forth between the awareness level, which eschews detail, and the ongoing consultation and support levels, which require it. Many consultants flounder as they experience difficulty inadvertently increasing the complexity of their awareness or initial trainings or, less often, oversimplifying their ongoing consultation and related work in the name of getting easy acceptance. Commins and Elias (1991) showed that such simplification is associated with reduced program longevity in schools, whereas presenting programs at an appropriate and realistic (but not excessive) level of complexity is associated with longer program endurance.

5. and 6. Program Evaluation (Including Implementation Monitoring, Consumer Feedback) and Intervention Development and Expansion

Whereas some level of accountability is a constant concern at every stage of consultancy (including the process by which the consultant monitors and evaluates his or her own efforts), systematic program evaluation efforts usually emerge once a leadership team, social development committee, or similar structure is established (Elias et al., 1997). Program evaluation is deceptively complicated, and consultants who are not trained in this area will find themselves needing to build their expertise or bring on consultative assistance. The first challenge is to find ways of monitoring what is actually happening with the program: who is carrying out lessons, with what frequency, and with what degree of fidelity. Without knowing how the program is implemented, it is impossible to make any inferences about the relationship of the program to any observed outcomes. Consumer feedback is also important, because a program that teachers and other school professionals do not like to implement and that students do not enjoy receiving is unlikely to be carried out in an effective and enduring way. This is not to say that consumer satisfaction is a primary criterion, but it is a necessary, though not sufficient, condition for long-term program success.

Intervention development is the process of refining a program based on feedback. Where something is not working for a subgroup of students, modifications must be made. This is not a simple process. Staff members need to be involved for maximum buy-in, and those modifying the program must know its key elements and make changes that do not change the character of the program (especially if it is an evidence-based program). However, programs tend not to be static, and the most

recent view about program effectiveness is that programs must be multiyear in nature. True skill gain in children is cumulative in nature, and so programs must be carried out over multiple years (Weissberg & Greenberg, 1998). If a given program has been created to operate over multiple grade levels, then at least the materials and structure are available for the consultant to work with. Sometimes, however, a program exists only through grade 3, or grade 5, and a school wants to expand it to the next grade level. This will require a new skill set for consultants and will take them into collaborative relationships with teachers and perhaps program developers. Thus, the consultant must develop new skills related to curriculum/program content and be prepared to serve not purely as a consultant but as a collaborator in program development and expansion efforts.

7. Contextual Integration

Another recent insight about SEL programs is that they need to be integrated into the structure, climate, and organization of the classroom if they are to succeed (CASEL, 2003). And if programs are to have an impact on the school, they also must be integrated into the overall structure and climate of the school. Social and emotional learning must become salient outside the classroom and influence what happens in the hallways, lunchrooms, bus rides, discipline procedures, and how everyone in the school interacts with one another. Further, students benefit most when SEL is continuous across schools.

None of this should be surprising because the points are the same for academic skill acquisition. If reading were to be limited to classroom lessons, not continued at all grade levels, not carried out from school to school, and, particularly important, not done with any consistent approach across settings, children would be quite impaired in their literacy development. If children do not receive SEL across grade levels in a coherent and high-quality manner, they may be at risk with regard to developing the skills they need to maximally carry out their responsibilities as adults. Consultants develop from being focused on the delivery of a particular program in one classroom to providing the array of supports necessary to ensure that children develop substantial SEL skills. An extended example of such development is provided in the accompanying vignette.

Developmental Area 5: The Child

The development of social and emotional competencies has been extensively researched. The scope of the topic

and the various subcomponents of many of these competencies contribute to the amount of research done. For example, emotional skills can be broken down into sub-units, including identification of emotions in oneself and others, the regulation of emotion, and the communication—both verbal and nonverbal—of emotions. It is not our intention to review this literature in its entirety. Rather, we trace the trends in the social and emotional expectations that can be held for students as they develop and that can become curricular foci for school-based intervention of the type described in this chapter.

A helpful rubric for organizing this complex literature is provided by Elias et al. (1997), who trace trends in social and emotional development through different age groups (early elementary, elementary/intermediate, middle school, high school) within various developmental contexts (personal, peer/social, family, and school- and community-related). This clustering of age groups not only simplifies understanding of the developmental trends, but also underscores the nondeterministic nature of a child's specific age. Although trends exist, great variability can be expected within any group of same-age children. As readers encounter this review, they might find themselves thinking, "This doesn't describe the 8-, or 10-, or 12-year-olds I know!" This response is anticipated by the authors and is a by-product of the variability within ages mentioned earlier. The approach we take here is one of reviewing what students at this age generally *can* do, especially with proper support from adults, rather than what might be seen in any given interaction or social situation. We take such an approach because the focus of this chapter is on how developmental issues can inform school-based programming. Such programming strives to help students achieve the types of competencies we describe here as reasonable expectations.

Early Elementary

In terms of the personal arena, early elementary students are generally developing the ability to express and manage basic emotions (such as fear, anger, excitement), can differentiate between negative and positive emotions, and can use increasingly complex language to express emotion. They are increasingly able to tolerate frustration and delay gratification and to manage turn taking, although these skills will be demonstrated inconsistently. "Although the preschooler begins to use language to facilitate self-control and begins to engage in cognitive planning in the service of frustration tolerance, the ability to effectively and automatically use these processes transpires primarily during the

One Consultant's Developmental Journey

One of the authors (MJE) worked with an urban school district over a 7-year period, allowing for a journey through all seven of the stages of consultant activity. This example is instructive because it also involves SDM/SPS. However, in the focal school district, an urban, high-risk setting in central New Jersey with poor test score performance, SDM/SPS had to be modified to be sensitive to the predominantly African American population and also the strong literacy needs of the students. Thus, at the 2-hour awareness workshop, attended by teachers from grades 2 and 3 across 10 elementary schools, an attempt was made to introduce SEL, introduce a specific curriculum program, Talking with TJ (Dilworth, Mokrue, & Elias, 2002), show its appropriateness with regard to culture and literacy, and provide teachers with a practice opportunity that would allow them to carry out an initial lesson. There was no additional opportunity to provide training to begin. Teachers were expected to begin, and I, along with an African American graduate student assistant, provided follow-up to teachers in all 10 schools. We did this by meeting with them during available slots between 2:35 and 3:05.

In the course of providing ongoing consultation and support, we became aware of how few teachers had a good feel for the program and recognized that this would have to be accomplished without formal training. We recruited Rutgers undergraduates, trained them in the curriculum, and sent them into many classrooms so that they could provide direct feedback and assistance to teachers and help to convey their feel of the program. This helped make our ongoing consultation efforts more useful. However, we also recognized the limitations of this approach over the long term. Thus, I turned my attention to working with the superintendent of schools and a special assistant assigned to provide administrative support to the SEL effort to develop a leadership team and support structure. My consultation involved a level different from working with and supporting teachers, which was continued by graduate and undergraduate students who had familiarity with the program but not with working with administrators. The key need was to provide channels of communication from the teachers to the Rutgers Social-Emotional Learning Lab team that was supporting the program, and also local building-based leadership in bringing SEL across grade levels and into the school climate beyond its presence in curriculum lessons. Opportunities to address the administrative cabinet were used to help principals understand the theory and pedagogy behind the program and to appreciate the specific actions they needed to take to support teachers in their work (e.g., ask them to submit lesson plans showing when they would implement the program, assist them in finding the time and context if they were having difficulty, and provide feedback based on the lesson plans and direct observation when possible). Administrators also selected "TJ captains" in each building; these were teachers who had the role of speaking with other teachers carrying out the program and raising concerns proactively with members of the Rutgers team. So the consultation task shifted from working with all teachers to working primarily with the TJ captains and occasionally working with teachers who needed special help.

Another consultation task was working with the building-based SEL coordinators. This involved helping them to see ways to extend SEL to schoolwide efforts, such as positive recognition of students and creating school citizenship and service activities, bulletin boards, plays focused on SEL themes, and literacy activities such as the Principal's Book of the Month. They also needed help communicating about SEL within their buildings, across buildings, and to parents.

There were other nuances of consultation not mentioned; for example, another diverse area was evaluation. Here, the primary consultee was the school superintendent. He wanted ways to monitor the implementation of the program and its outcome. Consultation required knowledge of formative and summative evaluation procedures, as well as how to convey them in a practical manner and deal with the logistics of carrying out this assessment in an environment already saturated by standardized tests. Consumer satisfaction surveys were put into place and completed by teachers and students. Teachers also completed an assessment related to levels of use. Teachers rated students' behavior on a standardized teacher rating scale, which was shortened and modified for use with urban, low-income minority populations (at the request of teachers), and students completed measures of SEL skills, self-concept, social support, and school violence and victimization. Clearly, this requires a very different kind of activity by a consultant than any previous stage.

As data from the program indicated positive receptivity and successful outcomes (Dilworth et al., 2002), there was a desire on the part of the school district to develop and expand the intervention. The development included adding a character education component, the Laws of Life essay, to the skills-based Talking with TJ curriculum. The expansion was creating a curriculum for grades 4–5 and then K–1. These changes required work by the consultant to integrate Laws of Life and Talking with TJ into the literacy curriculum. At the same time, the building-based SEL coordinators increased their efforts to better connect the program with other elements of the school day to increase the impact on school climate. For this to take place, the consultant needed to coordinate more with school principals and to grasp the big picture of how SEL could unfold within the culture of each of the schools. Managing this diversity across 10 schools is challenging, as is the need to continue the consultative cycle as each new component to the curriculum was added on.

Other skills that were required over the course of the 7 years included writing school board policy around SEL, dealing with high staff turnover, and following up the program into the two middle schools and high school. In each case, new areas of expertise were required, and sources of support and information had to be tapped for the consultant to effectively meet these needs.

elementary school years" (Greenberg & Snell, 1997, p. 106). However, they still often employ behavioral, rather than cognitive, strategies to deal with stressors (Brenner & Salovey, 1997). Students at this level are beginning to be able to consider the feelings and intentions of others in a reflective, role-taking capacity, even showing early signs of differentiating the feelings of different people in different contexts. They are becoming able to generate alternative possibilities for action in interpersonal situations.

Students at this age are learning basic skills that will remain vital to peer functioning. They are developing competencies in areas such as listening, sharing, cooperating, negotiating, and compromising. These students understand similarities and differences between self and others. They are able to demonstrate empathy toward their peers and become distressed at the suffering of others, and often respond by helping a child in need. They are also learning about themselves, can express themselves through artistic and dramatic representations, can express their likes and dislikes, and are learning about their own strengths. The ICPS, Second Step, and Responsive Classroom Programs are especially strong at this age level.

Middle Elementary

Students at a middle elementary level are moving ahead in many of those competencies initially begun earlier. Their repertoire of labels for emotions is expanding, and they can generally be expected to exercise more control over their anger. They can calm themselves down when upset and verbalize how they are feeling and describe what happened. They can learn strategies to cope with strong emotional situations. They are developing more positive ways to express their feelings. When they do lose their temper or become upset, they can generally calm themselves down, increasingly tending to use cognitive as opposed to behavioral strategies to deal with stressors, and they are forgiving regarding the situation. From this age into the next cohort, students are developing repertoires of coping skills and learning to match different strategies to different types of situations (Brenner & Salovey, 1997).

Students at this grade level are making advances in sociocognitive skills as well. They are increasingly able to set goals and to continue to work toward these even in the face of obstacles. Abilities to anticipate outcomes and consequences of actions are improving. Students at this level are becoming increasingly self-aware, particu-

larly regarding their own strengths and weaknesses and those of others. They are learning not to be derailed by failures. Skills in perspective taking continue to grow.

Social interactions at this level are more complex, with cooperative planning and joint problem solving taking place. They are grappling with a set of social skills such as making new friends and entering new and expanded peer groups. They are accepting of diversity and difference. They call on improved skills in being able to manage a reciprocal conversation and judge and anticipate the thoughts, feelings, and actions of others. They can modify their interactions—verbal and nonverbal—to suit different audiences (e.g., peers, teachers). With the increased peer interactions come an increased awareness of peer norms and sensitivity to pressures for conformity. Also, students at this age are developing skills in assertiveness, boundary setting, and dealing with rejection. In school, students at this age are increasingly able to work on teams and to see projects through to completion and experience pride in a job well done. The skills emphasis of Providing Alternative Thinking Strategies (PATHS; Greenberg & Kusché, 1998), SDM/SPS, and Open Circle are especially well matched to this age level.

Middle School and Beyond

As we turn our attention to middle school, we find students who are entering adolescence, with its attendant social and behavioral changes. In terms of social and emotional development, there are several trends that can be traced. Students at this stage are increasingly self-aware and, often, self-critical. Their sociocognitive skills are making great strides. They are able to understand multiple sides of arguments and disagreements. They are sensitive to perceived social norms and often judge their own abilities and self-worth by others' reactions to them. They can identify their own self-talk and acknowledge its importance. Although they are increasingly able to articulate goals, both long and short term, it is often difficult for them to modify actions to come into line with achieving these goals. As with those that precede it, there is often a great disparity at this age level between what one *can* do under structured conditions and what one *will* do in actual situations.

Peer interactions are undertaken with a great sensitivity to popular trends, but at the same time with increasing introspective thoughtfulness and ability to distinguish between good and bad friends. Belonging becomes an important issue to students at this age, and friends strive to develop ways to deal with conflict and

solve problems while maintaining friendships. Throughout adolescence, students are gaining skills in peer leadership.

As students progress into high school, perhaps the most important theme is that of increasing integration among the various developing social and emotional skills under the broad umbrella of developing a stable sense of identity and set of long-range goals.

During adolescence emotions noticeably become the basis of identity and ideals. What adolescents care about is usually what they feel strongly about—not only feel intensely but also feel variably. . . . Adolescents become aware of feeling everything, and this transforms their values and their understanding. (Haviland-Jones, Gebelt, and Stapely, 1997, p. 244–245)

Adolescents become more interested in questions of personal meaning, transcendence, and goals for personal accomplishment. One's own decisions and behaviors, including those regarding friendships and peer relations, school functioning, balancing independence and interdependence within one's family, all become crucial pieces in an ongoing process of self-definition.

Effective programs at the secondary level include Lions-Quest, and especially their Skills for Action service learning program (www.lions-quest.org), the Giraffe Heroes Program (www.giraffe.org; Graham, 1999), Facing History and Ourselves (www.facing.org), and the Resolving Conflict Creatively Program (www.esrnational.org; DeJong, 1994).

Special Populations

This section began with a caveat that variability is the norm in the development of social and emotional skills. However, consultants must be aware that students with clinical diagnoses or special educational classifications will often show particular patterns of deficit in the development of such skills. In fact, social and emotional skills deficits are in many cases pathognomonic of clinical diagnosis and a part of the defining feature of educational classifications. For example, interpersonal interactions marked by hostility, bullying, and cruelty are among the diagnostic criteria of Conduct Disorder (American Psychiatric Association, 2000). Anxiety and depressive disorders clearly have affective symptomatology as primary features.

Further, as we have discussed elsewhere, “Children with mild disabilities tend not to be accepted by their

peers, and they display shortcomings in the way they interact with parents and peers” (Elias, Blum, Gager, Hunter, & Kress, 1998, p. 220). Children classified as learning disabled face an array of social and emotional challenges. For example, as reviewed by LaGreca (1981), these students have more negative peer relations than their nondisabled peers, receive more negative responses from their peers, and are less adept at initiating helping behaviors. The specific nature of a child's learning disability may impact the social and emotional manifestations: “For example, students with more severe cognitive impairments may lack age-appropriate social understanding of complex interactions. Language impaired students may have appropriate understanding of social situations but may have difficulty communicating effectively to others” (Elias & Tobias, 1996, p. 124). As reviewed by Elias et al. (1997, p. 65), children with a variety of classifications, including learning disabled, language disordered, with mild mental delays, neurologically disordered, and with hearing loss, “often have related difficulties in the areas of social and communicative competence. They are more likely to show difficulties in effectively reading social cues from others and managing frustration and other high intensity emotions.”

Students classified as emotionally disturbed could be differentiated from their nonclassified peers on the basis of deficits in interpersonal problem solving (Elias, Gara, Rothbaum, Reese, & Ubriaco, 1987). For emotionally disturbed (ED) populations, the distinction between skill deficits (i.e., mastery of social skills) and performance deficits (i.e., lack of motivators to use skills that are possessed) becomes particularly salient. In addition, many ED students have incorporated previous negative outcomes in social situations into a set of expectations for continued difficulty and a negative self-image based on such expectations (Elias & Tobias, 1996). Students with a variety of classifications (including LD and ED) show deficits in nonverbal aspects of emotional interactions (see Kress & Elias, 1993, for a review).

Trends in the use of social and emotional skills have been studied in various clinical child populations. For example, depressed children and early adolescents were found to be less likely than nondepressed peers to use cognitive strategies for coping with negative mood states and more likely to use negative behaviors to cope in such situations (Brenner & Salovey, 1997). Research suggests that children with conduct and aggression problems may misread ambiguous nonverbal cues and make hostile attributions for the behaviors of others (Dodge,

1980). Surprisingly, few programs have been developed for special populations. Project OZ and the SDM/SPS program (Elias & Bruene-Butler, 2005a, 2005b, 2005c) are among those that have shown effectiveness in these contexts. Work done by the authors with the SDM/SPS program with a special needs population is highlighted in the discussion later in this chapter.

In conclusion, a consultant's attention to the area of children's development of social and emotional competence must be informed by both possibility and reality. As discussed in this section, there are trends in what can be expected from most students as they move through the school years. However, there is considerable variability in any group and some more systematic deficits found when dealing with clinical or classified subpopulations. As programs are targeted to student needs, efforts must build on strengths of, and address needs in, individual students to move them ahead in their social and emotional functioning. If this process is seen as a social and emotional skill analogue to the Vygotskian (1978) idea of the zone of proximal development, then the consultant is left with the question of how an individual's environment (in this case, primarily but not limited to the school environment) can facilitate skill development and use.

INTEGRATION: THE GRADIENT OF DEVELOPMENTAL RELEVANCE

The previous sections outlined several arenas that exhibit developmental change over the course of implementation. Although these arenas are reviewed individually and separately, it is our strong belief, grounded in our experience as consultants, that these arenas can be better understood as intersecting and existing in dynamic relationship. At any given point in the life of a programmatic effort, a cross-sectional freeze-frame can be taken of each of these arenas, but once the scene is allowed to progress, changes in one arena will bring changes in others. The dynamic nature of these interactions often makes it difficult to state where an evolution of these arenas begins, which is the cause and which is the effect.

As a matter of practice, the beginning of a consultation/intervention program defines the starting point along all of the dimensions, though the starting point is not necessarily at the beginning of the dimension. As an example, in the 2nd year of an intervention, the original group of students typically will be in the next grade

level. The faculty who implemented in the 1st year will now have a year of experience under their belts and will face a new group of students. However, new faculty will not be at that same point. Thus, the experience of the faculty, their need for consultation, and the experience of the students (as well as the impact of the program) will be different. If we look ahead to the following year, teachers in the next grade will find students coming in with greater variability than they experienced after the 1st year of the intervention. This is something for which they need to be prepared and for which consultation will have to take place. The situation is further complicated if the intervention is followed up in the next grade level. To what extent will the consultant be prepared to deal with these issues? They will require considerable flexibility, as well as deep knowledge of the intervention to allow for changes to be made that optimize what particular teachers can do. These new needs and the new perception of needs may necessitate a change in the original programmatic focus. To support this, a consultant may need to plan for increased training and support for a program that had been running with less oversight.

The picture is beyond one of intersecting lines, and more of interdependent forces. That is, although it is the case that any temporal cross section will reveal various points in each of the developmental trajectories, paths of any one arena will influence all the others. The scenario depends on where one starts the story, but in reality the arenas exist in dynamic interrelationship. As the program moves along, staff concerns will change, the needs of the students will change (based on natural factors and on the impact of the program), and the staff's perceptions of the students and their actions and needs might change. To make appropriate consultative decisions, a consultant must be able to judge options against where each arena is in its development. We use the term "gradient of developmental relevance" to refer to the conditions created by the interacting developmental needs of the various arenas. New information, decisions, procedures, and so on can be evaluated against the gradient of developmental relevance to assess where they fit within this ever-evolving system.

An apt analogy might be to the leader of an improvisational jazz band.² Each developmental arena can be seen as a band member, playing a particular improvised

²We are honored to continue Jim Kelly's line of jazz analogies applied to community psychology concepts!

line of music. Just as a bandleader might go in with a certain set of parameters in mind—a particular tempo or key—the consultant may be guided by research on effective practice (e.g., Elias et al., 1997). The consultant (who, in most cases, embodies all of the band members and has to serve as the conductor) has to work in a dynamic way, without a script, often by feel, to keep the instrumentation moving forward in a harmonious way. There is a framework for guiding the leader's decisions, but there is not note-for-note scripting. It remains up to the consultant to make it all come together. A consultant with an understanding of trends in each of the developmental spheres has the same advantage as a leader of a well-rehearsed (rather than a newly formed) jazz group. Although each member works on his or her own, the leader has come to know about the style and tendencies of each and can anticipate possible next moves (though there is always room for surprise). Likewise, knowing developmental trends allows the consultant to apply additional structure to decision making, while still remaining flexible enough to handle what is essentially a constantly shifting set of contextual realities.

DEVELOPMENTAL SNAPSHOTS

Our developmental snapshots are pulled from work at The Children's Institute (TCI), a private, nonprofit, out-of-district school for students ranging in age from 3 to 16. The school was founded in 1963 and is divided into preschool, elementary, and middle school levels. The school receives out-of-district placements from a broad area throughout northern and central New Jersey, with over 40 different districts represented. As such, the school population is quite diverse in terms of both socioeconomic status and ethnicity, although male students constitute a majority (90%) of the enrollment. Students are referred to TCI with one of three classifications: preschool handicapped, emotionally disturbed, and autistic.

Students at TCI receive instruction in all academic areas and, in addition, receive therapeutic services. These services are provided by two specialty areas. Crisis workers provide a frontline intervention for students exhibiting an acute behavior that can no longer be accommodated in the classroom. The model, at least early on in the chronology of the program, was for crisis workers to be called in an emergency and to remove the indicated student from the classroom until the crisis de-

escalated. The second line of therapeutic intervention was provided by social workers. In contrast to crisis workers, social workers saw children on an ongoing, scheduled basis. The social workers are the object of our first snapshot, and more will be said about them in the next section.

Although a school focusing on students with emotional disorders can be seen as addressing social and emotional needs on an ongoing basis, formal implementation of SEL programming began in 1989, with the implementation of the SDM/SPS program. SDM/SPS was created in 1979 through collaborative efforts among psychologists and educators from Rutgers University, the University of Medicine and Dentistry of New Jersey, and school districts in New Jersey. Over the years, curriculum guides have been developed for the elementary and middle school grades (Elias & Bruene-Butler, 2005a, 2005b, 2005c; Elias & Tobias, 1996). Books written specifically for parents helps carry-over of school-based programming (Elias, Tobias, & Friedlander, 2000, 2002). The program is implemented in the classroom by teachers (or other staff) who are trained to deliver the program. The program has undergone extensive research (Bruene-Butler, Hampson, Elias, Clabby, & Schuyler, 1997) and has received commendation from the National Education Goals Panel, the U.S. Department of Education's Expert Panel on Safe and Drug Free Schools, the Character Education Partnership, and the Collaborative for Academic, Social, and Emotional Learning (CASEL, 2003).

The general structure of the program is shown in Table 15.3. SDM/SPS can be broken down into three phases: readiness, instruction, and application. The readiness skills cover the fundamental components of self-control and social awareness/group participation. This part of the curriculum got its name from the idea that these skills are essential building blocks, or needed tools, for proper decision making. Lacking self-control and social awareness, we are unlikely to engage in productive problem solving and are subject to "emotional hijacking" (Goleman, 1995), which derails rational thought during high-threat situations. Table 15.3 shows the skills covered in the readiness phase. A major focus of the readiness phase has to do with setting the stage for effective conflict management and fostering self-discipline and socially responsible behavior even in the face of situations that might tax such positive outcomes. To begin to address these issues, teachers introduce an interconnected set of skills in conflict resolution and

TABLE 15.3 Basic Structure of the Social Decision Making Approach

<i>Readiness Skills</i>
A. Self-control skills:
1. Listening carefully and accurately.
2. Following directions.
3. Calming oneself when upset or under stress.
4. Approaching and talking to others in a socially appropriate manner.
B. Social awareness and group participation skills:
1. Recognizing and eliciting trust, help, and praise from others.
2. Understanding others' perspectives.
3. Choosing friends wisely.
4. Participating appropriately in groups.
5. Giving and receiving help and criticism.
<i>Skills for Decision Making and Problem Solving</i>
1. Finding feelings for yourself and others.
2. Identifying issues or problems.
3. Generating goals to guide your decision.
4. Thinking of alternative solutions.
5. Envisioning possible consequences.
6. Selecting the best solution.
7. Planning and making a final check for obstacles.
8. Noticing what happened and using the information for future decision making and problem solving.

anger management. In introducing this set of skills, a teacher may lead a discussion of the importance of being able to stay calm in stressful situations (e.g., by asking the students to share experiences where they had difficulty calming down and the consequences of that). The teacher may have students discuss situations when it is particularly difficult for them to stay calm ("trigger situations"), and internal "feelings fingerprints" that signal stress. "Keeping calm" is broken down into component skills, which are demonstrated and practiced, with feedback given to the students as they practice. The teacher often has students role-play use of skills as they are introduced. Particularly important, the phrase "Keep Calm" is established as a prompt and cue for the desired behavior. This behavioral shorthand can be used by the teacher and other staff members throughout the school to call for the skill when needed. Students may be prompted to "Keep Calm" during difficult times such as transitions or before exams. Teachers can model use of Keep Calm during situations where they might be feeling particularly stressed. As students become adept at using Keep Calm, the teacher can ask students to share situations in which they used Keep Calm in class or at recess. Aides and other staff can prompt students to use the skill as needed.

In the instructional phase of the curriculum, students are introduced to eight skills of decision making, as

summarized in Table 15.3. The acronym FIG TESPN can be used as a mnemonic to assist students in remembering the process. Notably, the first step focuses on feelings. Emotions are seen as important guides through the problem-solving process. The eight decision-making skills are taught directly and through the use of a guided facilitative questioning technique to help students move through the process.

Comprehensive programming involves infusion of SEL skills into all aspects of the educational experience. Application activities provide opportunities to practice new skills in academic and social situations. Once introduced, SDM/SPS skills can be applied to content areas. A teacher may use the terminology of problem solving to analyze a situation in a story (What was the character feeling? What was the problem?) or to make a decision about how a student will present material from a research project. Students can be prompted to use SDM/SPS skills in real-life situations such as recess and lunch, and then this experience can be processed with them.

Implementation of SDM/SPS at TCI began with a pilot group of six teachers and assistants and all of the social workers, crisis workers, speech teachers, and specialists (e.g., physical education). Consultation for the program was provided by graduate students (including JSK) familiar with the program and working under the supervision of one of the program's creators (MJE). From the beginning, the vision of the school leadership called for SEL programming that is "integrated within all aspects of the special educational setting throughout the entire school day" (M. Cohen, Ettinger, & O'Donnell, 2003, p. 127). As such, as the programming progressed efforts were made to train all school personnel and to orient any new staff to the SDM/SPS program. Throughout, consultation was provided by graduate students and their faculty supervisor at Rutgers University.

These descriptive snapshots are drawn from several sources. Aside from the reflections of the authors, who were each involved in a variety of consultative roles at TCI, data are drawn from several written documents. The primary source of documentation is a dissertation written by the school director (Ettinger, 1995) that documents the systemwide changes and initiatives that occurred during the period from approximately 1993 to 1995. Because SEL has such a central role in the school, the documentation of this period provides rich descriptions of the work done in this area. Also, the consultation team was able to publish two journal articles based

on their experiences (Kress et al., 1997; Robinson & Elias, 1993), and these provide an additional perspective on efforts at TCI. Finally, school leaders published a chapter describing their efforts (M. Cohen et al., 2003).

Developmental Snapshot 1: Resistant Clinical Constituents

Our first snapshot concerns a difficulty encountered in achieving the outcome of schoolwide implementation. As indicated in a previous section (cf. Novick et al., 2002), successful implementation of any SDM/SPS program depends on mutual acceptance of program goals, methods, and responsibilities on the part of those called on to implement the program. Looking at the developmental trajectory of the TCI implementers, it was clear that not all constituents achieved this, at least not within the same time frame. Within approximately 3 years of initial implementation, use among classroom teachers could be described as moving toward stabilization of programming. Supports were set up for new teacher-implementers, meetings were initiated in which implementers were able to share accomplishments and discuss obstacles, and a committee was formed to address SPS/SDM programming (Robinson & Elias, 1993). However, at the same time, it was noted that the school social workers were not actively participating in implementation efforts.

The participation of social workers emerged as a concern as early as 1993, when results from interviews conducted by the school principal led him to set social worker-teacher collaboration as a goal for enhancing SEL efforts. Further, the nonparticipation of the social workers was a source of dissatisfaction by the classroom teachers, who felt that their own efforts were not extending beyond the classroom.

The roots of the differential readiness of social workers (as opposed to classroom teachers) to implement the program can be speculated on. One cause might have to do with the educational background and subsequent theoretical perspective of the social workers. According to the school principal, "Clinical staff members had extensive training and education in psychodynamic interventions and understanding children's psychopathologies. However, they had minimal course work in education of the emotionally disturbed child" (Ettinger, 1995, p. 15), and in particular, very little with regard to the type of cognitive-behavioral approach that underlies the SDM/SPS program.

The reaction of the social workers to SDM/SPS implementation is best summarized from a segment from the administrator's dissertation tracing program implementation during the period at approximately the 4th year of implementation:

The social workers' graduate studies had prepared them to work in a traditional mental health setting using a psycho-dynamic approach emphasizing insight therapy with pullout mental health services. They were committed to treating children in a private confidential manner in settings separate and apart from the students' daily routines in school, the classroom, and in the community. They perceived their role with staff members as that of the professional consultant, providing recommendations and advisement. . . . Due to the clinical paradigm the social workers were clinging to, they were resistant and threatened by the psycho-educational model this staff development project promoted. Social workers had expressed concerns that implementing the behavior management program, participating in leading SPS sessions, and conducting social skills training would result in their losing their identities as therapists. (Ettinger, 1995, pp. 36-37)

It is possible to look at this snapshot through the lens of the developmental arenas described previously. The increased emphasis on the role of the social workers, and the concern at their resistance to assuming this role, can be seen as emerging from the developmental needs of the students in the setting. The students at TCI, by virtue of the presenting classification for their referral to the school, exhibit pronounced deficits in social competence, particularly in the areas of self-control. Efforts to remediate these deficits are complicated by the fact that many of these students exhibit learning problems that confound skill development. TCI students are involved with multiple educational and psychotherapeutic personnel throughout every school day.

Combined, these factors point out the need for intensive, coordinated efforts to address SEL outcomes in these students. For one constituency to fail to support this effort raises the concern that efforts will not be enough to overcome the challenges faced by the students. To address this, the intervention model itself began to develop as well. Individual teacher implementation efforts were augmented by ever-widening spheres of schoolwide implementation. In addition to featuring specific expectations placed on the social workers, the period of this snapshot was also characterized by increases in the number and variety of specialists and

other school personnel trained. Along with this came increased efforts at developing communication structures so that all implementers would target a similar set of skills with particular students.

This snapshot illustrates the potential for different cohorts of school-based personnel to be at varying developmental stages of both their usage and their concern with regard to an intervention. The concerns expressed by classroom teachers regarding the lack of carry-over by the social workers can generally be thought of as representative of those who have had experience working with an intervention and are looking for ways to maximize impact, particularly by finding others to support their efforts. From a development of implementation standpoint, the teachers were implementing and refining (Table 15.2). However, their efforts to move ahead to the next level of implementation, that of integrating their efforts with those of others, had been complicated by the social workers' resistance. In terms of the teachers' development as adult learners, a similar situation existed. Teachers were interested in the consequences of their work and in improving their efforts. However, movement to collaboration, a common next stage, was hindered.

The nature of the SEL intervention was itself in developmental flux, with increased attention being given to applying specific behavioral techniques to a focused effort on the readiness skills of self-control and social awareness. At this point in the implementation, the Rutgers-based SDM/SPS consultant was also working at several developmental levels. Part of the consultant's focus was on helping to provide training and consultative support, both basic and advanced; the development of institutional ownership (Kress et al., 1997) was a major goal as well. Major SDM/SPS implementation and leadership functions rested in the hands of a multidisciplinary team comprising school leadership and representatives from various school constituencies (teachers, assistants, clinical staff, specialists). The consultant was a member of this team, but did not assume a leadership role.

To summarize, this snapshot of resistance on the part of one constituency occurs within a gradient of developmental relevance understood as the convergence of developmental trajectories of the implementation process, the intervention itself, the needs and concerns of the implementers, the role of the consultant, and the needs of the program recipients. As student needs became clearer regarding collaborative efforts focused on social competence promotion, teachers became frustrated by per-

ceived impediments to the effectiveness of their efforts. The consultant was playing a supportive, rather than a leadership, role. Understanding this gradient not only helps in terms of problem definition—understanding the greater context in which the social workers' resistance took place—but also helps in conceptualizing the way that solutions were implemented.

School leadership, functioning at a point of increasing ownership of the SDM/SPS program, worked to redefine the job description of the social workers "to place more emphasis on social workers serving as case managers who coordinated in and out-of-school services and to include their role in sps [sic], social skill training, and parent education" (Ettinger, 1995, pp. 135–136). Social workers were expected to co-lead SDM/SPS social skills groups along with the classroom teachers and to provide carry-over for skill building in their individual clinical work. Recognizing that the social workers were at a different developmental point in both implementation and concern about the intervention, specific efforts were made to provide training with regard to their role in the skill-building endeavor. Leadership made efforts to make its expectations clear, even going so far as to remove a social worker from a case due to unwillingness to "support the [behaviorally based] plan due to [the social worker's] psychoanalytic orientation" (p. 169). Other structural components were put in place to provide opportunities to reinforce social worker efforts, as well as to increase accountability. For example, social workers and teachers were asked to present at staff meetings the joint social skill lessons they developed and implemented.

To increase the degree to which such training was consistent with the values and expectations of the social workers, the social workers were provided with literature and data regarding the efficacy of social skills interventions. In addition, further training and ongoing consultation were provided by a practicing clinician, who, although coming from a theoretical orientation different from the social workers', could more specifically address the clinical issues they confront. This clinician worked with social workers both on clinical case issues and on their work with social skills groups in the classroom, providing both professional modeling and links among their work. The addition of another consultant also had the benefit of allowing the Rutgers-based SDM/SPS consultant to maintain the focus on transferring ownership and leadership to school personnel. Close supervision and observation of a large cohort of the school might have sent an unintended message about

the consultant's interests in the school leadership being empowered to guide implementation.

These efforts appear to have had an impact on the role of the social workers in the school. Several years after the more intensive work with the social workers, M. Cohen et al. (2003, p. 137) updated the role of the school clinical staff: "The clinician combines a cognitive-behavioral approach, classical behavioral principles (TCI's Token Economy), and psychodynamic techniques to promote social competence through social-emotional skills training and social problem solving." However, this should not give the impression that the process was simple and linear. Social workers did not always report satisfaction with their new roles, and sometimes it took changes in staff before appropriate implementation occurred.

Snapshot 2: Integrating Interventions

The second snapshot plays out over the same period of time as the previous one. Feedback from various sources suggested that efforts to promote the desired SEL outcomes in the TCI population would be enhanced by "the use of a social skills curriculum that provides direct instruction and opportunities for practice, rehearsal, and application" (Ettinger, 1995, p. 7). The importance of a structured behavioral approach for emotionally and behaviorally disordered children and adolescents was stressed by program consultants and bolstered by the school executive's reading of research literature related to specific social skills deficits in these populations. The decision was made to integrate another social skills curriculum, Skillstreaming (Goldstein, Sprafkin, Gershaw, & Klein, 1980), into the school's SEL work.

It is notable that this desire for a structured behavioral curricular approach emerged from a setting that was in the midst of implementing a program that was based on a similar array of cognitive-behavioral principles. The "direct instruction . . . practice, rehearsal, and application" mentioned earlier are all elements of recommended practice in the SDM/SPS program. As mentioned previously, a major component of the SDM/SPS curriculum involves building readiness skills in the areas of self-control and social awareness. For example, a lesson on listening skills introduces a set of behaviors associated with "Listening Position" (sit or stand up straight, look at the source of the sound, etc.) and practice activities. Teachers are instructed to give feedback to student efforts and to prompt and rein-

force proper use of "Listening Position" throughout the school day.

It is worth exploring briefly the specific concerns about the behavioral skill content of the SDM/SPS and the perceived benefits of bringing in the Skillstreaming program. In comparing the approaches of the two programs, the school director emphasized the differences rather than the similarities: "Social skills training is behavior specific in comparison to SPS, emphasis is on teaching prosocial skills rather than cognitive strategies" (Ettinger, 1995, p. 57). Clearly, there is an element of perception involved here. As shown by the example of "Listening Position" in the SDM/SPS curriculum, there is a behavioral skills focus to the SDM/SPS program. Further, the Skillstreaming curriculum does contain a section on "Planning Skills," similar to the problem-solving skills of SDM/SPS.

However, perceptions notwithstanding, there are some significant differences between the two approaches. The (behavioral skills-based) readiness section of the SDM/SPS curriculum contains 16 skill areas (e.g., "Learning to listen carefully and accurately," "Giving criticism"). The Skillstreaming program contains 42 distinct behavioral skill areas, plus 8 more in the more cognitively oriented "Planning Skills" section. These 42 skill areas are broken down into a small number (generally 4 to 6) of performance steps. It is likely that this approach was seen as more consistent with the educational approach generally taken with students at TCI. Further, the discrete skill-based approach of Skillstreaming generally lends itself to a more structured approach to teaching the skills.

It is important to note that the approach taken at TCI was not one of replacing one curriculum with another. Rather, the two curricular approaches were integrated into a unique SEL approach. The work of integrating the curricula was guided by the school's interdisciplinary Social Problem Solving Committee, which, as curricular integration progressed, was renamed the Social Development Committee. This new name reflected the growing role of the committee in guiding SEL efforts, expanding beyond the implementation of a specific program. The committee's guiding vision was summarized by the school director: "The SPS curriculum would be followed, which provided the structure, developmental guidelines, and strategies for social skills instruction. The social Skillstreaming curriculum provided more detailed, specific skills to be integrated into the SPS curriculum and additional instructional strategies" (Et-

tinger, 1995, p. 98). As such, the committee kept the sequence and developmental structure of SDM/SPS while adding a more fine-grained breakdown of skills and extra behavioral rehearsal and practice that characterizes the Skillstreaming approach.

Curricular integration was supported by the consulting psychologist, who understood how to make the approaches work in a complementary way. A constructivist approach was used to bring the teachers along in their understanding of how the new structure might work. A half-day staff training workshop was held on the topic, and teachers developed and presented a lesson illustrating the integration. The implementation model called for classroom teachers and social workers to collaborate in developing and delivering SPS/Skillstreaming lessons. The Social Development Committee would collate the lessons into a unique site-based curriculum guide and spent 3 days during the summer break formalizing and organizing lessons into a “Social Development Curriculum Guide.” The guide, and training in using it, was presented to all staff when they returned for the following school year. Sharing of new social development lessons became a regular part of staff meetings.

This initial combination of SPS and Skillstreaming can be seen as the beginning of a cycle of curricular integration and adaptation that resulted in what has been referred to as the TCI Model (M. Cohen et al., 2003). The model is summarized as follows:

TCI uses a cognitive-behavioral approach with all students. . . . This involves a step-by-step process to teach students what they need to do to develop socially appropriate replacement behaviors. On a regular basis, students also participate in “practice and rehearsal” of skills specific to the needs of the individual child. It is through this technique that students learn to replace inappropriate actions with appropriate ones with a specific situation. This method is based on the extensive works of Dr. Maurice Elias (Elias & Tobias, 1996), Dr. Arnold Goldstein’s Skillstreaming curriculum (McGinnis & Goldstein, 1984), and Dr. Frank Gresham’s Social Skills Intervention Guide (Elliott & Gresham, 1992). These works focus on the social and emotional learning of all children: using the cycle of design, implementation, and feedback for more than a decade, TCI staff members revised—and continue to revise today—the works to reflect the unique needs of our students. We then added lessons promoting self-esteem and other social-emotional skills. This evolved into TCI’s Social Development Curriculum.

The TCI model incorporates the common vocabulary found in Elias and Clabby’s (1989) approach. . . . The use

of this shared language created far greater continuity in care for the students than had previously been in evidence. (M. Cohen et al., 2003, pp. 128–129)

The SDM/SPS provides the structure and language into which a number of other curricular pieces are integrated. The result is a unique product that speaks directly to the needs of the site in which it was created. As with any snapshot taken of a setting, the integration of Skillstreaming and SDM/SPS represents a convergence of the developmental arenas described previously. Perhaps the main motivator was concern for the developmental trajectory of the students and an increasing understanding of how best to address these concerns. Specific behavioral skill deficits, frequently found in populations such as TCI’s, seemed to indicate that a more focused skill-building approach was warranted.

As summarized in the previous snapshot, implementation at this point was inconsistent among the various school constituents. Classroom teachers were regularly implementing SDM/SPS lessons, but the clinical staff was generally resistant to refocusing their primarily psychodynamic approach. Teachers were ready to refine their work based on their experiences and the results of initial implementation, which gave rise to a desire for a behavioral skills-based focus. The consultant, as noted previously, was working with a goal of transferring major program SEL ownership to the setting, rather than outside support personnel. Finally, it is evident that this snapshot marks a major developmental change in the intervention itself, moving from the use of a specific program to the creation of an integrative new approach.

The gradient created by this convergence of developmental arenas can help in the understanding of how these events unfolded. In particular, this snapshot is notable for what *did not* happen. In the face of newly understood programmatic needs, school leadership refused to take the commonly trod path of revolving-door programming. That is, the SDM/SPS program was not replaced by Skillstreaming, and a new cycle of implementation was not begun. The decision of the school’s director and the Social Development Committee to adapt rather than adopt may be attributable to the already existing level of comfort and competence with the SDM/SPS program on the part of the frontline implementers. Further, school personnel had long-lasting positive relationships with consultants from the SDM/SPS program. This relationship had evolved to the point where the SDM/SPS consultant, rather than

supervising or overseeing implementation, was involved as a member of the Social Development Committee, attending meetings and voicing opinions on a par with all other members of this group. This might have helped the consultant, and the program he represented, to move with the committee, rather than setting up an either/or situation between SDM/SPS and Skillstreaming. Finally, school SEL leadership had an appreciation of the unique nature of their student population and recognized the opportunity to do something new in a way that would contribute to the field. For example, from the early stages of SEL curricular integration, the Social Development Committee and school leadership developed a proposal to present their approach at a statewide conference.

CONCLUSIONS

Although we acknowledge the centrality of the five developmental arenas reviewed here, there may be other developmentally linked areas of change that can impact implementation efforts. For example, factors involved in the school leadership might be of relevance. Is the principal new to the setting, or a veteran? What is the principal's history of working with (or failing to work with) various constituents in the school? How much does leadership know about and care about the intervention in question? A second additional area is the life span of the setting itself. How long has the setting been in existence? What other interventions, in SEL and beyond, are currently being implemented, or have been implemented in the past? A school still recovering from a difficult or controversy-filled implementation process of, say, a new block-scheduling approach may present unique challenges to efforts to again initiate something new.

For interventions to succeed, a convergence of a large number of what are essentially developmental influences must take place. Consultants, as well as school leaders, who attempt to implement innovations can hardly keep all of the possible areas clearly in mind and coordinate the affect, cognition, and behavior necessary to do so. Yet, some interventions, like SDM/SPS in TCI, succeed. We hypothesize that for this to happen, a critical mass of those involved in the implementation process must have a generalized, developmental understanding that pervades their work. It may take the form of a generalized expectancy (Rotter, 1954), a superordinate schema, or some other higher-order transactional orga-

nizing structure. This is a matter for future research. What is clear, however, is that our understanding of the implementation process (and consultation process) can be enhanced by adding the perspective of a gradient of developmental relevance and applying it to the context of interventions, as a complement to a developmental perspective on the student recipients and their match to developmental content of the intervention itself.

Resilience and Coping	626
COMMUNITY AS A CONTEXT OF HEALING: THE SHIFT FROM CLINIC- TO COMMUNITY-BASED INTERVENTIONS	627
Prewar Generic Anticipatory Interventions	630
War and Postwar Community-Based Generic Interventions	631

This chapter addresses children's war-triggered stress responses and the related mental health intervention options. Unlike most disasters, war does not comprise a short, single, violent event but rather a large-scale, protracted, complex, constantly changing, novel, and often unpredictable emergency that encompasses life-threatening exposure, targets an entire society, and creates shared mental suffering. War is a case of extreme societal violence that unsettles entire populations at the personal, familial, and broader social levels (e.g., community, ethnic group, state, or national), while damaging physical property and infrastructures. As a result, civilians' total life experience is disrupted, sometimes even replaced by a state of surreal existence; the victims' pain and suffering often seem devoid of rational explanation, a condition that contradicts the human need for a predictable environment and equilibrium (Kahana, Kahana, Harel, & Rosner, 1998; Williams-Gray, 1999). Wars may take various forms of deliberate, intentionally inflicted violent activities that especially target civilian populations. One such form of contemporary war uses long-range high-technology weapons with biological and chemical warhead capability to "surgically" remove a civilian target, devastating civilians and their environments. Such were the missile attacks by Iraq against populated cities of Israel during the 1991 Gulf War. An-

Enhancement of Coping and Resiliency in Generic Terms	636

other instance constitutes ethnic strife, as evinced particularly in the former Soviet republics, as well as in conflicts in the developing world and in the civil wars in the former Yugoslavia (in which harming women and children was often a war strategy). Ethnic fighting frequently results in forced evacuations or flight to refugee camps in neighboring countries. A third example is the "new" form of war targeting innocent civilians, represented by the recent large-scale terrorist attacks of September 11, 2001, on the United States and the massive attacks by suicide bombers during the second Palestinian uprising in Israel, and lately in Iraq. The threat of political terrorism as an act of war has recently succeeded in overturning the enduring sense of national security enjoyed by even the most politically stable, peaceful, and affluent democracies of the world.

As is inevitable in war, many children experience high levels of war-related stress. In this cumulative condition, children who are exposed to the stressors of war and/or political violence/terrorism exhibit *complex biopsychobehavioral disruptions*. These may involve significant alterations in cognitive, emotional, moral, behavioral, and psychosocial functioning. This condition incorporates cultural dynamics and an existential response to sociopolitical upheaval (Parson, 1996). To date, a substantial body of literature has accumulated on the

psychological consequences of war for adults, but less is known about the longer-term effects of war on children (Cairns & Dawes, 1996; Dybdahl, 2001; Dyregrov, Gupta, Gjestad, & Mukanoheli, 2000). Literature on psychological interventions with children in the midst of war is almost nonexistent, and so the literature on the effects of therapeutic interventions with children following war remains relatively scarce. Despite the desirability and value of empirical research data in the area of children's responses to and recovery from war, conducting well-designed research is problematic because of the scope, complexity, and uniqueness of war and the various operational pressures involved. Often, neither field conditions nor funds are available for conducting a well-controlled, detailed study during or immediately after war (Klingman & Cohen, 2004; Klingman, Sagi, & Raviv, 1993). In part, the available empirical findings conflict due to methodological diversity and flawed evidence collection (e.g., absence of proper controls, non-random selection of participants, use of dissimilar tools). In most cases, reported field experiences and projects and their in-house evaluation provide the best information on the subject of intervention in wartime or in war-affected regions.

This chapter therefore draws on theory and research but also leans heavily on reported field experiences, which are examined in light of theory and research findings. Furthermore, most empirical studies concerning psychological intervention in war have focused intently on Posttraumatic Stress Disorder (PTSD) or the risk for PTSD and on treatment of PTSD-related symptoms. However, this chapter aims to reach beyond a classificatory psychopathological approach to also focus on the overall quality of the child's needs for the adaptation process (American Academy of Child and Adolescent Psychiatry, 1998); the need to intervene with children's war stress reactions, not only with disorders; and the role of positive coping, resiliency, and trauma-induced growth in the recovery process. Many of the intervention cases discussed in this chapter illustrate a preventive response to a wide variety of children's war-related stress reactions and propose the adoption of a wider developmental psychopathology perspective in clinical intervention for PTSD-related symptomatology. Because intense war experiences are shared by children and the significant others in their lives, the multisystemic intervention approach seems especially relevant as the method of choice for war situations. Accordingly, this chapter contextualizes, examines, and treats the impact of war on

children at three levels (Ager, 1996; Klingman & Cohen, 2004): the direct personal, the family-mediated, and the broader social-mediated levels.

The purpose of this chapter is thus threefold. One aim is to present the unique war-related issues faced by children and their implications for intervention. The second is to present war-related multimodal psychological interventions with children in the context of a preventive, multisystemic, generic, society-focused (e.g., school-based, school-linked, and community-initiated) approach that emphasizes positive psychology. The third aim is to review specific war-related therapeutic interventions for individuals and small groups, focusing on those for which PTSD-related symptomatology is considered a useful reference point and which are complementary to and congruent with the two preceding aims.

THE WAR CONTEXT AND IMPACT ON CHILDREN

This section of the chapter presents the major factors constituting the magnitude and breadth of war's psychological effects on children. Interventionists' awareness of the prevalence and especially the combination of these factors will enable the identification of populations, groups, and individuals with special needs and with a high likelihood of developing disorders.

Children in war zones grow up in an atmosphere of *constant fear for life and limb*. In UNICEF's 1996 *State of the World's Children* report, it was estimated that wars in the preceding decade killed 2 million children and left another 4 to 5 million children disabled. Additional life-threatening conditions may result from difficulties in access to transportation, adequate food, medications, and immunizations (which may sometimes be intentionally denied). *Loss of significant others* constitutes another major threat, whose impact varies across the child's development. The greatest threat to an infant is likely to be loss of or separation from the primary caregiver(s) or serious injury to the functioning caregiver(s); adolescents have the potential to experience greater losses of friends and acquaintances outside the family (Wright, Masten, & Hubbard, 1997). In certain types of wars, children may also witness *repeated violent acts against their significant others* (e.g., torture, sexual violence, public display of executed persons). War may also involve large-scale extensive

violations of children's basic rights: Children may be forced to separate from their parents, be confined in concentration camps, and denied access to education or health services; in some wars, they are even raped or prostituted. In various conflict zones, children are exploited for ideological propaganda or enlisted into civil strife activities. The availability of very lightweight weapons enables younger children to become directly involved; in certain cases, they are recruited forcibly or coaxed into military service (child combatants); others are driven into war and war-related activities by poverty, alienation, discrimination, and/or the desire for revenge (see Silva, Hobbs, & Hanks, 2001). Exposure to the sustained stress of war and violence, combined with dwindling hopes for the future, may result in *desensitization to dangers*, whereby children begin taking further life risks in an effort to establish a sense of control (Garbarino, Dubrow, & Kostelny, 1991). Some children and youth engage in self-engineered patterns of reexposure to traumatic sensory repetition, seeking out situations of affective intensity, excitement, and danger such as child-soldier "status" (Parson, 2000). Children who live surrounded by land mines and dormant (cluster) bombs may become desensitized to them or attracted to their colors, or may think it is brave to be seen handling explosives; this may continue for some time after the war is over (Klingman, 2002c).

During war, *basic infrastructures* such as the economy, public health, medicine, education, social welfare, and psychological services may become overloaded, drastically restricted, seriously impaired, or incapacitated for lengthy periods, or may even collapse. Depending on the severity of the damage, a very long period may be required to reestablish infrastructures even after the war is over. This situation holds direct as well as indirect implications for children, specifically through closure of schools, restrictions on social/recreational activities, and unavailability (at least temporarily) of psychological and welfare services. Prolonged destruction at a societal level may cause adolescents (struggling to define themselves in a changed world) to question the value of schooling or work in a war-torn country or in a nation whose economy has been decimated (Wright et al., 1997).

Another major problem typifying many war-ravaged regions is forced evacuation and the resulting large number of *refugee or displaced children*, sometimes called the "forgotten victims of war." An estimated 12 million children became homeless due to armed con-

flicts between 1988 and 1998 (Southall & Abbasi, 1998). The refugee process advances through three phases: preflight, flight, and resettlement (Gonsalves, 1992). Before evacuation or flight begins, many children may be overwhelmed by war atrocities or undergo a lengthy process of traumatization typically experienced as a psychic trauma. The relocation or flight is in itself socially, culturally, and psychologically complex and can impede the normal process of child development, particularly if children are alone in their migration. In attempting to resettle, children may experience the distress of refugee camp life: malnutrition, which increases the incidence of childhood illnesses (Goldson, 1993); exposure to pervasive discrimination and bias due to their cultural background, skin color, racial origin, or religion; and children's often fundamental ignorance of the host culture (Parson, 2000; Reichman, 1993; van der Veer, 1992). They may have to conceal the actions they took while fleeing and may be suspicious of all authority figures (including psychologists), at least until they are certain about their future legal status. Moreover, refugee parents may instruct their children never to disclose anything to outsiders, which may hinder the process of helping children come to terms with their experiences (van der Veer, 1992; Yule, 2002).

The impact of *mass terror attacks* constitutes a war situation that deserves specific attention, particularly when such attacks become a chronic condition without discrete beginning and end points. A terrorist attack occurs without warning and selects symbolic targets that will not only weaken symbols of power but will also convey the idea that no one is safe (see Gidron, 2002; Klingman & Cohen, 2004). Civilians do not know how to prepare for or respond effectively to such an unfamiliar event and predominantly feel that neither they nor the authorities (police, army, government) can prevent such attacks. People find it hard, if not impossible, to make sense of or find meaning in such deliberate and indiscriminate malicious, violent, inhuman acts.

The specific threat of unconventional *chemical, biological, or radiological weapons* in international as well as domestic terrorism necessitates consideration of specific, direct health effects, and also the resulting primary and secondary psychological effects. Presumably, children will suffer more extreme effects from the release of chemical or biological weapons than will adults. For example, children's higher number of respirations per minute may result in exposure to a relatively greater

dosage of aerosolized agents such as sarin and anthrax. Children who witness the weapons' effect also risk developing psychological injuries from the experience. Moreover, the invisibility of biological and chemical agents may lead to false-alarm reactions that may result in mass episodes of sociogenic illness and associated anxiety (see discussion on such effects on children in Klingman & Cohen, 2004). Also, children may become confined indoors or to sealed (gas-proofed) rooms for most of the day due to the threat of unconventional war-head missile attacks. They may experience relative isolation, protracted boredom, and a lack of sustaining structure, as among Israeli children during the 1991 Gulf War (Solomon, 1995).

The previous outline mainly explored the magnitude and duration of war as they affect children. In the next two subsections, first the psychological risk mechanisms involved are detailed, and then the resilient responses. These constitute a complex range of factors present before, during, and after war.

War-Related Psychological Responses and Intervention Challenges

All mass disasters present problems that challenge the coping resources of victims and community services alike; the nature and consequences of war, however, present numerous unique challenges. The psychological effects of war involve contextual, personal, and recovery-environment factors and encompass a wide spectrum of emotional, cognitive, and behavioral outcomes. The practitioner's awareness of the prevalence and combination of these factors will facilitate the identification of populations, groups, and individuals who have a relatively high likelihood of developing distress, adjustment difficulties, and (consequently) disorders. Such awareness will also serve for planning relevant (especially preventive) interventions.

Warfare affects the *child's mental map*, or cognitive and emotional schemata, as life becomes inconsistent with prewar norms. Children of war are exposed to a continuous series of adverse experiences that are potentially traumatic in that they involve multisensory experiences of sights, sounds, and smells that a child may be incapable of comprehending or assimilating within the existing cognitive-emotional schema (Ager, 1996). Warfare forces children to process information that may challenge core beliefs and assumptions that people are

trustworthy, that the world is a meaningful, predictable, and secure environment, and that the self is worthy (Janoff-Bulman, 1992). In general, "maps" that previously guided the child through the world suddenly prove inaccurate, and life becomes unpredictable and untrustworthy. Fearing that the traumatic experiences may return, children may develop catastrophic beliefs. When no opportunities exist to engage in a search for meaning, children and especially adolescents are left with perceived unsolvable contradictions that may lead to greater distress. They may experience an inability to predict or project a meaningful future for themselves. Children may lose trust in others, especially if they witness violent acts by people or groups with whom they maintained a friendly, or at least a stable, prewar relationship (e.g., in Croatia; Williams-Gray, 1999). They may also face contradictions between the values and behaviors inculcated in them in the past (prewar) and those underlying apparently successful adaptations in the violent present. Those clinging to the past may be less prepared for the stresses of war, whereas children who discard prewar sensibilities for a self well-adjusted to the present war (especially child combatants assimilating the virtues of destruction of the enemy) may experience great difficulties with the advent of a peaceful future (Ager, 1996).

The complex childhood environment in war imposes unique demands with regard to children's developmental tasks, such as learning to live with constant fear, struggling with identity formation and moral reasoning, creating intimate relationships, and planning for the future. These may result in *interference with normative developmental tasks*, or with the smooth transition to the next developmental stage, such as emotional regulation in toddler years, controlling aggressive behavior in middle childhood, and forming intimate bonds in adolescence. War is likely to have wide-ranging influences on developmental tasks connected with the formation of successful peer relationships and adaptation to school. Furthermore, children are at risk of *losing previously acquired developmental skills* or regressing to a less mature behavioral mode. Serious risk also exists for growing up too fast and losing childhood too early, for example by being forced to resolve serious moral and emotional conflicts before full maturation (Punamaeki, 2002). Legitimate concerns about child safety in an unpredictable war environment may result in caretakers' overprotection and discouragement of increased inde-

pendence; conversely, parents attempting to cope with the war's hardships and stresses may expect their children to mature more quickly, thereby easing the demands on their parenting.

A prolonged period of warfare may cause *disruptions in the child's experience of social relationships*. These may stem, for instance, from curfews or restrictions on out-of-home movement, forced evacuation resulting in separation of family members and/or loss of parent(s), peers, or adult significant other(s), and the closure of schools. War-zone children may have problems in gauging interpersonal distance, experiencing attachments that are too close or too distant or vacillating between detachment and enmeshment (Parson, 2000).

Children in war may find themselves with *fewer social outlets and supportive resources* to deal with their adverse experiences. This occurs because war inevitably impinges (directly or indirectly) on both the child's natural (i.e., peer, family, and significant others) and formal (i.e., community psychological and social welfare services) support systems. War may also have indirect consequences, for example, when long-lasting economic damage affects parents' ability to take care of their children. Moreover, parents face the double challenge of processing their own subjective traumatic experience and managing their own individual reactions, while concurrently relating to the children's needs and often also those of other family members (e.g., elderly relatives). In addition, increased functional demands occur in the family, such as those related to a spouse's absence due to deployment or hospitalization or the adjustment difficulties of a homecoming war veteran. The numerous types of family stress may result in parenting change: a more authoritarian parenting style, less supervision of children, or less positive emotional interaction. Moreover, when a parent directly experiences a traumatic event, preoccupation with his or her own symptomatology may reach the point where it is impossible for that parent to appropriately monitor and effectively respond to the young child's needs. Furthermore, in wartime, children and parents often experience traumatization by the same event or different events, but the effects of each victim's symptomatology exacerbate the other's (Scheeringa & Zeanah, 2001). Psychological unavailability of the attachment figure as a secure base may lead to long-term psychological impairment (Cicchetti, Toth, & Lynch, 1997). Parental support is an important factor in explaining both children's resilience and in-

crease in problems (Dybdahl, 2001). Interventionists should strongly consider psychosocial interventions for parents with respect to parenting during wartime (for a detailed discussion, see Klingman & Cohen, 2004).

War necessitates the *adaptation of existing coping strategies and techniques as well as the development of new coping modes*. Effective coping with a prolonged traumatic situation requires the ability to shift and manipulate mental experiences, seek help, rely on soothing and consoling memories, construct new metaphors, and create comprehensive narratives to replace fragmented horrific pictures (Punamaeki, 2002). The child's adaptive coping strategies and techniques may differ across war-induced situations, and at different points in the course of the war new situation-specific needs may become central to the choice of strategy. For example, a problem-focused coping style may not be practical for a child in certain circumstances or points in time. Using a problem-focused strategy may serve as a reminder of the uncontrollability of the situation, whereas emotion-focused coping, or even high defensiveness (e.g., denial, avoidance), might offer the child time to assimilate the trauma more readily. Some data indicate that children who persisted in directly engaging in problem solving and other activities to change an unchangeable situation may have coped less effectively than those relying on emotion-focused coping (Klingman et al., 1993). A wide repertoire of coping modes and their situation-sensitive, flexible, and adequate employment are likely conducive to an enhanced recovery process. Coping modes' effectiveness must be considered in terms of personality differences and goodness-of-fit with the challenges that war situations pose for children. Thus, professionals and parents should not strip children of their personal ways of responding to trauma but rather should expose and guide them toward the utilization or even creation of a new and broader repertoire of strategies (Klingman & Cohen, 2004; Punamaeki, 2002; Rutter, 2000).

War conditions may involve the *intensification of pre-existing anxieties*. For example, Ronen (1996a, 1996b) detailed the case history of ten 9- to 11-year-old Israeli children who were referred for treatment a few weeks after the 1991 Gulf War. Unlike the other members of their families, these children's war-related anxious behaviors did not decrease after the war. They all evidenced anxiety reactions, sleep disorders, and features of separation anxiety as an outcome of the war. An accurate review of each child's past history revealed previous

anxieties beginning in early childhood. The war may have affected their prewar anxieties in several ways (Ronen, 1996b): by legitimizing expressions of fear, thereby increasing children's preoccupation with their own fears; by parents' ceasing to insist (as they had before, in peacetime) that their children invest as much in overcoming their fears, thereby reinforcing and maintaining new fears; by legitimizing avoidant behavior, in contrast to peacetime, when the children had been forced to expose themselves in one way or another to anxiety-provoking situations (e.g., remaining in their own beds); and by normalizing and thus reinforcing new wartime life patterns in which the children experienced staying at home and sleeping together with the family in the sealed room. This togetherness actually "released" these children from the need to cope with their anxiety and conditioned them to the new situation of staying at home with their family. Also, wartime may arouse the negative effects of earlier trauma, thus sensitizing an individual to subsequent stress and trauma and creating vulnerability for PTSD (Cicchetti et al., 1997).

The combination of trauma and grief often seen in war may lead to *traumatic grief or bereavement*, which involves a complex overlay of symptoms that arise from the difficulty inherent in moving on with grief work due to one's preoccupation with the trauma. Without first working through the traumatic experience and/or the traumatic nature of a significant other's death, this difficulty may impede the normal work of grief and resolution (Klingman & Cohen, 2004; Malkinson, Rubin, & Witztum, 2000).

Evacuation may involve children's *separation from family*. Several studies have indicated that children separated from their family during war proved more distressed by the separation than by exposure to bombings or by witnessing destruction, injury, or death (Klingman, 2002a, 2002b). Those who experienced constant bombing did not seem adversely affected, provided they remained with their mother or mother substitute and continued their familiar routines.

Discrete war-related effects may develop in children with regard to the *deployment of their loved ones*. (Note that this can have an effect on children even if the conflict is raging in a distant country.) Children must face the possibility that a parent could be wounded or killed in action. Additional stressors may occur as a result of up-to-the-minute information and vivid, often live, combat scenes transferred by way of conventional and satellite-transmitted television, commercial radio, com-

puter modem, fax machine, and the Internet (Figley, 1993a, 1993b). Misinformation and rumors spread easily via these means and cause harm. Reactions of children who are separated from a deployed parent range from sadness, jealousy of children whose parents are not deployed, and increased levels of unruly behavior and anger, to fears, separation anxiety, hostility toward the other parent, and guilt (Costello, Phelps, & Wilczenski, 1994). Some may experience depressive symptoms or (especially among younger children) exhibit acute acting-out behavior. A father's long absence may promote maternal overprotection, indirectly contributing to sex-role development difficulties (e.g., effeminacy, softness) and affecting later father-child bonding. Children may be burdened with extra tasks because of the parent's absence, which requires them to forgo age-appropriate activities and adopt adult-like responsibilities. As mostly fathers are deployed, mothers play the key role in determining whether or not children cope well when faced with their father's prolonged absence (Hunter, 1988).

The *parent's return and reunion* also deserves attention. A parent's prolonged absence may deeply affect children, who may respond with a mixture of relief and anger (which their parents may not understand) at both the prolonged absence and the reunion/reintegration (Figley, 1993a; Hobfoll et al., 1991). The reunion may cause considerable ambivalence, with relief and exhilaration. In addition to the psychosocial residue of combat, the returning parents face changes in society and in the family and may have to deal with new family conflicts related to their prolonged absence as well as the old ones, if they existed. The family may enter power struggles engendered by anxieties over parental role changes and shifts in parent-child loyalties.

Exposure to their *parents' posttraumatic stress* may also affect children. The relationship between parents' war experience and subsequent stress disorder and their children's problems is considered a secondary traumatization. Intense involvement of a child in the emotional life of such a parent may cause high levels of anxiety, guilt, and conscious and unconscious preoccupation with specific events that were traumatic for the parent. These children should receive help to disentangle their experiences from those being relived by their parents (Rosenheck & Nathan, 1985).

Silence and denial about previous traumatic experiences may be common in families exposed to war-produced violence; the basis for this is mutual protection of parents and children. An intergenerational communi-

cation pattern referred to as the “conspiracy of silence” has been found in families of survivors (Danieli, 1998). This silence between the survivors and their children regarding the parents’ traumatic experience emanated not only from the parents’ need to forget (e.g., “We should forget the past and look ahead”), but also from their belief that withholding information about the horrors of the war was crucial to their children’s normal development (e.g., “Opening up old wounds can only cause more suffering or harm to my child”). Their children, in turn, became sensitive to their parents’ need to keep silent (Bar-On, 1995, 1996). As a result, both generations often mutually supported a “double wall” of silence. Studies of families of the Holocaust survivors (Auerhahn & Laub, 1998; Felsen, 1998), Japanese American internment camps (Nagata, 1998), Dutch war sailors and resistance veterans (Op den Velde, 1998), and Vietnam veterans (Ancharoff, Munroe, & Fisher, 1998), taken together, suggest that the quality of parents’ (verbal and nonverbal) communication about traumatic experiences may have major consequences for the inner and interpersonal life of their children (Wiseman & Barber, 2004; Wiseman et al., 2002).

Children often attempt to shield their parents from knowing how much the children’s own trauma has affected them. Such protectiveness (or even denial) may be considered an adaptive strategy that supports the capacity of both parents and children to cope and survive in dangerous wartime situations, and it also serves the function of preserving the child’s internal representations of his or her parents as a secure base. Yet, it may become an obstacle if, as a result, the child is later (especially when the war is over) left with insufficient parental support and must deal alone with the effects of war trauma; clinicians need to take these family dynamics into consideration (Almqvist & Broberg, 1997; Wiseman & Barber, 2004).

War-relevant coping mechanisms may interfere with postwar adjustment. A wartime environment may render children’s dissociative mechanisms, for instance, to be not only normal but even necessary as an important functional defensive maneuver (i.e., a survival strategy) in adapting to danger, violent scenes, and evil. Such defense mechanisms spare the child victim the self-experiences of abject passivity, helplessness, unworthiness, and vulnerability to harm. In prolonged trauma-inducing war events, children may develop impulse-driven, aggressive self-defense responses that can interfere with problem solving and lead to overag-

gressiveness toward peers and parents, difficulty in modulating impulses, problems with social attachment and attention, lack of participation in preparing for the future, and the loss of trust, hope, a sense of agency, and meaningful attachments (Witty, 2002). Also, children in war-affected zones may adopt a revenge-oriented ideology as a simplistic coping mechanism; they may become intolerant and/or suspicious of peers from a different (racial, ethnic, or religious) background or political ideology, or to peers who show non-conforming behavior. In this sense, the role of society or the community in providing a solution to moral conflicts should not be overlooked. When the war is over, such conflicts may affect children’s adjustment; some, for example, will not (at least immediately) connect with regular school study projects or a peace dialogue. Moreover, the experience of wartime/political conflict and violence has shown links with aggressive and even delinquent behavior (e.g., Shoham, 1994) due to lowered levels of child supervision, an increase in thrill seeking resulting from excitement attached to the notion of war, social modeling, and the normalization of violence, as well as anxiety and loss of control experienced by children during war and protracted war-like situations (Cairns, 1996; Muldoon, 2000). Postwar psychological intervention should thus examine the need to focus on making these fixations movable again.

The observed *incidence of PTSD symptomatology* in children as a result of exposure to war or war-like events is highly variable. For instance, rates ranged from 6% who met all three symptom criteria (e.g., Dawes, Tredoux, & Feinstein, 1989; Klingman, 2001) to 32% in Cambodian children some 10 years after they witnessed the execution of family members (Clarke, Sack, & Goff, 1993). This variability in prevalence rates may be related to the number, the type, and the intensity of war traumas experienced. Based on a study of Lebanese children, Macksoud and Aber (1996) concluded that in situations of chronic armed conflict, where there is no respite from the traumas of war, children are at risk of developing “continuous” PTSD. Nevertheless, PTSD should not be the only criterion for launching an intervention; the long-term effect of traumatic experiences emerged, for example, in the case of Israeli adolescents taken hostage during a school outing. Most survivors who were investigated reported some forms of trauma-related symptoms even 17 years after their face-to-face encounter with the terrorists (Desivilya, Gal, & Ayalon, 1996a, 1996b). Experts agree that up to one-third of the

young people in a community may develop PTSD. However, to date, neither well-designed qualitative data nor quantitative longitudinal data exist to allow conclusions to be drawn on the duration and recurrence of traumatic exposure in children and adolescents following war or on their war-related mental health risks.

Resilience and Coping

These unique effects of war on children are related to various negative impacts. Yet some children *cope reasonably well* despite exposure to the extremely stressful circumstances. Others *cope better when they are offered a sensitive recovery environment*, that is, when their physical safety is ensured and social infrastructures are created (or reestablished) to meet their basic physical and emotional needs.

Successful coping with regard to war also entails an attempt to make the adverse situation more tolerable or to minimize the distress via distancing, denial, and habituation strategies used by children to manage the negative affect generated by a traumatic encounter (Muldoon & Cairns, 1999). Habituation may provide one explanation for findings showing that children exhibit a high level of adaptation to war and warlike situations (Klingman et al., 1993; Muldoon & Cairns, 1999).

It is also important to acknowledge that children actively and creatively engage in their situation and adopt constructive approaches to the management of risk, and in some cases contribute to family maintenance, protection, and survival. For example, children often bear responsibilities within the family for incapacitated adults or younger siblings.

Much of children's resiliency may be attributed to certain personality factors that are known to play a part in responding to and coping with danger. Temperamental dimensions such as the threshold for pain and pleasure, valence and intensity of fear, sadness, and anger, emotional arousal and regulation, and novelty-seeking behavior seem to be especially salient in the course of posttraumatic distress.

The role of parents in enhancing their children's resilience must be highlighted. Family members' responses and behaviors may influence young children's coping behaviors. Attachment-related working models explain how children interpret and evaluate danger and how they adjust to stressful situations (Punamaeki, 2002). There is evidence that young children's experi-

ences within the family, particularly with their primary caregivers, are central to subsequent coping and adaptation (Muldoon & Cairns, 1999). Plausibly, parents serve as a coping model for their children; children model family members' behaviors (e.g., their "calmness") and are influenced by their balanced or "positive" interpretations and outlook (e.g., optimism). The parents' actual behavior in wartime and/or its aftermath probably also significantly communicates to children concerning safety and optimism, which contribute to their resilience. Moreover, war conditions may create an opportunity for both families and children (especially adolescents) to become involved in taking care of or helping others, at the individual level or by joining in some kind of shared proactive, prosocial community activity. In this way, they engage in self-fulfilling activities and experience a sense of mastery and worth.

Furthermore, *response to war can be mediated through the initiation of preventive inoculation programs*, such as stress-inoculation programs. The extended warning or anticipatory period that usually precedes war indicates the need for anticipatory coping strategy interventions (Caplan, 1964), which are usually school-based in the case of children (Klingman & Cohen, 2004). Such intervention constitutes preplanned efforts to manage—reduce, minimize, master, or tolerate—an impending stressful transaction. Although this anticipatory period is extremely stressful and may require crisis intervention assistance in itself, professionals and educators can initiate anticipatory guidance programs to help children, parents, teachers, schools, and the relevant community/state agencies to better prepare, however partially, in real time for the impending war emergencies. Such an anticipatory intervention conducted in Israel prior to the 1991 Gulf War focused on children's familiarity with gas masks and other protective measures against chemical fallout as well as the related anxieties. This intervention was reported effective (Klingman, 2002a, 2002c; Klingman & Cohen, 2004).

The study of children in war and in war-torn zones has led to understanding that *the successful conclusion of difficult experiences can strengthen people* and better prepare them for new difficult experiences that are to come. Children may not only learn to cope better: For some, their struggle with the war ordeal may even positively change them in the long run. In planning interventions, professionals should not underestimate the positive resources of adaptive coping, resiliency, and growth.

Communality and a sense of community are notable recovery factors in wartime. Individuals undergoing the hardships of war pull together, join ranks, and experience a greater sense of community. Individuals thus resolve the suffering that arises in a social context shaped by the meanings and understandings applied to it (Summerfield, 1999). Social networks such as family members, close friends, relatives, and familiar clergy can greatly help people create a sense of safety and meaning under these circumstances.

Also associated with a sense of community and war are strong feelings of *patriotism and ideological commitment*. Some research findings (Punamaeki, 1996) indicate that ideology may contribute to adolescents' successful coping. Strong ideological commitment to a political struggle and active engagement can be protective and increase resilience, on the condition that the children's exposure to hardship is not overwhelming. Furthermore, children's, especially adolescents', attempts to make sense of the conflict (e.g., the cause of the war) may affect their mental health. It is also plausible that the political meaning they give to their mental suffering may lead them to interpret their symptoms as nonproblematic.

In this regard, local as well as national *leadership* such as clergy, local community leaders, and teachers play an important role in communal trauma recovery. By definition, wars affect entire communities, and there is much that community and state leaders can do (e.g., people/children often look to them as meaning makers), especially enhancing social morale. Although basically strong, leaders may become overburdened (if not overwhelmed) by the pressing needs of others in their community, so psychologists need to reach out to these individuals and give them the message that leaders must attend to their own needs as well (Hobfoll et al., 1991).

Considering the roles that communality, ideological commitment, and leadership play in times of war and recovery, it can be argued, as in Israel during the 1991 Gulf War, that the nonwar traditional therapeutic approach, with its focus on pathology and its emphasis on personal (as opposed to societal) recovery and well-being and its professed neutrality of values, may be inappropriate, even damaging, in times of war (Solomon, 1995). Interventionists must consider the collective capacity of survivor populations to mourn, endure, and rebuild, as well as individuals' capacity to cope and engage in self-healing, that is, to manage their suffering,

adapt, recover, and in some cases even grow (Klingman & Cohen, 2004; Summerfield, 1999). The therapist's role is thus not to first focus on or look for "proofs" of pathological response but to consider the natural human ability to self-recover, change, develop, and grow from adversity. The best immediate intervention may have a social focus (Farwell & Cole, 2001–2002; Wessely, 2003), centering on the empowerment of the recovery environments (i.e., social healing) as well as of personal resources (e.g., resiliency, strengths, benefit finding, and growth), which should take precedence. This approach has implications for both the natural recovery process and direct psychological interventions with war-affected children.

Children of war, then, undergo a variety of experiences, necessitating an array of carefully planned intervention programs (in variable war settings) to meet their diverse needs. Large-scale interventions should be the method of choice, and such interventions must be community-based, multifaceted, and generic in nature. To implement this, clinical psychology and community psychology should collaborate and complement one another, focusing on the benefits of a multisystemic approach to trauma due to its greater psychological impact, professional richness, and cost effectiveness.

COMMUNITY AS A CONTEXT OF HEALING: THE SHIFT FROM CLINIC- TO COMMUNITY-BASED INTERVENTIONS

Much of the current emphasis in the war-related trauma intervention literature lies on targeting and reducing PTSD. However, PTSD is not the only psychological consequence of war for youth. Also in war, and often in immediate postwar circumstances, any individual-focused intervention is impractical because both therapists and clients are preoccupied with safety and survival issues. In addition, although victims of war indeed experience acute symptoms and become distressed, these are not necessarily dysfunctional or indicative of a clinical disorder. Most children experiencing difficulties during war eventually adjust, given the availability of certain personal factors, coping patterns, and recovery-environment factors. Even for those whose basic ability to function is blocked, so that clinical labels may indeed be appropriate and helpful, it is possible that PTSD is

substantially overdiagnosed. In certain cases, this clinical concept has perhaps been stretched beyond any value by confusing psychiatric disorder with acute but, under the circumstances, “normal” distress (Wessely, 2003). More important, clinical treatment of the individual may not be required because the distress reactions relate to a social situation affecting a whole population. Cultural factors play an important role in individual or group expression of stress reactions, vulnerability to developing PTSD, and treatment responsiveness. Regarding the latter, certain cultures may evidence strong resistance by parents and children alike to mental health professionals or even to the entire concept of mental health intervention. Conversely, cultural routines, traditions, and rituals embedded in a particular culture may better aid distressed and traumatized persons who belong to that culture by defining helpful societal, culture-dependent pathways to recovery.

Accordingly, an expanded view of psychopathology and posttraumatic adaptation (Klingman & Cohen, 2004) advocates the consideration of children’s current and potential ability to adapt to the new situation, to invest in age-appropriate activities, and to self-recover. This more general emphasis on the implications of the war considers not only aspects of the acute traumatic experience, but also a range of psychological and socioenvironmental risk and protective factors related to the pretrauma, peritrauma, and posttrauma ecologies.

Multiple factors do influence children’s response to war. Some involve aspects of the environment, which may be more distal or more proximal to the individual child, and others lie within the individual child. Cicchetti and colleagues (1997) suggested an ecological transactional perspective for relating to intervention with war-affected children. The model’s several co-occurring levels in depicting the child’s war-affected environment is useful for understanding how the multiple risk and resilience factors described in the earlier sections can influence children’s responses to war. In referring to the *macrosystem*, which includes the beliefs and values of a people/culture, these authors asserted that ideological commitment may be one important protective factor. For example, children with a strong ideological commitment who were exposed to war-related hardships did not show an increase in symptoms of anxiety, insecurity, and depression, whereas those who revealed weak ideological commitment showed a nonlinear increase in symptoms (Punamaeki, 1996). In referring to aspects of the community in which families and indi-

viduals live, namely, the *exosystem*, Cicchetti et al. noted that fragmentation of community resources may place children at increased risk for psychological distress at times of war. Such are disrupted peer networks, which may result in the absence of one important source of social support for the children, and interrupted schooling, which might result in alienating an important base of continuity for many children. These authors then referred to the *microsystem*, namely, the immediate setting in which the child exists: the family’s level of adaptation in general, the parents’ in particular, and how they cope specifically with the stress of war. Parents’ level of adaptation can become one critical factor in determining how the individual child responds to the trauma of war. As for the *ontogenetic* developmental level, namely, factors within the individual connected to his or her own development and adaptation, Cicchetti et al. pinpointed the role played by the child’s affect regulation, attachment patterns, self-management, peer relations, and other extrafamilial relationships (e.g., school participation) in the child’s adaptation process. This ecological model provides the rationale for an *ecologically informed*, multisystemic intervention.

Multisystemic intervention refers to the active mutual interdependence of an individual child’s self system (e.g., self-esteem, ego identity, affect regulation, temperament) and its sustaining environment: the immediate nuclear family, the extended family, the community (structures, organizations, and services), and the society at large, including policies at the city, county, state, and federal levels of government, especially those underlying national and international psychological trauma intervention programs (Klingman & Cohen, 2004; Parson, 1996; Summerfield, 1999). Thus, intervention planners can direct their efforts at three levels. One is the child’s direct experience of the violent war event, or series of events, or their results. The second level relates to the link between family functioning and children’s adaptation; it includes difficulties in family members’ functioning (e.g., due to loss of home and/or economic resources), their psychological availability for support, and the meanings given by them to the violent acts. The third, societal level concerns the war’s impact on fundamental routines, on community resources, and on the mediating capacity of the broader social mechanisms. For children, as described earlier, the societal level of war may involve closure of schools, restrictions on social and recreational activities, and temporary unavailability of psychological and welfare services.

Conducted within the natural ecology of the youth and family (e.g., home, school, and community), coordinated interventions that are enacted simultaneously in more than one system exert a much stronger impact on recovery than does the cumulative impact of separate interventions. They target key factors within and between the multiple systems in which the child is embedded. The prime objective is to reactivate/mobilize the resourcefulness of children, their parents, other caregivers (e.g., teachers), and the community (including the sociopolitical community as a significant context). Such an approach does not view the impact of war as simply impinging on children who are passive recipients of environmental factors; rather, children's responses will vary as a function of their personal resources, the availability and quality of their support system, and their efforts at processing the war-related effects. Strong emphasis is placed on *preventive* strategies and techniques, adapted to massive use.

The multisystemic intervention may require a mental health professional to assume several roles: as a *consultant* to the community, as a *coordinator* of organizational interventions focused on mental health, and often as a *supervisor* to ensure that triage and risk screening are well coordinated and conducted in line with the generic approach. These roles may necessitate a temporary departure from the intervention mode usually practiced. Given the reality of war, the psychologist as a consultant must often take a proactive-directive approach, such as adopting a unilateral (rather than shared), coercive-directive consultation approach (Gutkin, 1999), often relying on his or her own judgment when recommending steps to be taken or when choosing among intervention strategy options.

Psychological intervention must thus be community-based and informed politically, socially, and culturally. This means initiating large-scale preventive measures, relating to the common responses, and first and foremost working for an adaptive resolution of the crises of the war and the postwar period. In other words, intervention should adopt a generic approach.

A primary tenet of the *generic approach* is that certain recognized patterns of response and recovery exist for all (or most) people in crisis, such as process components of grief and bereavement. A specific generic intervention plan should be designed to be effective for all members of the affected population, or a given group, rather than for the particular attributes of one individual, and should aim at an adaptive resolution of the trauma. In addition, such a

plan should emphasize positive psychology with a minimum of clinical therapeutic interference. The generic approach maintains that an individual-focused approach—underscoring the child's unique, diverse intrapsychic and interpersonal processes, needs, and difficulties—can always be initiated later for individuals who fail to respond to generic measures, thus complementing the initial generic intervention. One noted advantage of the generic approach is its feasibility: This mode of intervention can be learned and implemented by paraprofessionals and non-mental health professionals. In practice, generic intervention focuses on supporting children as they attempt to regain control by providing opportunities for ventilation, offering age-appropriate information, and training children in simple techniques of stress/symptom reduction (e.g., relaxation exercises), preferably in the child's natural setting of home, school, or community. Also, caregivers receive assistance in setting limited recovery goals relevant to any situation and in tailoring proactive, meaningful, age-related, solution-focused activities for the children, as much as possible within the specific circumstances.

The following are optimal generic intervention principles:

Immediacy ensures that measures are taken as soon as possible to prevent hiatuses that would deepen the sense of disruption.

Proximity maintains children in a familiar setting with their regular caretakers and prefers intervening in the natural setting.

Simplicity advocates avoidance of sophisticated intervention methods, establishment of limited and clear goals, and employment of situation-specific, easy-to-implement recovery activities such as ventilation, relaxation, and support.

Expectancy establishes confidence in personal as well as communal ability to recover.

Sense of community enhances feelings of belongingness.

Purposeful action espouses being active to serve as a powerful counterresponse to a sense of helplessness.

Finally, the *continuity principle* (Klingman & Cohen, 2004; Omer & Alon, 1994) is the unifying generic guiding principle. To counteract the extreme disruptions in everyday personal and community life triggered by war (or any large-scale disaster), this principle holds that the optimal intervention measures constitute preserving and

restoring disrupted continuities at the individual, familial, and organizational/community levels of a personal (historical), functional, and interpersonal nature. Cognitive and emotional working-through restores *personal continuity* by exploring what has happened, ascribing meaning to it, reframing the present situation, and setting modest, situation-specific, personal goals/tasks for the near future. Situation-relevant external action reestablishes *functional continuity* by starting to act, even if on a very elementary level, and gradually broadening the scope and complexity of functioning. Activating (or reinstating) mutual support and reestablishing trust in others aids in restoring *interpersonal continuity*. Normally, progress in any one of these continuities facilitates progress in others by a ripple effect. The generic approach serves best in cases of massive intervention for survivors of war and political strife.

Organizational continuity and continuity of care can both be added to the continuity principle. *Organizational continuity* entails the restoration of the connections between children and their natural community, in which they can resume their prewar roles. Regarding children's needs, the restoration and reorganization of school is the most important and highest priority (Klingman & Cohen, 2004). Identifying, reactivating, and empowering prewar societal institutions and especially nonstigmatizing, school-based services may significantly enhance a sense of control and expectation of a return to normalcy. This favors the reverberation of the process of recovery even further throughout all the circles of vulnerability.

Continuity of care ideally relates to the restoration of prewar social welfare and mental health community services. From a mental health frame of reference, continuity of care also refers to the proactive provision of a range of accessible multimodal preventive interventions. Specifically, mental health professionals must systematically and continually assess the development of and the reduction in reactions and symptoms in all war-affected children at different points in time, thus also enabling possible identification of delayed PTSD symptoms. Professionals must ensure that the interventions applied are provided as long as necessary and that new ones are offered as needed based on periodical assessments. Schools offer the optimal setting for implementation of continuity of care. In schools, all children can be systematically observed and assessed at different points in time as well as participate directly and indirectly in preventive and other nonstigmatizing recovery programs and activities.

Selected war-related interventions illustrate the implementation of organizational procedures and measures, the generic multisystemic approach, and the unifying continuity principle as employed in war and war-related situations. These are discussed next.

Prewar Generic Anticipatory Interventions

As noted earlier, in many cases, psychoeducational interventions can address war or some aspects of it even before it begins. This anticipatory period enables some preparatory interventions to target organizations (e.g., schools) and the media, thus reaching children and their parents and teachers. The preparations in Israel for attack by unconventional weapons prior to the two Gulf Wars (1991 and 2003) illustrate one aspect of such preparatory intervention with children. *Preparedness intervention* at this period aimed to ensure that children became familiar with and competent at using gas masks and other protective measures, especially for chemical fallout. The preparatory intervention, conducted in schools, involved dissemination of carefully composed, age-appropriate information, followed by gradual exposure and desensitization (a combination of *in vivo* and participant modeling). Group (separate classes and whole-school) simulations helped students gain a sense of control and envisage themselves withstanding the threat of (unconventional) warfare effectively, should it erupt (Klingman, 2002a, 2002c; Klingman & Cohen, 2004). Psychologists helped in planning a gradual exposure to the aversive aspects of some preparation components (e.g., staying for a long time in a sealed room with the gas mask on, getting acquainted with the large-size syringe, and training in self-injection).

During this anticipatory period, *the mass media* became a central source of information, giving meaning to events and calming fears. Israeli child psychologists appeared as interviewees on psychological educational programs on television and radio that provided parental guidance on various psychological problems. The psychological principles that guided these programs were adapted to the emergency situation. Popular children's television programs were adapted as well. For example, the Israeli version of the well-known *Sesame Street* program* used the familiar characters and puppets that ap-

**Rechov Sumsum*, the Israeli *Sesame Street* produced by T. Steklov, is a well-known program geared toward young viewers, based on the U.S. program, but produced in Israel by local professionals in conjunction with colleagues in the United States.

peared regularly on the program to transmit to child viewers psychological messages aimed at helping them cope with their fears and anxieties (for an extensive discussion and recommendations, see Raviv, 1993). Such programs can be expanded (whenever conditions allow) during the war. Although these measures were specific to Israel in response to the 1991 Gulf War, these and other media interventions can undoubtedly be employed in prewar, wartime, and the immediate postwar periods in other parts of the world.

Another intervention in the anticipatory period before the outbreak of war may concern notification that a parent will be participating in the war, preparation for parental departure, and the expectation of a marked change in the family system due to this absence. It is possible to reduce the impact of separation for children, focusing on factors that most influence their adjustment to parental absence. The most critical factor is explicit, supportive communication that gives the child a rationale and clear understanding of the parents' deployment in the war (Figley, 1993a, 1993b). Attention should be directed, too, to the deployment of other family members (older sibling, uncle, etc.).

The provision of a support group for parents during the anticipatory period (e.g., via schools and community centers) should also be considered. Such support groups enable parents to be more emotionally available to their children, as well as to improve their potential continuity in providing appropriate support for the children (Cicchetti, Toth, & Lynch, 1993). Support groups that address parenting issues relevant to children's fears due to an impending war may lessen the likelihood of insecure attachments (especially in infants and toddlers) at later stages. Children indeed benefit from interventions with parents (Klingman & Cohen, 2004), but during the prewar anticipatory stage, interventions can target children directly in their schools or involve children in small-group formats, especially around art activities in afterschool programs, to include some developmentally appropriate stress inoculation techniques (Meichenbaum & Cameron, 1983).

War and Postwar Community-Based Generic Interventions

Not all wars are alike. Sometimes intervention with children during a war is next to impossible. In other wars, conditions allow for psychologists' involvement (however limited), most often as consultants to parents,

teachers, and those handling emergency reorganization in a community.

Organizational Measures Based on a Generic Frame of Reference: The Case of Evacuation from an Attacked Zone

As an example of implementing the generic approach in wartime, we may examine the case of emergency temporary hotel accommodations provided for Israelis whose homes were badly damaged in the missile strikes by Iraq during the 1991 Gulf War. As the war progressed, many hotels in the Tel Aviv metropolitan area were gradually turned into absorption centers and provisional accommodation facilities. Families were led by the authorities from the rubble of their homes to register at an on-the-scene municipal command post through which they were directed to a designated hotel. The evacuated families would arrive at the hotels in a state of shock, and many expressed a variety of fears induced by the missile attacks, such as fear of remaining alone, fear of impending strikes, and fear of being "chased by the missiles" to this location outside the targeted communities. Some were afraid to part even temporarily from other family members. The victims were anxious and on edge, some still dazed and numb. Families were placed in very small rooms in the overcrowded hotels, therefore also experiencing a lack of privacy. Entire families lingered in the lobby or walked about the hallways, often restless or irritable. Some of the older children who had assumed parental roles and some of the mothers who were trying to "remain strong" for their family "broke down." In addition, the evacuees had to confront the complex bureaucracy that was mobilized to help them. The hotel grounds became flooded with both local municipality assistance personnel and well-meaning volunteers. The entire experience of the evacuees left them feeling helpless and out of control (for an extended discussion, see Solomon, 1995).

As head of the emergency mental health team of the Ministry of Education at the time, I was invited to fulfill the role of consultant to the various (mental health as well as non-mental health) officials in charge. Adopting the preventive/organizational and generic frames of reference, I suggested that priority be given first to concrete relief and organizational (logistical and practical) measures, which would then be followed by generic mental health measures. The logistical/practical measures included supplying basic needs (e.g., beverages to avoid dehydration) and actively engaging the families in their own process of settling down. This required, first,

the restoration of evacuees' personal continuity, namely, helping them regain their personal identity (e.g., reframing the present situation, setting modest personal goals, and involvement in simple situation-specific tasks). A basic organizational measure was the officials' restoration of a sense of order, as much as possible under the circumstances, via two means: encouraging informational, instructive communication of a soothing, placating nature by the personnel in charge (i.e., a calming effect) and establishing a situation-specific, relatively structured logistical environment (i.e., an organizing effect). Personnel's soothing communication was achieved by a benevolent yet firm (but not authoritarian) stance. Recall that clarity, structure, and local leadership's confidence building constitute generic measures for intervention in mass trauma.

Referring to the practical logistics, I asked, for example, that large, clearly printed, color signs be placed in the main lobby. These signs included a simplified, clear map of the hotel grounds and facilities, indicating registration points, and a short text about basic procedures to follow. Other signs in different colors directed families who had already registered to their assigned floor and room. Lists of instructions about how to proceed further were posted on each floor. The rationale was the need to convey to parents and children a sense of surrounding order and control and to enable these evacuees to resume at least some of their personal functioning by beginning to follow directions, taking control over making preparations to ease registration, and so on. These simple logistical measures aimed to start the process of transforming evacuees' self-concept from victim to survivor, replacing the experience of helplessness with an acknowledgment of their own resources, however limited under these conditions, in coping with the trauma.

In another organizational measure with corollary mental health objectives, a large, clearly written timetable for the day was posted in the main lobby, referring to organized children's activities and play groups. This timetable further conveyed to the children and their parents that they were expected to gradually resume at least some of their predisaster activities and functioning. These opportunities for children to join in developmentally appropriate, familiar, normative (pre-trauma) popular social and peer activities also encouraged functional and personal continuities. Group activities were both fun and relaxing as well as purposeful and useful (e.g., decorating, helping younger children). Thus, the activity itself, with its experience of

control and mastery, helped youngsters regain some sense of self-efficacy. Concurrently, a sense of belonging to a group or community and a sense of solidarity emerged. These experiences could also serve as an antidote to possible difficulties ahead. Some of the group activities enabled children to act out (e.g., in puppets) their worries and express their feelings and fears. Group leaders were recruited from volunteer adult (especially unmarried) evacuees who were experienced in leading children's activities; whenever possible, older adolescent evacuee volunteers were assigned to co-lead younger children's play groups; children identified as talented musicians were asked to entertain. The group leaders were asked to focus on very simple activities, in line with the guiding principle of simplicity.

On the following day, we called volunteer teachers who were familiar to many of the children because they taught in schools and kindergartens in the evacuated areas. These teachers had had prior contact with the mental health themes because they had previously incorporated mental health perspectives into their regular prewar teaching and had engaged in preventive interventions for their classes during the anticipatory period preceding the war. We asked these teachers to now serve as tutors in the hotels for noncompulsory, 1- to 2-hour daily school-related study sessions in small groups or individually. Beyond their teaching expertise and familiarity with the evacuees' background, these teachers also served as attachment figures, mental health promoters, and "clinical mediators." Having prior experience in mental health prevention programs, these teachers required minimal introduction to their new (nonjudgmental) tutoring role and very little help with communicating accepting, empathic, and caring concern, or with conveying reassurance and structure to the children. They also needed little ongoing support from the mental health team in the implementation process. Whenever it was appropriate and feasible, we encouraged parents to join in and become actively involved in sports, drawing, or painting activities. The parents' presence and involvement aimed to enhance their sense of resuming the parenting role.

Parents became a major focus of preventive intervention, inasmuch as this organized evacuation program had intentionally avoided separating children from their family, in line with the view that family was the "first circle" of security for the children. Thus, we guided the parents in establishing a volunteer parents committee to meet daily to discuss parents' and children's pressing concerns and to become proactively in-

volved in planning, organizing, and following up on measures and activities in response to these needs. The most pressing need voiced by the parents concerned guidance on parenting in the present circumstances. In response, we offered parents small-group guidance (rather than counseling) sessions led by mental health professionals. The guidance meetings adopted a structured, solution-focused approach (de Shazer, 1985) in the form of solution-focused guidance (Klingman, 2002b, and see later in this chapter). Only very brief personal ventilation was allowed (as well as some airing of parents' logistical concerns), and then the discussion moved right on to focus on parenting. Early on, these group discussions often touched on individual parents' unhelpful tendencies, such as overprotection, denial, and avoidance; later, parents were led to discover mutual concerns and engage in finding solutions based on their mutual resources as a group. The group facilitators focused on parents sharing their successful means of coping with the situation, and especially how they tapped their inner strengths and familial and social resources, to foster parental empowerment. (See Klingman & Cohen, 2004, for other forms of parents' small-group work relating to trauma designed to attend to different parental needs in other war-related circumstances.)

Our intervention also focused on intensively supporting the mental health professionals involved with the evacuees over the period during which the war continued. By that time, professionals from several mental health disciplines were involved in the hotel-based intervention: psychiatrists, psychologists, social workers, and school counselors. Briefing and debriefing group meetings for the mental health staff were established, to be held twice a day. The morning session consisted of a very short briefing lasting about 20 minutes, which reviewed the upcoming day's schedule, specific assignments, clarification of policies, and so on. The late afternoon sessions comprised a short-term intervention that combined ventilation on the one hand (i.e., sharing and supportive listening via briefing and limited debriefing) and a solution-focused approach on the other hand, which directed attention to both the professional and personal needs of the staff. These mental health professionals found it extremely difficult to dissociate themselves from the war ordeal because they were exposed to the same conditions as the children and their parents and because child victims in particular evoke protective nurturing feelings. The professionals needed to come to

terms with and regulate their own war-inflicted reactions before attempting to help others, especially children. The staff also required psychological refueling during their extensive involvement in the trauma work. Considering these circumstances, the daily afternoon meetings provided a short (1-hour), relatively simple, support and empowerment, "helping the helpers" program. Such an intervention with school counselors in different (war-related) situations is discussed later in this chapter; a discussion on its effectiveness and details of the intervention development and protocol is presented elsewhere (Klingman, 2002c).

School-Based Intervention Following a Terrorist Attack Incident

In line with the unifying continuity principle, large-scale interventions should be delivered whenever possible via the school system. The school is the children's natural community system, where they spend much (if not most) of their waking hours, can socialize with peers, and can learn to benefit from adult (teachers') support. Schools may provide a relatively secure and predictable environment by means of a new routine reestablished as soon as possible after the outbreak of war. Substantial improvement in child functioning and adjustment can be rendered by prioritizing the reestablishment of educational and recreational opportunities as soon as possible for the postwar recovery process. Regardless of the inadequacy of the school's physical plant or the inexperience of its teachers at the time, the school remains the major community institution where most if not all children can be reached by mental health professionals through consultation (Klingman & Cohen, 2004; Yule, 2002).

An example of war-related, trauma-focused, school-based intervention utilizing *cognitive-behavior therapy principles with school children in a group* concerns the case of Israeli schoolchildren after a massive terrorist shooting attack on and around their neighborhood beachfront (Klingman & Ben Eli, 1981). The application of expressive and creative processes aimed to forge some sense of mastery and to help make frightening communication more tolerable. To help children examine what had happened more objectively, the psychologist asked them to create a model of the shooting site using clay, Play-Doh, and scrap materials. The psychologist then introduced various age-appropriate relaxation exercises and guided imagery to simulate how they would behave should such a situation occur again, exploring realistic

precautions to be taken. Next, the teacher made active efforts to help the children implement their imagined preparations, to decrease their sense of vulnerability and helplessness. The transformation of children's ideas into practical, situation-specific action aimed to address the children's repeated, even somewhat compulsive fears concerning the possibility of more attacks in the very near future (which indeed was a very real concern). The children were thus encouraged to plan specifically how each of them would behave, to look for possible hiding places, and to devise escape routes. Next, in an in vivo desensitization procedure, they were encouraged to visit (in groups and with the teacher) the place on the beach where the incident started. Since the night of the attack, when the terrorists had arrived by boat and landed on that neighborhood beach, the children had not dared approach the place, which was normally very popular with the town's children.

Expressive Activity in Large-Scale Interventions

Many, if not all, large-scale war-related interventions with children reported in the literature involve playing, drawing, and other symbolic activities. Strikingly, for example, almost all supportive interventions in the former Yugoslavia offered art and crafts to war-affected children (Kalmanowitz & Lloyd, 1999). Therapists regard symbolic and imagery processes as effective means to enhance coping under war conditions. However, structured art therapy in itself does not necessarily reduce the symptoms of distress, as attested by a large study of 600 primary school children in Bosnia (Bunjevac & Kuterovac, 1994). Nevertheless, as a means for assisting children to cope with war trauma, art, puppetry, and drama often predominate interventions and are particularly useful with latency-age youngsters affected by the crisis of war. They can act out their worries and express their fears and feelings in ways that are developmentally in tune with their ego development (Williams-Gray, 1999).

Play has been widely acknowledged as an extremely powerful modality for treating children's problems (Chazan, 2002). Given a choice, younger children prefer to interact in a playful way. Play usually supersedes verbalization in the preschool years. Although some play materials may be spurned by latency-age boys who consider them "girls' toys," these same boys may willingly engage in play with animal puppets, for instance. Playing can serve as a safe refuge when anxiety mounts and the child needs to retreat from verbalized connections to his or her "own world." In play, children process their traumatic experience by symbolizing it and modifying

its consequences; symbolic activities allow children to divide their excessive and painful experiences into small quantities, work through them, and assimilate them into their existing schemas.

Puppets can serve as an appropriate release for aggression and tension, while allowing the children to control and master a situation (Webb, 1999). In a case of peer group intervention with refugee children adjusting to their new life in the United States (St. Thomas & Johnson, 2001), puppetry served as an important action medium. All these children had experienced one or more traumas induced by the death of a relative or a close friend, were forcibly uprooted from their homeland, and faced immediate issues of survival and adjustment to their new life in an unfamiliar country. At one point in the peer group, a dragon puppet was chosen as an all-powerful character that was merciless toward all other animals. One by one, all the other animal puppets tried to stop the dragon's psychic and verbal abusive onslaught, but to no avail. Each character was jumped on physically and verbally, dismissed, or frightened away. The group facilitator then asked the participants to create a personal puppet that represented power in the natural or imaginative world. Superheroes and superheroines emerged as the youngsters drew and decorated their power symbols, utilizing the puppets to express personal needs. Asking other puppets for help, children exhibited themes of caring, friendship, support, and concern. Altogether, the children talked (through their puppets) about how abused and mistreated they felt as war victims and shared their current fears. Some talked about their hardship adjusting as refugees to the new strange environment.

By late latency or middle childhood, children's verbal communication skills increase; they become significantly more reality-oriented, thus necessitating less reliance on symbolic play. More verbalization, reality-oriented games, and large-muscle play are used. *Board games*, for example, may become useful. In a war zone in Israel, a board game was found especially effective in helping schoolchildren achieve a sense of intellectual control, and it significantly reduced their state of anxiety following a massive terrorist attack in a border town (Klingman & Cohen, 2004; Ophir, 1980). The students actively participated in creating and structuring a customized board game that included moving security and terrorist forces around the board. They thus learned the best positions for placing security forces in and around the town, considered the different security measures taken, assessed the probability of terrorists reaching

(the game's) neighborhood, school, class, and homes, and discussed possible steps in case of another attack. This enabled students to positively focus some of their energy on planning, taking action, devising solutions, and gaining a sense of control.

Although well-controlled empirical research has not yet established the specific therapeutic effect of art and play activities, or of their components, reports of large-scale interventions in war-torn zones indicate that they are widely used with children and adolescents, especially in the recovery process. *Art and play activities* include singing, storytelling, dancing, learning to play musical instruments, game playing, and creative-expressive art activities by means of masks and puppets, movement, socio- and psychodrama, creating photo journals, and building simple playing devices out of scrap or accessible natural materials. In the former Yugoslavia, play, drawing, and drama were used with children not only to encapsulate past experiences but also to develop adaptive constructions of the world for their future life (Ager, 1996; Kostarova-UNKOVSKA, 1993).

Undoubtedly, the use of art and play intervention offers an effective way to engage many children in purposeful, active self-healing when there are not enough mental health professionals to reach out to so many children and adolescents (as is the case in wartime and in war-torn regions). This intervention can be primarily handled by local staff in the educational and community settings, and may well involve local artists, too, with only one mental health professional (or very few) present as a consultant. This intervention mode also appears extensively in war-torn regions because traditional therapy is an intervention unfamiliar to children, and most of them are more comfortable exploring psychological issues through familiar play and the expressive arts. In essence, any intervention involving play and the arts is therapeutic in that it provides a supportive, structured, and supervised environment for self-exploration and the processing of emotions and thoughts in a variety of ways. The arts as an expressive medium aptly engage affective, cognitive, and perceptual capacities and allow children to use their own pace in the push and pull between the senses and cognition, between catharsis and control, and between free and structured activity. Beyond providing an avenue for children and adolescents to indirectly express their feelings and thoughts about their war experiences, art and play activities unmistakably involve generic recovery processes that overlap with established trauma-related interventions. Such are gradual exposure, desensitization, cognitive restructuring, re-

framing, and distraction. Via repetition of actions, thoughts, and emotions, the children experience and thus may gain increased tolerance and a sense of mastery. The processes involved also provide a psychological space that enables children to self-examine issues related to identity, relationships, and hope and to identify strengths and assets in the self for engaging in self-healing. When utilized as a doing-and-sharing process, the art and play activities also promote feelings of common bonds and thus enhance the discovery of safety within a group of peers. Children who find it difficult to engage in art activities can be activated in other ways in art projects, such as physically arranging for and creating exhibition space for the artwork of others.

Large-scope play and art activities are especially advantageous in a multicultural setting because they serve as a common language that is basic to all children, overcoming diversity in culture, language, and ethnic background. In addition to the work conducted directly with children, training workshops should target local mental health-related professionals and semiprofessionals, artists, educational staff, and selected volunteers to become qualified to participate in these projects. These training workshops aim to activate local persons and enable them to partake fully in the project, thus ensuring that the direct work with children continues after the mental health professionals leave.

A detailed illustration of this is a project targeting school-age children who suffered traumatic experiences during the war in Kosovo, where schoolteachers underwent training as "mental health promoters" to conduct a comprehensive intervention independently (Simo-Algado, Mehta, Kronenberg, Cockburn, & Kirsh, 2002). This project was based on a community-centered approach (i.e., focusing on the inner potential possessed by communities), a transcultural approach (i.e., reflecting the values and traditions of the culture), and a holistic approach (i.e., incorporating the physical, social, psychological, and spiritual dimensions). Each structured session began with Kosovarian poems and songs (integrating cultural aspects), continued with an indoor or outdoor game, and then moved to an activity such as painting with a free theme. Play included fun activities that, based on play theory (Morrison, Metzger, & Pratt, 1996), were considered therapeutic. Initial discussions focused on helping children identify different feelings. The children gave their artwork a title or a theme and described what they had created, why they chose it, and what they had felt while creating their product. Puppet play helped teach children to realize the importance of

discussing emotions. Play activities aimed to provide support, promote insight, and facilitate ventilation of feelings, positive experiences, and success in activities. Most of all, play served as a powerful tool for “the children’s return from a land of war to a land of children” (Simo-Algado et al., 2002, p. 205). Children’s drawings, performances, and free play evolved from darker themes to more positive thoughts. The fun activities were also reported to be the best moments to observe the children’s nonverbal behavior, which allowed teachers to identify children in need of individual attention.

In certain war situations, it may be possible to engage children in art activity while the war is still on, as in Israel during the 1991 Gulf War. Decorating gas mask boxes (which children had to carry with them at all times) became a popular activity with children and adolescents of all ages. Besides the advantage of furnishing creative activity (as previously discussed), the decorations helped disguise the frightening contents, including an atropine injection against nerve gas and powder for burns. Thus, this activity rendered the boxes less threatening and more personal. Also during the war, schools remained closed but Israeli museums remained open and offered unique art projects. Museum paintings were removed from the gallery walls and stored in underground shelters to prevent damage during the massive missile attacks. Large sheets of paper were hung on the empty wall space, and schoolchildren were invited to paint murals and pictures of their perceptions and views of the war. One such project involving children who were evacuated from their destroyed homes served primarily a therapeutic purpose. It consisted of four stages. First, the room was covered with visual images from newspapers. The children were asked to draw their personal stories in comic-strip style with a fine black pen. Pen and ink were used in the second stage and water colors in the third stage. The final result appeared on a large piece of white painted plywood. Many creations depicted destroyed houses and missiles. Interestingly, some of the missiles were drawn to appear floppy instead of straight, perhaps indicating the children’s desire to neutralize them. The wish to diminish the power of the missiles also manifested itself in the size of the houses, which towered over the missiles (Shilo-Cohen, 1993).

Nature-assisted projects constitute another way to help children cope in wartime as well in the postwar recovery period. In the former Yugoslavia, children were organized into garden clubs that engaged in planting and finding ways to protect their plants from damage during

enemy attacks (Berk, 1998). The therapeutic value in such programs lies in providing children of war with life-renewing energy by promoting active coping, creativity, caring, and a future-oriented outlook.

Nature-assisted support programs are yet another innovative intervention when employed for enhancing children’s recovery. Such an intervention can be a nature-oriented program in itself or just one activity within a wider spectrum of activities. Pardess (2002) conducted such an intervention with Israeli children who experienced traumatic loss as a result of ongoing terrorist attacks. Some children had lost several close family members in one attack. This nature-oriented intervention program incorporated verbal and nonverbal techniques such as movement therapy, storytelling, creative art projects, and pet therapy. Its focus was on a multisensory nature hike combined with discussion group sessions led by an expert botanist and supervised by a mental health professional. The hike centered on the process of regeneration and rebuilding following a forest fire or other natural disaster. This activity evoked strong responses among the children and facilitated a discussion about survival. It was followed by an art session entitled “Telling the Story of the Hurt Tree.” The children drew and told the story of the recovering tree, thus acknowledging their own loss and considering a personal narrative that may be shared with others (Klingman & Cohen, 2004).

In another *combined action and art activities* program (St. Thomas & Johnson, 2001), refugee children took a nature hike to a large waterfall. They were encouraged to observe the natural world and to gather any natural objects that reminded them of their own strength or ability. These authors also reported that an outing coupled with drawing, journal writing, fishing, guided imagery, playing games, and dramatic play opened the door for personal stories and grief.

Enhancement of Coping and Resiliency in Generic Terms

Many difficulties associated with war loom large and complicated for children. From a generic frame of reference, one of the most effective coping strategies in managing the stress of war involves *breaking down major problems into more manageable subcomponents* (Hobfoll et al., 1991). This may enable more effective coping and the experience of more positive outcomes. Even very small gains lead to a greater sense of mastery and con-

trol over the environment. This, in turn, helps individuals to feel and become more effective (Bandura, 1982; Meichenbaum, 1985) and move away from their victim role. Interventionists should thus assist children in disentangling the jumbled aspects of their situation. From the generic frame of reference, this involves setting up small, accomplishable tasks and goals, where the child is rewarded for small successes.

Also, children should receive encouragement to engage in helping behaviors. By taking part in finding solutions for their own family, their peers, and their community, children and adolescents can develop an enhanced sense of mastery and control over their lives and cope more effectively with stressful war events (Hobfoll et al., 1991). For example, during the anticipatory training to use gas masks and other protective equipment against unconventional weapons immediately prior to the 1991 Gulf War, trainers conveyed to the Israeli children the expectation that they should help train younger siblings and older persons in the household and should also help them don the masks properly in real time. This anticipatory guidance intervention was school-based and included all students nationwide. Many schoolchildren were reported to have been very helpful in these roles during the war. Indeed, by becoming involved in problem solving and a part of the solution to others' problems, children can move out of their victim role and enter a mastery role (Klingman & Cohen, 2004).

Experience with war-related generic interventions for children, parents, and teachers attests to the benefit inherent in a broad-spectrum group intervention, especially in the *multimodal coping and resiliency intervention* approach implemented in Israel and in the former Yugoslavia (Klingman & Cohen, 2004; Krkeljic & Pavlicic, 1998; Lahad, Shacham, & Niv, 2000). This approach borrowed from Lazarus's (1997) multimodal psychotherapy, which focused on seven core modalities summed up as the acronym BASIC ID (behavior, affect, sensation, imagery, cognition, interpersonal, and drugs). One such model's modification in terms of generic coping enhancement and resiliency (Lahad et al., 2000) proposed an organization around six BASIC Ph modalities (beliefs, affect, social, imagination, cognition, and physiology). Klingman and Cohen (2004) suggested intervention with parents around eleven integrative components, BASICS PhD B-ORN (beliefs, affects, sensations, imagination, cognitive abilities, social or interpersonal, physiology, drive, behavior-organization, reflective ability, and narrative

systems). The first eight of these parent coping resources (BASICS PhD) may be activated at the beginning, whereas the last three (behavior-organization, reflective, and narrative) require some time to activate.

Smith et al. (1999) developed a more structured and trauma-focused program for large-scale intervention that includes a manual for "Teaching Recovery Techniques." This psychosocial-educational program's five main sessions concentrate on helping children deal with the troubling symptoms of intrusion, arousal, and avoidance. The group facilitator takes children through various warm-up exercises and helps them adopt a problem-solving and group-sharing approach to the difficulty. With regard to intrusion, children learn distraction techniques and dual-attention techniques (similar to some eye movement desensitization and reprocessing [EMDR] techniques). To reduce arousal, children learn to identify their reactions and then to relax at will. With respect to avoidance, children practice imaginal exposure followed by self-reinforcement. Above all, children are encouraged to look to the future rather than to the past. A single session with parents to explain the intervention and give them suggestions on helping their children constitutes an essential element in this package (Yule, 2002). As with the BASIC Ph, this program design permits delivery by persons who possess a minimum of mental health intervention experience, but who receive training and supervision by someone with more mental health expertise. In general, these and similar interventions derive from established theoretical orientations and sound clinical experience; reports on their effectiveness indicate that they are suitable and useful. However, their specific effectiveness still awaits systematic evaluation.

Written generic crisis intervention guides, manuals, or kits for schools also appear helpful. They can serve as a blueprint for the school while organizing in preparation for war, as well as for teachers during war and in the postwar recovery process. Yule and Gold (1993) developed a booklet to help schools in the United Kingdom prepare for responding to crises. The booklet addresses such topics as reactions to major stress in young people, who is likely to be affected, and what the school can do in terms of short- and medium-term action and longer-term planning. This booklet, mailed to every school in the United Kingdom, received very positive feedback on its usefulness (Yule, 2002). Similarly, I developed a guidebook (Klingman, 1991) and an emergency kit (Klingman, 1997) to address Israeli school-based crisis

intervention in mass trauma, as well as offering teacher-led classroom activities and tools. The structure and contents are described elsewhere (Klingman & Cohen, 2004, pp. 105–106). The guidebook stated that the activities presented are examples and that teachers are expected to come up with their own; schools should also examine what is best for their individual setting in the specific crisis situation at hand. The Israeli Ministry of Education distributed the guidebook and the kit to all school psychology services and to every school in Israel. The kit was extensively used in schools located in war zones (especially in the occupied territories), which provided highly positive feedback on the materials' helpfulness. In examining the guidebook's usefulness about a year after its distribution, I sent a questionnaire to a sample of 280 school counselors in war-affected areas. From the 227 questionnaires returned, 98% of the counselors reported that the guidebook had been used in their schools, 72% reported that they independently added tools and content from other sources, and 47% reported "creating" (at least two) new tools based on the guidebook's suggestions and tool samples and using them with or instead of the tools offered in the guide. Such guides, manuals, and kits, based on sound clinical experience and the generic approach, do indeed appear useful, whether used as is or employed as a stimulus to select or create school-specific tools. One of their advantages is their package format that can be implemented by paraprofessionals and adults with a minimal level of mental health background and experience. Their cost-effectiveness in reaching a vast child population affected by war should also be noted. Despite these guidebooks' reported usefulness, future systematic evaluation must examine their specific effectiveness.

The School as a Focal Point for Generic Intervention

Many generic measures can be successfully carried out by schoolteachers (Klingman & Cohen, 2004). The schoolteacher is placed in a number of significant roles in times of mass trauma, beyond his or her traditional role as an expert in instruction (see Wolmer, Laor, & Yazgan, 2003). The teacher in wartime and its aftermath may actually serve as a "clinical mediator." Although teachers may initially be reluctant to assume such a role, our repeated experience in war-torn zones attests that with appropriate and relatively brief training, teachers can successfully employ active listening and can act as role models who encourage, inspire, and facilitate con-

structive coping with the children. Teachers are valuable in helping children apply coping skills to their everyday life and to new concerns and conflicts as they arise. The teacher also has numerous opportunities to closely observe and follow up students in their natural setting. Practical considerations (e.g., limited resources, shortage of mental health professionals, cost-effectiveness, and the reluctance of victims to seek professional help) and conceptual considerations (e.g., nonstigmatizing approach, "normalization" of stress, empowerment, positive psychology) mandate that intervention efforts should involve as many children as possible by working with them in groups in their natural setting. Local teachers are the most familiar with local traditions and are able to integrate or add them to any generic intervention program. My experience has shown that when schools follow the generic approach and the unifying continuity principle, they become a sort of *therapeutic milieu* and a valuable *focal point for mass (multisystemic) intervention*. The cooperative efforts of the school organization, homeroom teachers, parents, and community (especially welfare and mental health) agencies can proactively create a "protective shield," accentuating empowerment, resiliency, strengths, growth, and a positive outlook in coping with the war's adverse events.

Helping the Helpers

Naturally, most efforts must be invested in the plight of the directly war-affected children. However, a lesson learned from recent wars revealed the vast importance of helping mental health interventionists when they are helping others, especially children. Compassion fatigue (Figley, 1995) poses a major risk for vicarious or secondary traumatization among interventionists in war-torn regions. In many war zones, mental health providers have shared the war experience or the same traumatizing circumstances as the treated population (e.g., a "near miss"). Some professionals may have been exposed to morbid experiences themselves; others may continue to be worried about the recovery of their own children and other family members; and for others, seeing and hearing about the adversities (especially those the children went through) takes its psychological toll. Interventionists often feel overwhelmed by the scope of the recovery task ahead. They may not have immediate relevant answers to many of their clients' needs. Shortage of professionals often results in overwork; the combination of work overload, high commitment, and emotional exhaustion leads to quick burnout. Although

the adoption of the generic approach and principles and the unifying continuity principle serve well as a partial solution to this problem, for many professionals this approach entails a shift in professional orientation as well as roles, especially for those who were not previously involved in intervening in mass trauma. Thus, "helping the helper" interventions must become an integral part of any mass war-related intervention with children.

In this regard, *group psychological debriefing* may furnish a suitable tool. Debriefing originally evolved to assist emergency personnel in adjusting to their emotional reactions to events encountered in the course of rescue work (Mitchell & Everly, 1997). Psychological debriefing usually underscores ventilation of feelings, experiential reviewing, and emotional sharing in small groups. Commonly employed helping-the-helper interventions in many war-related specific circumstances in Israel include supportive listening and debriefing-focused methods, especially those focusing on catharsis and attempting to direct participants' attention to internal affects and thought processes through insight-oriented methods. Gal (1998) reported an extensive program for mental health professionals in the former Yugoslavia that involved training in various trauma-relief issues, along with debriefing sessions that dealt with the helpers' stresses and burnout.

However, experience shows that what is needed in wartime and in the immediate postwar circumstances often goes beyond emotional intervention. Professionals also need longer-term *practical support* for handling the enormous tasks at hand. To empower interventionists to cope more effectively with their role-related issues and professional dilemmas, they often need to arrive at practical solutions. This support addresses situation-specific instrumental and personal coping resources as well as effective strategies and techniques for mass intervention. For example, a war-related helping-the-helpers program with school counselors utilized solution-focused methods following a structured brief version of process debriefing (Klingman, 2002b). This intervention was based on a structured group process and directive-active group leadership roles, assigning great responsibility to the group leader(s) to proactively establish a climate favorable for short-term group processes. The debriefing part of the intervention consisted of an introductory lecture; limited in vitro exposure, involving precise labeling for feelings and thoughts to allow limited ventilation of feelings but also to indicate the role of cognitive processing of the affective responses; sharing personal coping, in-

cluding past and present strategies and skills; discussing role-related problems, including clarifying role definitions; and a focus on the positive lessons learned.

The *solution-focused orientation* of this intervention aimed to move quickly onward to focusing on participants' resilience and shifting their attention outward and toward other people and external practical tasks. Purposeful questioning and other techniques helped professionals gain a more realistic sense of what was feasible in the given adverse situation. Dealing with situation-specific practical goals and participants' expectations proved very helpful for setting more modest and manageable goals and expectations for themselves and their clientele. The intervention included discussion of alternative solutions suggested by the participants. This promoted active engagement and a mood of expectation regarding desirable outcomes, and, not least important, it enabled participants to see that no immediate dramatic actions on their part were required, whereas some small steps could be taken effectively. Overall, this solution-focused guidance, rather than a counseling or therapeutic approach, emphasized a gradual but relatively swift shift from "problem talk" to "solution talk," concentrating on strengths and inner resources. A solution-focused approach derives flexibly from several models of social and individual psychology and borrows various techniques from other therapeutic approaches, yet retains its own theoretical integrity.

Another reported intervention adopting the narrative approach (and in part matching the solution-focused approach) was employed extensively with Israeli school psychologists and counselors in areas affected by frequent massive terror attacks (e.g., Shalif & Leibler, 2002). This intervention addressed coping abilities, exceptions to the negative influences of the terror attacks, and meaning giving. It focused on "reauthoring" the talk about the traumatic events, exploring different possible meanings of the traumatic events, and adopting the most validating and empowering ones. Specifically (and in line with some of the solution-focused guidance approach), it included externalizing conversations to create a "reflective distance," mapping the effects of the problem (i.e., discovering areas and spaces where the problem/difficulty has less influence and where greater opportunities of counteracting these influences exist), and finding the exceptions and unique outcomes (i.e., areas in which the problem or difficulty did not take over, against all odds: experiences that instead strengthened or "organized" the person, the

community, and society). This specific intervention demonstrated to the participants how attention to language and the power of ideology, religion, and community support could play a central role in deconstructing the negative meaning of “trauma” and in supporting the potential for growth.

INDICATED INDIVIDUAL AND SMALL-GROUP SYMPTOM-FOCUSED INTERVENTIONS FOR POSTTRAUMATIC STRESS DISORDER

Above all, the scope of war’s effects on children, and the difficulties involved in reaching out to so many war-affected children, necessitate the adoption of large-scale, generic, community-focused, and preferably school-based intervention. As described earlier, conceptually, the war-affected children, their parents, and their natural community and culture do possess mechanisms for natural recovery. Therefore, an emphasis on community-focused preventive intervention in trauma work is preferable to an emphasis on the reduction of symptoms. Thus, this chapter has heretofore called for an alternative flexible, continuous, health-oriented, generic approach, which addresses various needs at different phases of coping with traumatic war experiences. However, there are exceptions. Some children’s symptoms do not remit, but even worsen to fit a clinical diagnosis of PTSD or other trauma-related disorders such as anxiety or depressive disorders. Some children experience the intensification of preexisting problems or evidence delayed posttraumatic responses. For others, extensive war-specific fears may put them in immediate danger, affecting their safety. Children whose problems persist despite the generic intervention efforts will benefit from indicated interventions, which focus less on the generic approach and more on the unique needs and problems of individuals, through individual or small-group counseling or therapy.

War-related symptoms in children may develop around specific war-related fears; such fears, which are based on reality, may become generalized or elicit more fears. Although children are rarely treated in the midst of a war, and almost no reports appear in the literature on individual child treatment at the impact stage of a war, such cases can often be successfully treated with short-term intervention for specific fears.

For example, a *fear-focused intervention* during the impact stage of the 1991 Gulf War targeted a 5-year-old

Israeli boy who refused to put on his gas mask during air raids (Klingman, 1992). Here, a short-term, family-mediated, cognitive-behavioral intervention was the method of choice. At intake, the parents’ interview centered first on ventilation of their anxiety due to the urgency of the situation: the very high probability of chemical or bacteriological missile warheads and their concern for their son’s safety. This was followed by an analysis of the child’s behavior (noncompliance, angry tantrums), discussion of the relevance of behavioral principles for compliance, and development of a contract agreement. The parents received step-by-step instructions in recording their child’s behavior for the baseline and control phases and in using at-home story reading bibliotherapy, play, and cognitive-behavioral prompts on the target behaviors. They received a specifically designed story and coloring booklet for their child. This booklet depicts a family preparing for and actively coping with the ordeal of the war (e.g., missiles, chemical warfare, confinement in a sealed room, problems with gas masks, anxieties). The story centers on a child’s teddy bear, who is very “confused” and “afraid,” and for whom a gas mask is made. The boy in the story deals with his teddy bear’s noncompliance and anxiety. The story also focuses on looking beyond the ordeal, such as the funny and positive aspects in the present situation (e.g., “My parents look so funny in this mask”; the family’s intense experience of togetherness) and a positive future/optimism (e.g., going back to kindergarten when the war is over, and the reunion scene in the kindergarten). The parents received instruction on how to respond to their child’s noncompliance by agreeing about the difficulty but not implying that there was any choice about it, by responding with “That’s just the way things are,” for example. They were told how to praise him with “you” compliments (e.g., “You must be proud of yourself”) rather than with “I” compliments (e.g., “I am proud of you”) to encourage his self-esteem and confidence. Story sharing, coloring, and playing created psychological space and a relaxed atmosphere.

The results of this intervention, based on a single-case research design (Klingman, 1992), supported the application of the combined procedure. This intervention represents the successful use of a relatively short parent-implemented, home-managed, crisis intervention in the midst of a war, utilizing a combination of contact desensitization and cognitive-behavioral prompts via behavioral guidance to parents, the use of a bibliotherapy-based psychoeducational play method with the child,

conveying to the child an expectation of recovery and behavior change, and reinforcing the desired behavior change. The need for professional contact with the child was replaced by training the parents both to assess and to intervene. The professional served as a change agent providing psychological support, training, and some corrective feedback in the course of a 3-day time span. This example demonstrates that in certain cases, when war conditions allow, reactions that center on war-related fears can be treated in the midst of a war using a short-term, problem-focused, or solution-focused intervention. A major component of such interventions concerns conveying the clear message to children that they can overcome the specific difficulty and do what must be done (which may involve suggesting specific alternatives to the child). In addition to the practical advantage in having the parent(s) as the clinical mediators in real time during an ongoing war emergency, most important was the parents' involvement in the treatment. Parents' involvement helps prevent them from projecting their own concerns and anxieties onto the child around his or her difficulty. For example, in war situations, parents may especially tend to shield the child rather than prompt and reinforce independence or self-care behaviors. Such behavior might unintentionally preserve or even enhance the child's sense of helplessness, and in some cases encourage secondary gains that can become predominant in the child's behavioral repertoire.

Interventionists have successfully utilized *play therapy* with children who have been traumatized (Bevin, 1999; Gil, 1991; James, 1989; Pynoos & Eth, 1985; Terr, 1983). Bevin reported on rather extensive use of reconstructive play in a therapy for a 9-year-old Nicaraguan boy a few months after arriving in the United States, representing the typical experience of many children from war-torn countries who enter the United States. The boy, who survived the traumatic experience of illegally crossing a border and watching his mother being raped, received a diagnosis of suffering from symptoms consistent with PTSD. The main treatment goals were to increase his speech production and social interaction and to improve his mood, while decreasing his panic-like reactions, passivity, and tendency to worry excessively. He was treated individually for 1 hour twice a week at school, and the therapist visited his home one evening a week to allow his parents to participate in family sessions as cosurvivors of the trauma. After several initial sessions that included talking, storytelling, drawing, and playing guessing games, more directive

play therapy sessions began. Every session started with a period of relaxation. Through manipulation of dolls, the boy could subconsciously identify his own maladaptive coping techniques and thus be helped to conceptualize the aftereffects of his trauma at some level and to recognize his posttraumatic behaviors and feelings. It was impossible (as it is in many cases) to identify one factor that was critical in the management of this case. Whereas the play reenactment evidently helped turn passivity into activity and provided an outlet for his frustration and anger, overall the therapist attributed the positive outcomes to a combination of the treatment approach and the methods used. In this case, the nine-session directive play therapy was integrated into a longer-term intervention. Also, the involvement of the parents in therapy, their willingness to work with their child, their high level of cooperation with the therapist, and their ability to face their own (trauma-related) difficulties and anger were of primary importance to their child's recovery. The introduction of toy replicas representing aspects of the traumatic event and the therapist's active though sensitive encouragement of the child to process a set of sights and emotions can expedite the child's resolution of difficult aspects of the traumatic experience (Nader, 2002).

In contrast to directive play therapy, some therapists (e.g., Ryan & Needham, 2001) support a nondirective approach to play therapy with traumatized children. They argue that nondirective models avoid direct confrontation with the trauma itself and thus minimize the risk of strong negative reactions in children with PTSD.

Several forms of therapy for posttraumatic response and for PTSD conform to the continuity principle. Apparently, at least in war situations, psychotherapists intuitively choose to work with this principle in mind regardless of their formal, preferred, habitual therapeutic approach (Alon & Levine Bar-Yoseph, 1994). Alon and Levine Bar-Yoseph reported an intervention with children that followed the unifying continuity principle. This 10-session case study dealt with an Israeli family whose apartment block had been targeted in a terrorist attack, resulting in several deaths and injuries. All family members narrowly escaped but could not find one another during the event. Although at first they responded well, a financial crisis unrelated to the trauma brought about full-fledged PTSD in all of them. The two sons, ages 6 and 9, were treated at home, and the parents were asked to serve as cotherapists and coaches for the children

between sessions, thus fostering vicarious learning as well as the resumption of habitual roles.

First, a debriefing session asked each member to recount his or her actions during and after the assault. A combined picture, depicted in diagrams and broadened as a result of the therapist's questions to include thoughts and emotions, revealed everyone's resourcefulness and delighted all, especially the proud parents. Then, freedom of movement at home was reestablished by conjointly making a hierarchy of fear of the various apartment rooms, from most horrible and therefore not to be tackled before the following week's session, to the most bearable. The children were trained to move from the "panicking room" to their parents' safe room while singing a "Song of Fear," a humorously lamenting, wailing song improvised by the therapist. In the following weeks, family members learned self-relaxation. Next, they underwent desensitization to the place in the house where they had encountered the terrorists; this involved playing ball near the site in such a way that the children would spontaneously run after it when it dropped. Reestablishing and reinforcing family routine and cohesion was achieved by starting each session with a joint family-and-therapist lunch under the pretext that the therapist came from a distant city and needed some refreshment. Discussions with the parents about children, about trauma and its implications, and about the parents' image in the children's eyes all served as an indirect suggestive intervention for the parents. A 2-year follow-up showed satisfactory adjustment.

In sum, the following points deserve note: This intervention taught children self-hypnosis for relaxation and better sleep and provided desensitization to places in the house where they had met the terrorists; the continuity principle was applied throughout the intervention; indirect discussions about the children, about trauma, and about its implications all served as indirect suggestive therapy for the parents; and by asking the parents to serve as cotherapists and coaches for the children between sessions, the therapist fostered not only vicarious learning but also the resumption of habitual roles.

To date, little evidence has shown that drug treatments have a central role in the treatment of children; therefore, cognitive-behavioral treatments have constituted the main interventions aiming to help child survivors make sense of what they experienced, promote emotional processing, and master their feelings of anxiety and helplessness. The problem for the therapist lies in finding the optimal means to help children reexperience

the traumatic event and the emotions it engenders in such a way that the distress can be mastered rather than magnified (Yule, 2002). One means, exposure under supportive circumstances, has been reported as helping children deal well with both intrusive thoughts and behavioral avoidance.

Single-case studies with children's war-related post-trauma symptomatology reported the general efficacy of *in vitro flooding*. This method was employed in treating Lebanese children individually some time after the traumatic incident (Saigh, 1987a, 1987b, 2000). In one case (Saigh, 1986), a 14-year-old male who was abducted and held by militia for 48 hours was referred for evaluation by his school principal 6 months after the abduction. The complaints involved symptoms that were not evident before the trauma: anxiety-evoking recollections of the trauma, abduction-related avoidance behaviors, depression, temper outbursts, and difficulties concentrating and recalling information. Saigh chose *in vitro flooding* based on the suggestion that it involves fewer treatment sessions than systematic desensitization and that earlier attempts to treat cases of PTSD through systematic sensitization were unsuccessful. The treatment identified four anxiety-evoking scenes involving the chronological sequence of events of the traumatic abduction, and then stimulus-response imagery cues were presented across scenes. A single-case design analysis revealed that this treatment had a positive influence on the client's affective, behavioral, and cognitive outcome measures. The treatment procedure involved therapist-directed relaxation exercises. Other cases reported by Saigh (1987a, 1987b) revealed positive changes using *in vitro flooding* to treat a 6-year-old boy 25 months after being exposed to a bomb blast, two 11-year-old girls (one who witnessed two pedestrians die during a shelling incident and the other who witnessed the shooting to death of a man by a sniper), and a 12-year-old boy whose home had been partially destroyed during a shelling incident. The overall results suggest that the *in vitro flooding* package had a palliative influence on the children's affective, behavioral, and cognitive parameters, and these improvements occurred after 8 to 15 treatment sessions.

Criticism of *in vitro flooding* with children has focused on the risks elicited by the exposure component. Persistent talking about traumatic events to children who are embarrassed or highly resistant may in fact worsen symptoms. Exposure may be counterproductive when excessively gruesome details that evoke strong

emotions leave children in a heightened state of arousal, thus sensitizing them rather than helping to habituate anxiety. Younger children in particular may be unable to imagine certain traumatic material, tolerate exposure, or follow relaxation procedures. Avoidant children may resist carrying out instructions to confront the avoided thoughts and images. However, dealing with traumatic issues indirectly through the use of art (e.g., drama, play) may be helpful in such cases. Asking children to draw their experience often assists recall of both the event and the associated emotions, thus employing drawings not as projective techniques but as ways of facilitating talk about the experience. Also, treatment with children is not usually limited to exposure per se: Participants generally receive a multifaceted treatment package that includes parent-child education regarding PTSD, education regarding the flooding process, relaxation training, prolonged imaginal exposure, and debriefing (American Academy of Child and Adolescent Psychiatry, 1998; Klingman & Cohen, 2004; Saigh, 2000; Saigh, Yule, & Inamdar, 1996).

Ronen (1996b) reported a war-related short-term, group-based intervention based on *self-guided, self-control exposure therapy* to treat 8- to 11-year-old Israeli children 4 to 6 weeks following the end of the 1991 Gulf War. All children exhibited anxiety reactions as an outcome of the war and features of preexisting separation anxiety disorders that continued or intensified throughout the war. The children and their parents attended one individualized intake session, two parent-child group intervention sessions, and one follow-up group session. The parents' active participation involved them and the child in constructing graphs together that plotted the improvement in the child's anxiety levels (before, during, and after each exposure assignment), reinforcement procedures for the child's achievements of reality-based predictions, and completion of exposure assignments. A tendency emerged for children's decreased anxiety levels and increased calmness during exposure compared with other days, and the parents learned to compliment the child for small steps toward success every day, compared with the day before. As part of the exposure assignments, the children themselves were placed in charge of selecting the individual kinds of exposure tasks, degree of exposure, and length of exposure. Self-control methods for exposure were the use of imagination, self-reinforcement, commands to the brain, and self-compliments. Preliminary findings indicated that self-guided self-control exposure therapy conserves the

therapist's resources and facilitates rapid improvement in both postwar fears and prewar-initiated separation anxiety. Nonetheless, this intervention's success depended much on the parents' full cooperation.

With regard to PTSD in children, the treatment of children of war is often based on PTSD diagnostic criteria as presented in the *Diagnostic and Statistical Manual of Mental Disorders IV (DSM-IV)* (American Psychiatric Association, 1994). The *DSM-IV* guidelines, however, tend to be "adult-o-centric" (Yule, 2001) and should be viewed as a work in progress with regard to children. For example, children do not usually experience the unexpected flashbacks that characterize adults' PTSD. Based on research findings, some researchers (e.g., Scheeringa & Zeanah, 2001; Terr, 1985) have suggested accommodations and changes in the use of PTSD criteria for children, especially under the age of 6 years. The suggested *child-specific trauma-related symptoms* that differ from those of adults include repetitive play (possibly a behavioral equivalent of the more cognitive intrusive thoughts and imagery of adults), regression (e.g., to babyish games, baby talk, bedwetting), and a sense of a foreshortened future as a predominant symptom in adolescents. Children, more than adults, may express their distress somatically and demonstrate self-blame. Other child-specific symptoms include restriction of social play, social withdrawal, restricted range of affect, loss of acquired developmental skills, new aggression, new separation anxiety, and new unrelated fears (Klingman & Cohen, 2004; L. Miller, 2003; Scheeringa & Zeanah, 2001).

An *expanded view of posttrauma adaptation and psychopathology* focuses more on the developmental implications and the successful progression of developmental processes of children under the influences of war trauma. It considers a range of psychological and socioenvironmental risk and protective factors related to the pretrauma, peritrauma, and posttrauma ecologies. Such a view targets those factors that cause continuous stress and the natural recovery processes rather than merely using the classificatory psychopathological approach and thus treating only the individual's symptoms (Klingman & Cohen, 2004; Layne et al., 2001; Saltzman, Pynoos, Layne, Steinberg, & Aisenberg, 2001; Saltzman, Steinberg, Layne, Aisenberg, & Pynoos, 2002; Shalev, 2002).

Along these lines, Ronen (2002) discussed in some detail the difficulties in assessing traumatic reactions in children and suggested guidelines for the assessment and

treatment of traumatized children from a cognitive-constructivist frame of reference. She suggested that assessment should derive from PTSD criteria, the context of normal childhood behavior problems, and developmental considerations. Cognitive-constructivist treatment focuses on the child's developmentally linked powers of personal monitoring and meaning making, and on the child's awareness of the processes involved and their functions. Children learn to understand and accept traumatic events as part of life and to give these events new meaning, which can generate better coping and potential growth and maturation (Ronen, 1996a, 2002).

Close to this approach, several *psychosocial group programs* for the treatment of youth exposed to trauma and traumatic loss have been established and studied in recent years. These interventions usually targeted postdisaster stress symptoms (e.g., Chemtob, Nakashima, & Hamada, 2002; March, Amaya-Jackson, Murray, & Schulte, 1998; Saltzman et al., 2002). Although these programs have not yet been specifically developed in the context of war-related events, their structure and techniques lend themselves readily to such use. March et al.'s program emerged as safe, effective, and durable in alleviating PTSD symptoms (as well as depression and anxiety) among 10- to 15-year-olds who evinced a primary, full PTSD diagnosis and who had each individually suffered a single traumatic incident. The intervention consisted of a school-based, group-administered, 8-week, cognitive-behavioral intervention protocol. The design derived from a theoretical model integrating the social and biological foundations of PTSD with social learning theory, conditioning theory, and cognitive information processing. It included anxiety reduction using relaxation training, skills for coping with disturbing affects and physiological sensations, anger control, and positive self-talk.

Another program, the UCLA Trauma Psychiatry Program, was implemented in postwar Bosnia (Layne et al., 2001). This 16- to 20-week intervention comprised trauma- and grief-focused group psychotherapy. Its main foci were the traumatic experience, trauma and loss reminders, secondary adversities, grief, and developmental impact. Unique to this program was its focus on identifying adolescents' missed developmental opportunities and their current difficulties in functioning, and in initiating more desirable developmental progression and prosocial adjustment. Whereas March et al.'s (1998) program did not include the parents, the UCLA program included family therapy. Both these programs seem optimally suitable for the treatment of adolescents.

By contrast, Chemtob and his colleagues (2002) developed a four-session, individual or group integrative psychosocial intervention for postdisaster trauma symptoms in elementary schoolchildren. This program included a standard box of play and art materials and incorporated experiential activities designed to elicit reflections relevant to each session. The interventionists reported the program's effectiveness in reducing disaster-related symptoms in children 2 years after a hurricane disaster. Interestingly, although the group and individual treatments did not differ in efficacy, fewer children dropped out of the group treatment.

Considering that political violence may also affect children indirectly through its impact on their mother's health and well-being (K. Miller, 1996), the best and sometimes the only way to reach out to traumatized children during wartime conditions may be to *help parents in groups* to overcome their anxieties. Thus, parents can develop better situation-specific functioning in the family environment conducive to the recovery of their children. At the same time, this treatment mode addresses the practical limitations of treating massive groups in need with the shortage of mental health professionals available. For example, preschool children who had lost their Iranian soldier father were found to be best helped through supporting their mother to overcome her grief and help her provide a well-functioning home environment (Kalantri, Yule, & Gardner, 1993).

Dybdahl (2001) developed a manualized psychosocial support intervention program consisting of semistructured group discussion meetings designed to help war-exposed mothers with their own psychological problems as well as those of their children, and to facilitate improved mother-child interactions. All participants were victims of the war in Bosnia and Herzegovina, through both war activities and having to flee their home to seek refuge in another part of the region. The psychoeducational approach included provision of information about trauma and trauma reactions in adults and children, as well as suggestions on how to meet common posttraumatic needs and problems. Emphasis was placed on strengthening the participants' own coping, but the group did not receive traditional therapy. The groups reinforced basic communication and interaction skills that already existed. Mothers shared their experiences about the topics discussed, their feelings, and their coping strategies, and also discussed suggestions raised by the group leader. Although the effects of this intervention program on children's symptom reduction and increase in positive char-

acteristics were modest, they coincided with the results envisaged for this type of program. Furthermore, the effects of the intervention were notable relative to the program's simplicity, low expense, and duration (weekly group meetings for 5 months).

As most of the reviewed cases demonstrate, treatment of children during wartime and in war-torn zones should focus particularly on active parent involvement. Furthermore, in many cases, parents are called on to participate actively as cotherapists or even to assume the role of interventionist (clinical mediator), with the professional therapist as a consultant. Such cases involve short but extensive situation- and child-focused parent training.

A review of the available controlled treatment outcome studies for PTSD in children in general does not establish the clear advantage of one treatment over another. Existing data substantiate the need for comprehensive, broad-spectrum, multimodal, and multidimensional treatments of children suffering from PTSD and other trauma-related disorders (American Academy of Child and Adolescent Psychiatry, 1998; Woodcock, 2000). Indeed, several empirically sound studies revealed that cognitive-behavioral therapeutic components proved most effective in treating war-traumatized children. However, results in all these reported cases were obtained through the application of a multicomponent treatment package (i.e., including education, relaxation, and self-monitoring), thus precluding the attribution of success to one sole component (e.g., in vitro flooding) within the overall package (Saigh, 2000). Also, except for one case (Klingman, 1992), the children and their parents were not in any immediate danger due to a state of war at the time of treatment, nor were the activities involved in treatment (e.g., behavioral walks) dangerous.

OPEN QUESTIONS AND CONCLUDING REMARKS

The literature review at the beginning of this chapter surveyed the impact of war on children and their psychological responses to it. Clearly, many of the reviewed topics underwent careful observation but lack sound systematic research data. As one illustration of this gap, the psychological aspects of young people's physical recovery processes have not been directly addressed in the literature, nor are developmentally focused controlled studies available, despite the large number of young

people injured during war. Clinicians emphasize that adolescents, in particular, may be traumatized by their wounds because, for them, the smallest bodily imperfection is of enormous significance (Bronfman, Campis, & Koocher, 1998; Green & Kocjan-Hercigonja, 1998). Plausibly, even minor wounds may pose considerable risk for posttraumatic difficulties and perhaps disorders in children and adolescents. In addition to processing traumatic war experiences and perhaps the loss of significant others, these children possibly have to deal with loss of personal control, injured self-image, dependency, stigma, isolation, anger, intense emotionality, and fears of death or of the future. Moreover, the injured parts of the body may act as a constant reminder of the trauma, further interfering with the processing and resolution of traumatic experiences. Also, as in the case of the combination of trauma and bereavement (see Klingman & Cohen, 2004, for details on this high-risk combination), unsuccessful attempts at processing the traumatic injury may easily complicate the psychological recovery from injury. Despite some clinical testimony and the clinical speculation concerning these issues, at this point in time we must rely mostly on limited clinical observations of nonwar cases, such as the detailed clinical issues for acutely injured and medically traumatized children described by Bronfman et al. (1998). Research is needed in this area, considering that wounded children must be helped with their difficulties in psychological processing of the war-related injurious event. This problem holds true, of course, for many, indeed most, of the other topics presented in the beginning of this chapter.

Obviously, developmental differences in posttraumatic symptom expression require thorough future study, especially with respect to younger children. Some of the *DSM-IV*'s PTSD items (American Psychiatric Association, 1994) require verbal descriptions of experiences and internal states, which are beyond the capacity of infants, toddlers, and even some older children. Indeed, an expanded checklist of behaviorally based, developmentally sensitive symptoms is now available (e.g., Scheeringa & Zeanah, 2001); however, much more remains to be done to facilitate better diagnosis of war trauma in younger children.

PTSD should not be the only phenomenon to concern interventionists. Posttraumatic stress reactions, rather than disorder symptoms, persist in children and adolescents, although their intensity somewhat diminishes over time. Yet, wartime events continue to influence children, potentially affecting their development of personality,

moral values, and outlook on life. The psychological impact of war is not over when the fighting ceases (Dyregrov, Gjestad, & Raundalen, 2000; Dyregrov, Gupta, et al., 2000). More research would do well to address obstacles hindering developmental progression and transitions. Researchers working in the attachment theory paradigm (e.g., Wright et al., 1997) should focus and further highlight the long-term effects of war on children's development. Child assessment must consider children's progress in the ability to relate to war and war events without excessive avoidance and distress, as well as advances in children's resumption of "ordinary" life and ability to invest in and enjoy age-appropriate activities (Klingman & Cohen, 2004).

Considering the growing capacity of the mass media (e.g., Internet, television, third-generation cellular phones) to reach out to populations at war concerning mental health, the psychologist's role in the public domain deserves reconsideration. I have stressed here and elsewhere (e.g., Klingman, 2002a, 2002c; Klingman & Cohen, 2004) that resources like the media, the Internet, and the telephone have proved useful as large-scale alternative support systems to reach a population during war, especially because they may be accessible to children and families who are housebound or limited in their ability to travel due to wartime circumstances. In this regard, prior to and during a war or war-related disaster, child psychologists are called on to counsel the public over radio, television, and the Internet, especially with regard to children's reactions and coping. On the one hand, this intervention meets the public's (especially parents') needs for information. On the other hand, the flood of psychological advice and especially the focus on fear, stress, trauma, anxiety, and PTSD-related symptoms may convey the message that the population cannot cope with difficulties on their own. Moreover, psychologists may concentrate excessively on anxiety and disorder-related symptoms, often overemphasizing the value of expression of the anxiety as a major means of coping with the ordeal. The emphasis on anxiety ventilation, more particularly the advice given to parents that they encourage their children to cry and voice their fears and anxieties, may in certain cases be problematic, or even counterproductive, when professional supervision is not readily available, if at all, which is typical in times of war. In their messages, psychologists often overlook the varied human response to stress, including the benefits in such mechanisms as partial denial, repression, avoidance, and isolation, which

are considered counterproductive signs of problems in the clinical setting but may well be functional for different people under different circumstances. In general, messages that are appropriate when addressed to patients in the privacy of the therapeutic setting may be inappropriate and even damaging to the nonpathological population reached through the media (Solomon, 1995). These criticisms are true especially for psychologists who have no experience with, or any background in, mass trauma intervention.

Another, perhaps more fundamental, criticism is that in times of war the task of the psychologist is also to encourage people to trust the local or national leadership, to use modes of overcoming fears, and to use active means of coping not only with their anxieties but with the external threat. Practical advice such as staying alert, keeping informed, and taking measures to promote personal and familial safety can be viewed as important wartime messages for psychologists (as consultants) to incorporate in their traditionally (clinically focused) mental health orientation.

Nor should mental health professionals ignore that the struggle with wartime hardships often leads to positive gains. Some children go beyond mere resiliency. In constructively confronting the traumatic experience, youngsters may also experience greater self-confidence, adopt new coping skills, and develop greater appreciation of life. This phenomenon of trauma-induced growth (Calhoun & Tedeschi, 1999) coincides with the positive psychology approach (Seligman, 2002). In my experience (for further discussion, see Klingman & Cohen, 2004), these and related issues must be discussed with psychologists who are to be involved with the media; an emphasis in the media on potentially strengthened relationships with others, increased closeness and intimacy, altruistic activities, and an augmented experience of oneself as capable and self-reliant should be upheld.

It is also imperative that programs aimed specifically at children, which operate through indirect means, be distinguished from programs geared to parents and teachers, who possess a greater capacity to make use of direct guidance and advice provided by psychologists and to apply them in helping children (Raviv, 1993). When times and circumstances allow, it may be wise to develop a special curriculum for training psychologists in counseling techniques and interventions through the media during war in general and with regard to specific war conditions; these psychologists must be trained for their appearance in the electronic media.

The possible overinvolvement of mental health professionals in the various media should be noted as well. One of the fiercest objections to this overrepresentation in Israel during the 1991 Gulf War was that this was a time for people who could offer moral support, not psychologists. The psychologists undoubtedly meant well, but they were criticized for weakening rather than strengthening the nation during that war. The question, though, should not be whether psychologists should be involved in the various media during war, but how often, to what extent, delivering which messages, and whether they have the proper training in mass disaster intervention. The public activities of well-meaning mental health professionals should be constantly checked and rechecked against their natural wish to help by relaying their pre-war professional knowledge that may be inappropriate, or perhaps personal motivations such as the need to alleviate their own anxiety or the desire for self-promotion. (For an extensive discussion of these and related issues as observed in Israel during the 1991 Gulf War, see Solomon, 1995.) Systematic analysis of the amount and types of psychological messages transmitted to the public in war through the media is lacking. It is important to carefully address and further study the foregoing issues. Technology is progressing and the various media are available in ever larger parts of the world, so wars are likely to be accompanied by increasing intervention by mental health professionals through the media.

The role of intervention for recovery from war-related ills does not end with the cessation of hostile activities or with the signing of a formal peace treaty. In times of war, collective narratives play a major societal role, subsuming and determining attitudes, stereotypes, prejudices, and actions that emanate from them (Bar-Tal, Raviv, & Freund, 1994). When the war is over, *reconciliation* (the “art of making peace”) between the warring groups entails adjusting their attitudes to one another. Volkan (1990) described the central role of projection mechanisms as a process of inner splitting that takes place in individuals and groups during inter-group conflict. The “good” splits from the “bad,” and the rejected elements (e.g., meanness, hatred) are denied as parts of the self and ascribed to the “other” person, group, or nation. When steps toward peacemaking or reconciliation begin to be taken, these psychological mechanisms need to be addressed through psychoeducational programs targeting peace, reconciliation, and coexistence. Salomon (2004) suggested that such psychoeducational programs focus on reversing the de-

legitimization of the collective narrative, leading to the acceptance of the “other’s” collective narrative as legitimate and thus addressing perceptions of and tolerance for collectives.

Peace education in most regions of intractable conflict entails elements of conflict resolution, multiculturalism, antiracism, cross-cultural training, and the cultivation of a general peace-oriented outlook. Such education efforts face a number of severe challenges, such as conflicting collective narratives, shared histories, and beliefs; grave inequalities; excessive emotionality; and unsupportive social climates (Bar-Tal, 2004; Salomon, 2004b). The underlying psychological principles and strategies and the educational methods of school-based conflict resolution for peer mediation (especially in multicultural school contexts; e.g., Johnson & Johnson, 1996) show some practical commonalities with the practice of peace education in regions of active political conflict and tension. However, these principles, strategies, and methods in themselves do not suit, or suffice in, regions that experience active political conflict, which necessitates a focus on a narrative-based view of coexistence education. At this point in time, despite the urgent need and the relatively large number of peace education projects operating all over the world, very little research or program evaluation accompanies such activities (Nevo & Brem, 2002). Hardly any information is available concerning their ultimate effectiveness. Although researchers are currently making a noted effort in this area, thus far, only scarce and unsatisfactory guidelines have emerged for psychological practice and peace educators seeking efficient data-based methods to establish reconciliation. This poses a new challenge for social and clinical psychologists as well as for educationalists.

Although much of the foregoing discussion (especially the case studies and conclusions) may be viewed as largely a product of research and experience from the industrialized or developed world (some specific to Israel), my observation of wars elsewhere indicates that the generic principles for large-scale, ecology-based support systems can undoubtedly be employed in international emergency situations in general. In contrast to the Western mental health approaches that focus on the individual, non-Western collectivist cultures focus on the family and the traditional group and therefore need culture-sensitive, community-based generic intervention. Variables such as sense of community, needs and preference for certain types of help, motivation, honor,

and pride about getting help (especially psychological aid), political systems, leadership patterns, and political leaders' involvement are but a few of the variables affected by cultural differences. I assume that while following the generic approach and the unifying continuity principle, psychologists in other parts of the world and in different war contexts will engage in creatively translating the knowledge base and experiences presented and discussed in this chapter into their own culture-based war-focused or trauma-focused interventions. This actually holds generally true now, as we live in increasingly multicultural societies the world over.

In sum, from the literature, especially concerning PTSD, it is indeed evident that wars seriously challenge the coping systems of those affected and constitute a considerable and sometimes serious mental health risk to children. It is now generally acknowledged that a high proportion of war-exposed children develop mental health problems. Although mental health professionals have no control over the contextual features of war, we do have much to offer in creating a positive, culturally sensitive recovery environment. First and foremost, professionals should recognize that many war-affected children in need of psychological help can be helped *indirectly* by investment first in the reconstruction of their community institutions (schools, churches, recreational centers, community centers, and afterschool care). Next, consultation should be provided to primary caregivers such as the parents and teachers (the natural support system) and to the persons who operate and supervise these institutions, regarding the children's mental health needs. Psychologists, being experts in traditional clinical interventions, may overlook the other interventions at the community level that may be applied.

Another important message to be gleaned from this chapter is that more emphasis than currently exists should be placed on empowerment, positive coping, morale building, strengths, resilience, and growth. Professional observations, personal accounts, and some of the reviewed literature contend that individuals possess an impressive ability for creatively utilizing inner and outer resources in war and its aftermath to regain mastery over traumatic experiences. The study of war and war-torn zones has led to the understanding that more often than is usually considered, exposure to increased stress also builds up protective mechanisms, and that children in particularly difficult situations can and do learn to cope better (Aptekar & Stoecklin, 1997; Klingman & Cohen, 2004). A further shift is needed

from the purely medical-clinical model, which focuses on individual treatments of those children identified as suffering from a disorder as an outcome of war, to multiple emphases on the recovery environment of all involved children, on preventive efforts within the children's natural environments, and on the use of generic principles.

There is a pressing need to now invest in developing, testing, and evaluating large-scale generic interventions. With the recent rise in wars and war-like events all over the world, including world terrorism, nationalism, violent political conflicts, and civil wars associated with tribalism, a vast number of children are affected. Hence, our best investment would be in (a) tailoring culture-specific versions for the implementation of the generic principles and (b) developing measures to assess the effectiveness of various components of generic interventions across different cultures and war contexts. Of course, this should not come at the expense of continuing to expand our knowledge of specific manifestations of PTSD in children across and within the various cultures, or of conducting better controlled longitudinal studies of children's PTSD and other war-related disorders.

Interventionists must acknowledge that, however good their intentions, knowledge, funding, and intervention designs, no intervention will erase the painful memories and the traumas of war. However, an investment in the generic, multifaceted, multimodal, and multisystemic approach seems a most promising avenue for alleviating the effects of war and displacement on children, helping them develop positive social and emotional skills, and facilitating their capacity to live fulfilling lives despite their painful memories. Such an investment may eventually enable children to adjust to the new postwar normality and to restore their lives as near to normal as possible, with the focus on ensuring the successful progression of developmental processes.

CULTURAL PATHWAYS TO INDEPENDENCE AND INTERDEPENDENCE

Our foundational theme is that many children in the United States (and other immigrant-receiving countries) are raised in home cultures that place a higher relative value on interdependence as a goal of development than does the dominant surrounding culture, where independence is more highly valued. This situation derives from differences between the dominant cultural orientation of society at large and the cultural value system of families' ancestral cultures, often Latin American, Asian, African, Native American, or Native Hawaiian (Greenfield & Cocking, 1994). A cultural orientation of independence yields one pathway through universal developmental issues; a cultural orientation of interdependence yields a different one (Greenfield, Keller, Fuligni, & Maynard, 2003). In North America, Australia, Canada, and many parts of Europe, these diverging pathways can cause children and families with a more interdependent home culture to be caught in a conflicting cross-current of socializing influences. Because of the large number of immigrant and Native families in the United States, such conflict constitutes a significant social problem.

This chapter is an extensive revision of a chapter in this *Handbook*'s fifth edition, "Culture and Human Development: Implications for Parenting, Education, Pediatrics, and Mental Health," by Greenfield and Suzuki (1998). The sections titled "Three Approaches to Culture and Human Development" and "Criticisms of Independence/Individualism and Interdependence/Collectivism as Basic Cultural Paradigms" were adapted from "Cultural Pathways through Universal Development" by Greenfield, Keller, et al. (2003). For the first edition of this chapter, the authors would like to express special appreciation to Helen Davis for insightful comments on early drafts, for editing, and for help with manuscript preparation. We also thank Ashley Maynard for reading and commenting on the first draft. And we remember with appreciation the very constructive review of the late Rodney R. Cocking. For the revised chapter, we thank the FPR-UCLA Center for Culture, Brain, and Development for providing a stimulating atmosphere in which to discuss and learn about the issues of culture and human development. We also thank HopeLab for their support of the revision. This revision was completed while the first author was a Fellow at the Center for Advanced Study in the Behavioral Sciences, Stanford, California.

PLAN OF THE CHAPTER

We first review research from around the world demonstrating these two developmental pathways, each with its distinctive socialization goals and practices. We organize this review into four sections according to age periods and agents of socialization: early socialization at home, later socialization at home, socialization by peers, and socialization by the school. After reviewing the relevant research in each section, we discuss implications for practice. At the end of each section, we also present an intervention designed to alleviate conflicting socialization pressures between home and the outside community and the cross-cultural misunderstandings that arise from them.

THREE THEORETICAL APPROACHES TO CULTURE AND HUMAN DEVELOPMENT

Our conception of cultural pathways draws on three major types of theory: the *ecocultural*, *sociohistorical*, and *values* perspectives. Philosophically, the ecocultural approach emphasizes the causal influence of material conditions in the environment. The values approach, in contrast, emphasizes the causal influence of ideals or meanings inside the psyche. The sociohistorical approach emphasizes the causal influence of social factors: the interactional processes and symbolic tools used in cultural learning; these processes and tools develop over historical time. We begin with the values approach, the most central to our model of cultural pathways through human development.

The Cultural Values Approach

On the side of social development, the distinction between independent and interdependent pathways of development originates in cross-cultural comparative research identifying altruism and egoism as outcomes of different socialization practices under different environmental conditions (J. W. M. Whiting & B. B. Whiting, 1973/1994). On the side of cognitive development, the distinction between a collectivistic and an individualistic worldview originates in Greenfield's (1966) research in Senegal in which she found an assumption of greater unity between self and world, both social and physical, in the indigenous Wolof culture. This contrasted with greater metacognitive self-awareness—a cognitive sepa-

ration of self and world—as a result of the Western institution of formal schooling (Greenfield & Bruner, 1966).

Out of these historical beginnings has grown a conception of alternative pathways of development. In an independent developmental pathway, social obligations are individually negotiated; opportunities to select social relationships (personal choice) and to act freely in those relationships (individual rights) are maximized (Raeff, Greenfield, & Quiroz, 2000). In an interdependent developmental pathway, in contrast, social obligations and responsibilities are given greater priority, and individual choice is much less important. An independent pathway prioritizes individuation as a developmental goal; an interdependent pathway, by contrast, prioritizes conforming to established social norms as a developmental goal (Kitayama, Markus, & Lieberman, 1995; Nsamenang & Lamb, 1994; Weisner, 2000).

Culturally relevant developmental goals are represented in the form of implicit ethnotheories of development, that is, systems of beliefs and ideas concerning the nature of the ideal child and the socialization practices necessary to achieve this ideal (Goodnow, 1988; Harkness & Super, 1996; McGillicuddy-DeLisi & Sigel, 1995). These ethnotheories are shared (and negotiated) among members of cultural communities. Values concerning preferred developmental goals can be expressed explicitly, as in parental ethnotheories, or implicitly, as in cultural practices, particularly discourse practices (Keller, Voelker, & Yovsi, 2002; Ochs & Schieffelin, 1984; Sigel, McGillicuddy-DeLisi, & Goodnow, 1992). The growing emphasis on indigenous conceptualizations of parenting goals (Chao, 1994; Gutierrez & Sameroff, 1990; Yovsi & Keller, 2003) has unraveled independence and interdependence as core dimensions, applicable to all developmental domains.

Participants from non-Western cultural communities, such as Chinese (Chao, 1994), Japanese (Rothbaum, Weisz, Pott, Miyake, & Morelli, 2000), Indians (Keller, Voelker, et al., 2002; Saraswathi, 1999), West Africans (Ogunnaike & Houser, 2002, for Nigeria; Nsamenang, 1992, and Yovsi, 2001, for Cameroon), and Puerto Ricans (Harwood, Schoelmerich, Ventura-Cook, Schulze, & Wilson, 1996), subscribe to the cultural ideal of interdependence: Their ethnotheories stress closeness, decency (social responsibility, honesty) and proper demeanor (politeness, respect for elders, loyalty to family) for various developmental domains (Harwood, 1992).

Participants from Western industrialized cultural communities, such as Germans (Keller, Zach, & Abels,

2002), European Americans (Harwood et al., 1996), and Dutch (Harkness, Super, & van Tijen, 2000), subscribe to the cultural ideal of independence: Their ethnotheories stress self-maximization and independence (creativity, curiosity, assertiveness, self-esteem). These particular parental goals and practices socialize children to operate effectively in an individualistic society such as the United States. “So basic is the concept of individualism to American society,” it has been said, “that every major issue which faces us as a nation invariably poses itself in these terms” (Gross & Osterman, 1971, p. xi). Socialization practices that function to actualize the ethnotheoretical framework within cultural communities begin at birth or even before.

The Ecocultural Approach

The ecocultural approach, pioneered by anthropologists Beatrice Whiting and John Whiting (1975; see also D’Andrade, 1994), sees the child’s behavioral development and the acquisition of culture as resulting from the interaction between human biological potentialities and environmental conditions. In short, the ecocultural approach emphasizes development as an adaptation to different environmental conditions and constraints (Berry, 1976; LeVine, 1977; Munroe & Munroe, 1994; Super & Harkness, 1986; Weisner, 1984; B. B. Whiting & Edwards, 1988; B. B. Whiting & J. W. M. Whiting, 1975).

From the ecocultural perspective, particular economic and environmental conditions create different social structures that favor different developmental pathways (cf. Berry, 1994). The pathways therefore arise as adaptations to these physical and economic conditions. Thus, the interdependent pathway appears to be an adaptive response to small face-to-face communities and a subsistence economy; these communities value tradition and therefore change slowly. The independent pathway, in contrast, appears to be an adaptive response to large, anonymous communities and a commercial economy (Greenfield, 2000, 2004; Greenfield, Maynard, & Childs, 2003; Keller, Zach, et al., 2002); these communities value innovation and therefore change more rapidly. In slow-changing, subsistence-based ecologies, ethnotheories are transmitted vertically from generation to generation, maximizing historical continuity. In complex and fast-changing societies, on the other hand, parental ideas are negotiated horizontally within generations, relying on public discourse (media) and experts (e.g., pediatricians), with

substantial differences among generations (Hewlett & Lamb, 2002; Keller, Miranda, & Gauda, 1984).

Correlatively, high socioeconomic status (SES) and formal education are associated with a more individualistic orientation (Keller, Zach, et al., 2002; Palacios & Moreno, 1996; Tapia Uribe, LeVine, & LeVine, 1994). Nonetheless, these cultural orientations persist across various socioeconomic and educational backgrounds (Harwood et al., 1996; Keller, Zach, et al., 2002).

The Sociohistorical Approach

The sociohistorical approach emphasizes processes of social construction, particularly cultural apprenticeship, cultural practices and artifacts, and the historical dimension of these processes (Cole, 1996; Lave & Wenger, 1991; Rogoff, 1990; Saxe, 1991; Scribner, 1985; Scribner & Cole, 1973, 1981; Vygotsky, 1962; Wertsch, 1985; Zukow, 1989). Social construction is seen as a set of situation-specific activities.

The sociohistorical perspective is crucial to the model of cultural pathways through human development. According to this model, each pathway results from a value orientation that generates the social construction (often called co-construction to reflect the active involvement of the child) of socializing practices and behaviors in particular situations. These social construction processes include apprenticeship from cultural “experts” in the adult generation, as well as peer interaction (Greenfield & Lave, 1982; Maynard, 2002). The interactional routines and artifacts that are utilized in cultural learning have a key role in socializing a child to proceed on a developmental pathway (Greenfield, 2000; Mistry & Rogoff, 1994; Rogoff, 1990; Saxe, 1991). Construction processes become particularly salient in bicultural people, where one or the other value system can become prominent in a particular situation (Garcia Coll, Meyer, & Brillon, 1995).

CRITICISMS OF INDEPENDENCE/INDIVIDUALISM AND INTERDEPENDENCE/COLLECTIVISM AS CULTURAL PARADIGMS OF HUMAN DEVELOPMENT

One common criticism of this approach is that it is too simplistic and reductionistic; the dichotomous binary quality of independence/individualism and interdepen-

dence/collectivism is seen as problematical (Killen & Wainryb, 2000; Rogoff, 2003). However, we do not see these concepts as dichotomous. They are not all or none, but rather exist to different degrees in different individuals in different cultures at different times in different domains (Greenfield, Maynard, & Childs, 2003; Morelli, Rogoff, Oppenheim, & Goldsmith, 1992; Raeff et al., 2000). They also vary with geography, SES, and formal education (Hofstede, 2001; Tapia Uribe et al., 1994). In addition, they are seen as developing through dynamic processes of socialization, which are themselves an important object of study (Greenfield, Maynard, et al., 2003).

The notion of independent and interdependent concerns coexisting in the same culture is put forth as another criticism of the framework (Killen & Wainryb, 2000). In response, we register our agreement, but note that individual enterprise (independence) and social relationships (interdependence) each have distinctive modes of expression in the two cultural frameworks. For example, freely chosen relationships are valued in the independent framework, whereas implicit social obligations are a more valued relationship premise in the interdependent framework (Raeff et al., 2000).

As a closely related response to this same criticism, a given behavior may be valued in both types of culture, but its relative priority may be different. For example, sharing with siblings is valued by parents in mainstream U.S. culture, but sharing is considered a matter of personal choice. Among Mexican immigrants to Los Angeles, by contrast, sharing has a much higher priority; it is simply expected (Raeff et al., 2000). Prioritizing one value over another may involve setting boundary conditions for the exercise of the preferred value (Wainryb, 1995). Boundary conditions may also reflect intergroup contact and cultural change processes. For example, the collectivistic Druze community studied by Wainryb is surrounded by the greater individualism of mainstream Israeli culture. Under these circumstances, the development in Druze children of boundaries on the rightful exercise of authority and the obligation to obey may, among other things, reflect contact with the surrounding national culture.

The existence of individual differences in the same culture is also seen as a criticism of the independence/interdependence framework. For example, Wainryb and Turiel (1994) found more orientation toward autonomy among males than females in collectivistic Druze culture. However, this criticism treats cultural characteris-

tics as independent (*sic!*) traits and fails to take into account the systemic nature of cultures. In response to their example, we see female respect for male authority, a relational feature of collectivistic cultures, as the root of such differential autonomy.

Sometimes the between-culture variability among collectivistic or individualistic cultures is taken as a criticism of the paradigm (Harkness et al., 2000). Qualitative and quantitative variability has been found in both systems (Harkness et al., 2000; Hofstede, 1991). The two value systems are merely ideal paradigms that get instantiated in a multiplicity of concrete and historically differentiated cultural contexts.

CULTURAL PATHWAYS: CONFLICT, INVISIBILITY, AND IMPLICATIONS FOR PRACTITIONERS

When home culture and societal culture differ for any particular family, interesting and, at times, vexing situations arise. Children may be faced with conflicting messages from home and from the outside world (particularly from school) as to the proper values, attitudes, and behaviors they should follow. Parents are also in the position of having to reassess their cultural framework in a new setting where many of their own values may be in direct conflict with those of society at large. Choices will need to be made as to which values in what contexts should be used in raising their children.

The difficulty of such choices is all the greater because cultures are “invisible” (Philips, 1972). That is, they are interpretive lenses that are taken for granted by the wearers. Like the air we breathe, under ordinary conditions, these value frameworks do not rise to conscious awareness. This lack of awareness exacerbates the potential for both personal conflict and interpersonal misunderstanding in multicultural environments. People tend to experience the other pathway’s response to a particular situation as “wrong” rather than as simply reflecting a different cultural orientation.

Because they have the task of assessing the behaviors of parents and children who come from diverse cultural backgrounds, counselors, social workers, educators, and health care professionals who work with families must be aware of these intercultural dynamics. Behaviors that may appear strange and perhaps dysfunctional in one cultural context could in fact be seen as normal in others. The professional community that comes into contact

with families of differing backgrounds has the challenge of understanding the values and child developmental goals behind cultural differences. Otherwise, they cannot hope to correctly diagnose the source of any problems that arise.

Perhaps even more important, an understanding of diverse cultural values and associated rearing practices reveals the strengths of socialization and child care practices used in diverse cultural groups. Equally important is the awareness of the losses that come from giving up one’s ancestral culture in the process of assimilating to the dominant cultural surround.

This is the background for considering cultural pathways in infancy, children’s relations with parents, peer relations, and school-home relations. We begin with infancy.

INFANT CARE, SOCIALIZATION, AND DEVELOPMENT

Culture inundates us with information on what is “appropriate” infant rearing. A great degree of variation exists even within middle-class American methods of infant rearing; when we look cross-culturally, we see an even greater variance in child-rearing practices and goals.

What Are Parents’ Goals for Their Infants?

In general, parents’ goals for their infants include some combination of the following: infant survival and health, the acquisition of economic capabilities, and the attainment of culturally appropriate values (LeVine, 1988). Culturally defined parental goals are crucial in parental behavior toward infants and in the child’s eventual socialization process. Normative parental goals both reflect and affect the structure and functioning of society as a whole.

In the United States, parents have many different goals for their children, but one of the most basic and general is the desire to have their babies grow up to be independent and individuated adults. For example, guiding children to learn to make their own decisions and establish their separate, individual existence was found to be one of the most important parental goals mentioned by mothers of infants in Boston (Richman, Miller, & Johnson Solomon, 1988). In infancy, others’ contingent responses to babies’ autonomous signals support the development of their independent agency (Keller, 2002).

In contrast, parents in Japan showed a different trend in parental goals. Rather than focusing on independence, in Japan, mothers were more likely to perceive themselves as being “one” with their infants. For example, Kawakami (1987, p. 5, quoted in Morelli et al., 1992) claimed, “An American mother-infant relationship consists of two individuals . . . on the other hand a Japanese mother-infant relationship consists of only one individual; that is, mother and infant are not divided.” Furthermore, an immediate or even anticipatory reaction to infants’ distress signals minimizes the self-other distinction in Japan (Rothbaum et al., 2000), as in Cameroon (Yovsi & Keller, 2000), India (Saraswathi & Pai, 1997), and Mexico (Brazelton, Robey, & Collier, 1969).

This value of extreme closeness between mother and infant is another indication of the interdependent goals of traditional Japanese parenting and is manifested in patterns of interaction, such as in *amae* behavior (variously translated as “dependence” or “interdependence”), that children express toward their mothers (Kim & Choi, 1994; Lebra, 1994). Just as the United States is an example of a society in which individualism is both valued and institutionalized, Japan has been a society in which collectivism—an emphasis on strong, cohesive in-groups (Hofstede, 1991)—has been both valued and institutionalized. However, this may be changing, as we note later in the section on culture change.

How Are Sleeping and Feeding Arrangements Affected by Parental Goals?

One readily observable dimension of cultural difference in the first 2 years of life is the organization of infant sleeping arrangements. In this section we argue that the cultural structuring of parental goals can play a part in determining infant sleeping arrangements.

Where Do Infants Sleep Worldwide?

In the United States and Germany, most infants sleep alone in a separate crib, most often in a separate room from their parents (Keller, Voelker, & Yovsi, 2002; Morelli et al., 1992). However, in many cultures around the world (particularly in Africa, Asia, and Latin America), cosleeping is the predominant sleeping arrangement (Konner & Worthman, 1980). In fact, in a survey taken of sleeping practices around the world, it was found that mothers in approximately two-thirds of cultures surveyed slept with their infant in their bed, and this portion was much higher if mothers sleeping with

their baby in the same room were included (Barry & Paxson, 1971; Burton & Whiting, 1961).

Examples of cosleeping cultures include Japan, where children traditionally have slept with their parents until 5 or 6 years of age (Caudill & Plath, 1966). This cosleeping is often referred to as *kawa*, or “river,” in which the parents form the symbolic riverbanks for the children sleeping in their own futons between them (Brazelton, 1990). People from many other cultures share similar cosleeping arrangements with their children.

Although the dominant culture in the United States adheres to separate sleeping practices, many minority and immigrant groups still hold onto cosleeping practices from their ancestral cultures. Many people in the United States have immigrated from countries in which infant-mother cosleeping is customary. For example, Schachter, Fuchs, Bijur, and Stone (1989) found that 20% of Hispanic families in Harlem slept with their children at least 3 times a week. This was in contrast to the 6% of European American families that did so. Lozoff, Wolf, and Davis (1984) found a similar pattern, with more African American than European American infants and toddlers regularly cosleeping with their parent or parents. Although African Americans have been in the United States for many generations, it may be that their original incorporation by slavery provided separation from the broader society and therefore less assimilation to its norms.

What Preferences and Constraints Do Sleeping Arrangements Reflect in the Dominant U.S. Culture?

In the dominant culture of the United States, there is a distinct pressure on parents to push their infants to sleep alone (Brazelton, 1990). In fact, middle-class families who practice cosleeping realize they are going against cultural norms (Hanks & Rebelsky, 1977). According to Morelli et al. (1992), since the early 1900s, American folk wisdom has considered early nighttime separation to be crucial for healthy infant development.

A stress on independence training is an important factor connected to separate sleeping among middle-class parents in the United States (Munroe, Munroe, & Whiting, 1981). Parents have goals of training infants to be independent and self-reliant from the first few months of life, before an undesirable habit of cosleeping may be established that can be difficult to break (Morelli et al., 1992).

Another side of the coin may be parents’ need for independence. Adults from the dominant U.S. culture con-

stitute the developmental end point of independence training. A dependent infant threatens parents' own autonomy; therefore, an important motive for separate sleeping arrangements in infancy must be the parents' need to maintain their own independence. Research on the interrelations between parents' goals for themselves and their children is very much needed.

Loss of privacy associated with parental intimacy is another reason for the disapproval of cosleeping (Shweder, Jensen, & Goldstein, 1995). The privileging of marital ties is typical of cultures that stress autonomy or independence as a developmental goal. In contrast, the privileging of intergenerational ties, such as that between mother and child, is typical of cultures that stress interdependence as a developmental goal (Lebra, 1994; Shweder et al., 1995).

Survival as a reason for separate sleeping arrangements has also been cited by parents in the United States. This includes reducing risks such as smothering or catching a contagious illness (Ball, Hooker, & Kelly, 2000; Bundesen, 1944; Holt, 1957; Morelli et al., 1992). Other reasons include psychoanalytic Oedipal issues and fear of incestuous sexual abuse (Brazelton, 1990; Shweder et al., 1995). These rationales have led many middle-class European American women (and others who are part of the dominant U.S. culture) to adhere to sleeping separately from their infants.

Pediatricians, and even the federal government, reinforce this practice. Lozoff et al. (1984) cite sources from pediatric advice books (e.g., Spock, 1976) to government publications that advise parents not to take their children into their bed for any reason. When parents read such advice, however, the authors are viewed as "well respected professionals" (Smaldino, 1995), rather than bearers of folk wisdom or carriers of culture-specific ethnotheories of development.

What Preferences and Constraints Does Cosleeping Reflect?

In many cultures, cosleeping is considered a desirable practice. In fact, separate infant sleeping arrangements are often met with shock. For example, Brahmins in India believe that it is wrong to let young children sleep alone in a separate room in case the child awakens in the middle of the night. They believe that it is the parents' obligation to protect their children from fear and distress at night (Shweder, Mahapatra, & Miller, 1990). Maya Indians and Japanese also express shock and pity when first learning of the American practice of having

infants sleep apart from parents (Brazelton, 1990; Morelli et al., 1992). On learning that American infants sleep in a separate room from their parents, one shocked Maya mother remarked, "But there's someone else with them there, isn't there?" (Morelli et al., 1992, p. 608).

It has been suggested that resource constraints such as lack of space may also be a factor in cosleeping (Brazelton, 1990; Shweder et al., 1995). For example, in many cultures, homes have fewer beds or fewer rooms allotted for sleeping purposes than is common in the United States. Resource constraints, however, may play a relatively small role. For example, the shock and sadness that Maya mothers express when learning of the North American practice of separate sleeping arrangements is an indication that cosleeping is not merely a practical concern. Rather, it constitutes a commitment to a special kind of relationship with the infant (Morelli et al., 1992). Indeed, in large parts of Africa, Asia, and South America infants sleep with their mother because separation of the infant from the mother is beyond imagination (Morelli et al., 1992; Shweder et al., 1998; Yovsi, 2001).

Indeed, in their study of cultural variability in the United States, Lozoff et al. (1984) found that there was no significant relationship between space constraints (number of sleeping rooms available, household size, or the ratio of household size to sleeping rooms) and sleeping arrangements during infancy and toddlerhood. Instead of resource constraints, there seem to be reasons related to cultural values and goals that affect even the seemingly simplest of practices, such as infant sleeping arrangements.

However, other kinds of ecological factors can play a role in moderating the enactment of a culturally specified developmental goal such as independence. For example, in Lozoff et al.'s (1984) study, there was evidence that European American babies were accepted in their parents' bed under constraining conditions, such as when there was familial stress (such as a move or marital tension) or infant illness, or when the baby was old enough to get out of bed by himself or herself and walk into the parents' bedroom or bed.

The Relationship of Sleep to Feeding, Holding, Carrying, and Nursing

Parents in Asia, Africa, and indigenous America put their babies to sleep by nursing and holding (e.g.,

Brazelton et al., 1969; Hewlett, Lamb, Shannon, Leyendecker, & Schölmerich, 1998; LeVine et al., 1994; Miyake, Chen, & Campos, 1985; Morelli et al., 1992; Super & Harkness, 1982). This practice is part of a pattern of almost continual holding, carrying, and nursing (e.g., Brazelton et al., 1969; Miyake et al., 1985; Super & Harkness, 1982).

In cultural communities that value interdependence, the early relational matrix is founded in the ethnotheory of a continuously close mother-child relationship entailing close body contact during the day (holding and carrying) and at night (cosleeping). One Cameroonian Nso mother said in an ethnographic interview that a baby needs to be bonded to the mother's body (Keller, Voelker, & Yovsi, 2002).

From a neurological perspective, Restak's (1979, p. 122) research shows that "physical holding and carrying of the infant turns out to be the most important factor responsible for the infant's normal mental and social development." Hence, we must strongly consider the possibility, suggested by Konner (1982), that sleep problems are a major cultural problem in infant care in the United States precisely because professional advice and the culturally dominant practice are fighting the biology of the human infant that has evolved over hundreds of thousands of years.

What Can We Learn from a Cross-Cultural Perspective on Infant Care Practices? Implications for Parents, Pediatricians, and Other Practitioners

Cultural views and goals may make it difficult for people to realize and incorporate different modes of behavior. Indeed, there can be unintended consequences of changing one piece of a complex, interrelated cultural system. Nonetheless, there are cases in which much can be gained by observing and understanding the practices of other cultures.

Sleep Problems

Many have claimed that in North America, sleep disturbance is one of the most common concerns among parents of young infants today (Brazelton, 1990; Dawes, 1989; Nugent, 1994). In fact, children in the United States who slept alone were more engaged in complex bedtime routines and had longer-standing and stronger attachments to sleep aids and security objects than did

cosleepers (Hayes, Roberts, & Stowe, 1996). Yet sleep problems are less common or even nonexistent in a number of other cultures. For example, Nugent reports that "sleep problems or night waking are less commonly reported as clinical concerns in Japanese settings" (p. 6). Similarly, Super and Harkness (1982) noted that sleep problems were nonexistent among the Kipsigis in Kenya.

Cross-Cultural Exchange

It is clear that there is much to be learned from infant-rearing techniques practiced in different cultures. In terms of the superordinate goal of infant survival, cosleeping may play a part in fostering the development of optimal sleeping patterns in infants (McKenna et al., 1993). This may be because cosleeping permits the sleeping infant to take tactile and rhythmic cues from his or her parent, and these cues help regulate an immature breathing system. This interactive process, in turn, may decrease the risk of sudden infant death syndrome (SIDS; McKenna, 1986). Indeed, in many countries worldwide, cosleeping is associated with low rates of SIDS (McKenna & Mosko, 1994).

The Cultural Relativity of Risk

Perhaps Japanese parents, who traditionally put their babies to sleep by nursing and holding, would agree with the U.S. experts that this practice encourages dependence. However, the Japanese interpretation of dependence would be quite different. Certainly, the Japanese would be in profound disagreement with the "experts'" negative evaluation of dependence as a "risk" factor that could "impair" a child's development. In this way, the notion of developmental risk is clearly culture-bound (Nugent, 1994).

Issues for Pediatricians and Parents to Consider

Thus, many issues surround infant care practices such as sleeping arrangements. Of import are the child's physical well-being (e.g., reducing the risk of SIDS), emotional well-being (e.g., nighttime comforting), parental sleep patterns (e.g., parental privacy, nighttime feeding issues), practical constraints (e.g., housing situation), adult needs (e.g., for autonomy), and cultural goals (e.g., independence versus interdependence). These are issues to consider for parents and pediatricians alike.

Pediatricians have traditionally concluded that infant-parent cosleeping is a risk factor for healthy development. However, have they considered infant sleeping

arrangements from all of the relevant angles: physiological, psychological, and cultural? As Nugent (1994) points out, cross-cultural studies demonstrate that the notion of risk is a cultural construction. Pediatricians must be cautious before imposing their own cultural construction on members of various ethnic or social groups with whom they do not share a common culture or common ecocultural niche for infant development.

Differences, Not Deficits

Clearly, there are many ethnic and immigrant groups in the United States (and other industrialized nations) for whom ancestral heritage of infant care practices are apparent. Being aware and accepting of these cultural differences is, in itself, important and beneficial. Because multicultural societies such as the United States contain a variety of ethnic groups and family contexts with a variety of sleeping practices, parents deviating from the dominant norm should not be made to feel they are doing something harmful to their child.

For example, understanding that sleeping alone and cosleeping are two different cultural modes, each with its own set of risks and benefits, will lead to pride in rather than shame for diverse cultural heritages. For members of the dominant majority, such understanding leads to respect for rather than denigration of “nonstandard” practices such as cosleeping. Similarly, understanding the reasons behind alternative practices can also help immigrants understand the cultural norms in their new cultural surround. The dissemination of information on such practices among pediatricians and parents can help in developing this kind of mutual respect.

How Are Attachment Behaviors Affected by Parental Goals?

While the role of cultural goals is readily observed in infant sleeping practices, cross-cultural differences in parental goals are also manifest in attachment behaviors. Harwood, Miller, and Lucca Irizarry (1995) begin their book, *Culture and Attachment*, with Bowlby's (1969) classic definition of “attachment as ‘the bond that ties’ the child to his or her primary caretaker” (p. 4) and attachment behaviors as “those behaviors that allow the infant to seek and maintain proximity to his primary attachment figure” (p. 4). Nonetheless, the classic attach-

ment assessment procedure, the Strange Situation presented by Ainsworth and Wittig in 1969, uses reactions to brief separations rather than opportunities for proximity maintenance as the foundation for measuring infant attachment.

Infant Responses to the Strange Situation

In the Strange Situation paradigm, *securely* attached children are differentiated from *insecurely* attached children in a laboratory test involving leaving an infant alone with various combinations of mother, stranger, both, or neither. From observations of infant behavior in these situations, infants can be assigned into the categories of avoidant attachment (Group A), secure attachment (Group B), and resistant attachment (Group C). The Group B behavior pattern in the Strange Situation has long been seen as an indicator of such things as healthy mother-infant interaction and emotional growth (Ainsworth, Blehar, Waters, & Wall, 1978).

The role of the mother, particularly maternal sensitivity, is also seen as important in infant attachment. For example, it has been proposed that mothers of future Group A babies express anger and rejection of their babies, mothers of Group C babies are insensitive and inept, and mothers of Group B babies are more affectionate and effective in soothing their babies (Ainsworth, 1979; Campos, Barrett, Lamb, Goldsmith, & Stenberg, 1983; Main & Weston, 1982).

These generalizations, however, do not take into consideration the cultural reasons an infant may behave in a particular way and how a mother might interpret that behavior. Because mothers are the carriers of culture to the next generation, especially during their child's infancy, it is important to consider cultural reasons for the mother's behavior. Some have argued that attachment behaviors in different countries are so different that indigenous theories of attachment are needed to fully describe attachment in different cultures (Rothbaum, Weisz, Pott, Miyake, & Morelli, 2000, 2001); others conclude that attachment is a valuable framework for examining general questions about mothering, biology, and culture in development (Chao, 2001b; Posada & Jacobs, 2001). Whatever the case may be, it is clear that mother-infant attachment is an important phenomenon to consider in studies of culture and development.

In Japan, compared to the United States, more C or resistant babies have been identified from the Strange Situation assessment. In contrast, A or avoidant babies

are common in the United States, but rare or absent in Japan (Miyake et al., 1985; Takahashi, 1990; van IJzendoorn & Kroonenberg, 1988). Why this difference in the way cultures deviate from the “norm”? Cultural differences in parental goals may be the reason. Traditional Japanese mothers, with parental goals such as having the parent and child “become one” (Kawakami, 1987), rarely leave their babies in the care of strangers such as babysitters. Thus, the various separations that take place in the Strange Situation paradigm cause extreme and unusual stress to the infants (Miyake et al., 1985; Takahashi, 1990).

Supporting this hypothesis, a study of working Japanese mothers found the same distribution of attachment patterns as in the United States (Durrett, Otaki, & Richards, 1984); there were avoidant as well as resistant and secure attachments. Clearly, such babies would have had experience with temporary separations from their mother. Confirming this point, studies in the United States by Lamb and colleagues (Lamb & Sternberg, 1990; Roopnarine & Lamb, 1978, 1980) show that unaccustomed separations from the mother, as when a baby begins day care, can raise anxiety about separation that is revealed in Strange Situation behavior, but that habituation to temporary separations removes the behavioral manifestations of this anxiety.

As Takahashi (1990) proposed, the separation history of the child affects responses to the Strange Situation; this separation history is conditioned both by cross-cultural variability in value orientations and by ecological factors within a culture, such as day care. The higher proportion of resistant babies found in Japan could therefore be due to different modal patterns of separation that take place in the daily interactions of Japanese and U.S. mother-child dyads.

In another study, German babies were found to be more likely to be categorized as Group A, or avoidant, and less likely to be labeled as Group C, or resistant, when compared to children in both Japan and the United States (Grossmann, Grossmann, Spangler, Suess, & Unzner, 1985; van IJzendoorn & Kroonenberg, 1988). Like the Japanese and U.S. patterns, this pattern can also be attributed to culture-specific parental goals for their children. In Germany, for example, parents desire their children to be nonclinging and independent (Grossmann et al., 1985). Therefore, the greater proportion of A infants in Germany may be a culturally desired outcome of German parental goals and strategies (Campos et al., 1983).

The United States falls between Japan and Germany in the frequency of both avoidant, independent (Group A) and dependent, resistant (Group C) babies (van IJzendoorn & Kroonenberg, 1988). If we think of the independence value as having originated in Germany and other parts of northern Europe, this pattern makes sense. The value would have attenuated in its travels to the United States, where it came into contact with people from all over the world, including indigenous Americans, most of whom valued interdependence in their ancestral cultures (Greenfield & Cocking, 1994).

In line with this explanation, Grossman et al. (1985) observe that in Germany,

as soon as infants become mobile, most mothers feel that they should now be weaned from close bodily contact. To carry a baby who can move on its own or to respond to its every cry by picking it up would be considered as spoiling. (p. 253)

LeVine (1994) notes that German infants not only sleep alone, they are also left alone in the morning for an hour after waking up. In addition, mothers leave babies alone to shop, and German babies are left alone in the evening after 1 year of age. These methods of fostering independence seems more extreme than those used by mothers in the United States. Hence, it is logical for the United States to be between Germany and Japan in both avoidant, independent A babies and resistant, dependent C babies.

However, within the United States, it has been suggested that day care is also associated with more avoidant attachments (Belsky, 1989). This is an ecological factor that could push the value of independence farther than would otherwise be the case. Clarke-Stewart (1989) has suggested that, “although children who are accustomed to brief separations by virtue of repeated day care experiences may behave ‘avoidantly,’ their behavior might actually reflect a developmentally precocious pattern of independence and confidence rather than insecurity” (quoted by Lamb & Sternberg, 1990, p. 360).

Implications of Cross-Cultural Differences in Attachment for Practice

What, in a multicultural society, is the adaptive significance of minority interpretations of attachment that differ from those of the majority? This is an important

question for practice that has not been explored in research. Are minority infants at risk for later maladaptation to the majority culture because their mothers have a different interpretation of the attachment relationship? Psychologists and practitioners concerned with issues of attachment should keep this issue in mind; in understanding attachment for clinical purposes, it may be necessary to go beyond attachment behaviors to understand the culture-specific meaning of those behaviors for the mother-child dyad.

Implications for Measuring Attachment across Cultures and across Subcultures

The stress level engendered by the Strange Situation in Japan raises the question of whether the measuring instrument itself is too culture-specific for cross-cultural research. Indeed, it was originally developed as a culture-specific instrument for the dominant culture of the United States (Clarke-Stewart, Goossens, & Allhusen, 2001). Because it is based on reactions to separation from mother and reactions to strangers, is it a valid measure of attachment in cultures characterized by almost continuous mother-infant contact and the absence of contact with strangers?

On the other side of the coin, the Strange Situation is based on the assumption that brief separations from the mother will provoke mild to moderate stress. Clarke-Stewart, Goossens, and Allhusen (2001) therefore note that the Strange Situation may not be valid for cultural settings (such as day care) in which an infant becomes accustomed to frequent brief separations from the mother and, therefore, is not stressed at all. Clarke-Stewart and her colleagues, in response to these problems with the cross-cultural (and cross-subcultural) use of the Strange Situation, have developed a new attachment measure, the California Attachment Procedure, that does not involve separation from mother and is therefore not affected by experience (or the lack thereof) with brief separations from mother. In line with Bowlby's (1969) evolution-based notion of attachment, their measure operationalizes attachment as the use of a close relationship for a safe haven when danger is sensed. Moderate stressors (such as a loud noise) are presented to the baby in the presence of the mother, and the baby's use of the mother (the safe haven) to cope with fearful reactions to these stressors is then noted. Because it is not affected by specific experience with maternal separation, a measure based on this type of universalistic definition of attachment is much more likely to have cross-cultural validity than the Strange Situation.

How Are Communication Behaviors Affected by Parental Goals?

In this section, we provide evidence that parental goals for child development are also realized through parents' communication strategies with their infants. In some cultures, these strategies are more geared to fostering technological intelligence; in others, they are more geared to fostering social intelligence.

The Content of Communication

Fernald and Morikawa (1993) observed American and Japanese mother-infant dyads playing with toys. The differences found in conversational topics was striking: American mothers tended to focus on calling attention to the object names of the toys. An example given of a typical American interaction is, "That's a car. See the car? You like it? It's got wheels" (p. 653). In contrast, Japanese mothers were less interested in object labeling; instead, they focused more of their attention on verbalizing polite social exchanges. An example of such an interaction is translated as "Here! It's a vroom vroom. I give it to you. Now give it to me. Give me. Yes! Thank you" (p. 653).

Japanese mothers were also more likely to engage in routines that arouse empathy with the object, encouraging positive feelings toward the toy by saying things like "Here! It's a doggy. Give it love. Love love love while patting the toy" (Fernald & Morikawa, 1993, p. 653). In sharp contrast, many U.S. mothers explained that their goals in the interaction were to attract their child's attention and to teach him or her new words. Here, a distinct value is placed on cognitive development. In contrast, Japanese mothers explained that their goals were to talk gently and to use sounds that the infant could easily imitate. The Japanese concern for explicit teaching of cultural norms for politeness in speech was also expressed (Clancy, 1986; Fernald & Morikawa, 1993).

These differences are an operational demonstration of different parental goals. Mundy-Castle (1974) conceptualizes the European-based (Western) way of socializing children as geared to the goal of technological intelligence (intelligence that is related to manipulation of the physical world), and the African way as geared to the goal of social intelligence (intelligence related to the knowledge of others). Clearly, the Japanese mother quoted earlier is also emphasizing the development of social intelligence.

The role of adult-infant communication in actualizing the parental goal of social intelligence is seen in the following interpretation of Bakeman, Adamson, Konner, and Barr's (1990) research among the !Kung, African hunter-gatherers in Botswana. In this culture of intimate social bonds and minimal property, objects are valued as things to be shared, not as personal possessions (Berk, 1993, p. 30).

In !Kung society, no toys are made for infants. Instead, natural objects, such as twigs, grass, stones, and nutshells, are always available, along with cooking implements. However, adults do not encourage babies to play with these objects. In fact, adults are unlikely to interact with infants while they are exploring objects independently. But when a baby offers an object to another person, adults become highly responsive, encouraging and vocalizing much more than at other times. Thus, the !Kung cultural emphasis on the interpersonal rather than physical aspects of existence is reflected in how adults use objects in their interactions with the very youngest members of their community (Berk, 1993, p. 30).

Similar to the !Kung's emphasis on social rather than technological intelligence, the communication of West Africans in Africa and West African immigrants in Paris focuses on integrating the infant into a social group (Rabain, 1979; Rabain-Jamin, 1994; Zempleni-Rabain, 1973). African mothers manifest this emphasis by using verbalizations that relate their infant to a third party, either real (e.g., telling the baby to share some food with brothers or sisters) or imaginary (e.g., "Grandma told you," said by the mother of a family that has immigrated to France, leaving the grandmother in Africa). They also respond more frequently to child-initiated social activity than French mothers do.

European mothers (e.g., French, German, Greek), in contrast, focus on the child-centered mother-child dyad (e.g., face-to-face communication) and on their infants' technological competence (e.g., object manipulation; Keller et al., 2003; Rabain, 1979; Rabain-Jamin, 1994; Zempleni-Rabain, 1973). For example, in comparison with the African mothers, French mothers manifest this focus by more frequent reference to the child's speech (e.g., "What are you saying to your mommy?"; "Is that all you've got to say?"), by less frequently relating the child to a third party, and by responding more frequently to child-initiated object manipulation (Rabain, 1979; Rabain-Jamin, 1994; Zempleni-Rabain, 1973).

One conclusion is that there may be a connection between an independent orientation and technological intelligence. An early orientation to the nonsocial world of things and objects stresses independence from social relationships, for example, in Germany (Keller, Zach, & Abels, 2002) and in France (Rabain-Jamin & Sabeau-Jouannet, 1997). An absence of emphasis on social relationships seems correlated with the presence of an emphasis on the physical world. Although our earlier discussion of sleeping arrangements focused on whether an infant was alone or with a parent, there is another aspect of this difference: When infants are left alone in a crib or playpen, they are usually given toys (e.g., mobiles, rattles) to amuse themselves with. Because toys provide early cognitive socialization for technological intelligence, there is a connection between the socialization of independence and the socialization of technological intelligence. The child left alone with toys is both learning to be alone and learning to interact with the physical world of objects. In contrast, people are more important than the object world in the development of an interdependent orientation or social intelligence.

The Process of Communication

Dyadic communication is the norm in an individualistic value system. However, multiparty communication is the norm in a collectivistic framework (Quiroz, Greenfield, & Altchech, 1999). This leads to differences in the deployment of attention by caregivers and their toddlers in the process of communication. In a Maya community in Guatemala, where interdependence is an important developmental goal, mothers and their toddlers often kept two simultaneous and continuous lines of attention and communication going when there were two competing sources of attentional demand (e.g., an older sib makes a bid to play with a toddler, who is already interacting with his or her mother). In Salt Lake City, Utah, an individualistic setting, mothers and toddlers more often carried on one dyadic interaction at a time when there were two competing bids for attention (e.g., both a toddler and an older sibling want the mother's attention; Chavajay & Rogoff, 2002). In other words, the process of communication between parent and toddler, itself a socializing force in development, reflected the two respective models of human development.

Cultural Coherence and Individual Differences

The different customs and practices of infant care are not random. They are motivated by underlying cultural

TABLE 17.1 Contrasting Cultural Models of Infant Development and Socialization

Developmental Goals	Independence	Interdependence
Valued intelligence	Technological	Social
Socialization practices	Infant sleeps alone; more use of devices (baby seats, strollers, cribs, playpens) that allow separation of awake infant; objects to explore and amuse	Parent-child cosleeping, more holding and carrying, objects to mediate social relationships
Attachment behaviors	More avoidant behavior in response to the Strange Situation	More resistant behavior in response to the Strange Situation

models with overarching socialization goals that provide continuity from one developmental domain to another. How infants are viewed, the developmental goals of the parents for the child, and parental behavior toward the child are all inextricably intertwined with the cultural background of the parents and the child. The coherence, on a cultural level, of developmental goals, socialization practices, child outcomes, and adult interpretations is illustrated in Table 17.1, which serves as a kind of summary of this section.

Philosophical Differences in Child Rearing between Individualistic and Collectivistic Cultures

The two models presented in Table 17.1 must be taken as two idealized systems of cultural norms. Within each ideal type, different societies and cultures will exemplify different varieties of both individualism and collectivism (Kim & Choi, 1994).

Because individual differences are central to U.S. culture and to psychology as a discipline, it is important to point out that, within every culture, there will always be important individual variation around each cultural norm. In other words, cultural typologies do not eradicate or minimize individual differences; they simply point to the norms around which individual differences range. Nonetheless, we must also point out that the scientific and popular concern with individual differences reflects a cultural orientation in which individuation is a primary emphasis (Greenfield, 2004).

Culture Contact and Culture Change

In addition, there will be conflict and compromise between the two idealized models presented in Table 17.1 in situations of culture contact or culture change. Culture contact is particularly important in multicultural societies (e.g., Raeff et al., 2000). Culture change is particularly important in societies undergoing processes of technological or commercial development (Greenfield, 2004; Greenfield, Maynare, & Childs, 2003).

Japan and China, for example, have been undergoing processes of rapid culture change over the past generation. For example, a recent study in Taiwan and the United States did not find more collectivistic child-rearing values in Taiwan (Wang & Tamis-LeMonda, 2003).

Earlier we mentioned that a study of working Japanese mothers found the same distribution of attachment patterns in that subgroup as in the United States (Durrett et al., 1984); we have interpreted this finding as reflecting the greater independence of babies who experience regular brief separations from their mother. But in the period since that study was published in 1984, a much greater proportion of Japanese mothers have gone to work outside the home. We would therefore expect that overall patterns of attachment in the Japanese population as a whole would have become more like the pattern in the United States. We would also expect the cultural ideology about attachment to shift accordingly, adapting to new conditions. Indeed, the most recent studies in Japan that we could find showed no differences between Japanese and U.S. mothers in their preferences about interactions, physical proximity, and contact with their infant (Posada & Jacobs, 2001).

It is also known that the ecologies of wealth (e.g., Georgas, van de Vijver, & Berry, 2004), formal education (e.g., Tapia Uribe et al., 1994), and urban environments (e.g., Fuligni & Zhang, 2004) favor more individualistic adaptations. Germany is a country that has become wealthier, more urban, and more highly educated over the past generation. The first historical study of these issues, by Keller and Lamm (in press), has found that infant care practices in Germany have also moved toward greater socialization for independence of infants. Present-day mothers and fathers of 3-month-old infants display significantly more face-to-face contact and object play and significantly less body contact and body stimulation during free play interactions than parents in similar life conditions 25 years earlier.

Cultural Frameworks and Ethnocentrism

It is an all too natural response to criticize the attitudes and practices generated by a cultural model different from one's own, with no understanding of the model behind the overt behaviors. LeVine et al. (1994) provide a wonderful example of ethnocentric criticism in their comparative look at the Gusii in Kenya and the middle class in the United States:

The Gusii would be shocked at the slow or casual responsiveness of American mothers to the crying of young infants. . . . This signals incompetent caregiving from their perspective. They would be similarly appalled by the practice of putting babies to sleep in separate beds or rooms, where they cannot be closely monitored at night, rather than with the mother. (pp. 255–256)

According to LeVine et al., the Gusii would think American toddlers unruly and disobedient as well, largely due to the excessive praise they receive and the maternal solicitations of their preferences.

Likewise, LeVine et al. (1994) believe that Americans would also find problems with the way the Gusii choose to raise their infants. For example, leaving an infant under the supervision of a 5- or 6-year-old child, a common practice among the Gusii, would be viewed as neglect in the United States.

However, a 5- or 6-year-old Gusii infant caregiver probably has much more know-how about taking care of babies than a typical U.S. child of the same age would have. Sib caregivers observe and practice caregiving under the watchful eye of the mother in many parts of the world (Ochs & Schieffelin, 1984). They develop sophisticated skills that aid them in carrying out this responsibility (Rabain-Jamin, Maynard, & Greenfield, 2003).

LeVine et al. (1994) also believe that:

[Americans] would be appalled that Gusii mothers often do not look at their babies when breastfeeding them . . . and that praise is more or less prohibited in the Gusii script of maternal response. . . . They would see the Gusii mothers as unacceptably authoritarian and punitive with children. (pp. 255–256)

In this way, infant care practices that are viewed as moral and pragmatic in one cultural context can be viewed as “misguided, ineffective, and even immoral” (p. 256) in others.

In a multicultural society, ethnocentric criticism has disastrous practical and social consequences. Instead, it

is necessary to understand how each model has made sense in its historical context. This means that assessments of pathology or deviance by parents, pediatricians, teachers, and clinicians must always be based on an understanding of the cultural meaning that particular behaviors have for the participants in a social system.

For example, Schroen (1995) explores how a lack of cultural understanding can lead to misinterpretations by social workers. She documents how negative judgments by social workers of cultural practices they do not understand, using criteria from their own culture, can lead to tragedy. For instance, social workers can misinterpret sibling care (a practice in many cultures worldwide) as child neglect, leading to children being taken away from loving parents who may have been following a different cultural model of competent parenting and child development.

One can imagine other situations in which cultural practices may be misinterpreted as forms of neglect or abuse. For example, cosleeping or cobathing practices (acceptable in many cultures, such as in Japan) may be misinterpreted as sexual in nature. Social workers, like other clinicians, must therefore be trained to recognize differences between cultural variations in practice and truly abusive situations.

Teachers and day care workers must also be made aware of these differences in infant rearing practices. For example, the crying (or lack thereof) of children when they are dropped off at school in the morning may be partially attributable to cultural differences in the strangeness of separation. Through a better understanding of these differences, infant care professionals can become more understanding and helpful to the child's transition between home and day care.

Costs and Benefits of Different Cultural Models

Each cultural model has its own set of benefits and costs (LeVine et al., 1994). These can still be seen throughout the life span. For example, the mother-child bond remains strong throughout life in Japan, but the husband-wife tie is of a less romantic and close nature than in the United States (Lebra, 1994).

The costs and benefits of each cultural model are perceptible by the participants and a culturally sensitive outside observer. For example, although European American mothers generally subscribe to the benefits of autonomy as a developmental goal, its cost to them can be seen as the “empty nest syndrome.” In this culture, adult children are often gone physically, as well as emotionally.

Different patterns of costs and benefits provide opportunities for useful cross-cultural exchange. From the perspective of both insider and outsider, each cultural model has its strengths and weaknesses, its costs and benefits, and its pathological extremes. For this reason, cross-cultural exchange of values and practices can sometimes serve as a corrective force to counteract the weaknesses, costs, and pathologies of any given cultural system. For example, McKenna and Mosko's (1994) experimental research documents the potential physiological benefits of cosleeping for infants in a society (the United States) with a relatively high rate of SIDS. This practice, which many of the study's participants have brought with them from Mexico and Central America, have direct relevance to pediatric advice on sleeping arrangements.

However, recommendations for cross-cultural exchange of infant care practices must be tempered by the finding of Weisner, Bausano, and Kornfein (1983) that there are strong ecological and cultural constraints on cross-cultural exchange in this domain. An example of such a constraint is the fact that parent-infant cosleeping, while decreasing the risk of SIDS, also decreases husband-wife intimacy, so valued in the United States. Consequently, ecologically valid research on the benefits and costs of adapting infant care practices from a variety of cultures is needed. Cultures are not isolated practices, but coherent wholes. So cross-cultural borrowing must be done with caution: A change in one element may have unwanted repercussions in other domains or at later developmental points. Nonetheless, parents, pediatricians, clinicians, and day care workers are often not fully aware of the range of options available to them in terms of infant caregiving practices.

Culture Conflict

When infants and toddlers from a more collectivistic home culture enter their first mainstream educational institution, the day care center, they often find an institution where individualistic values are simply taken for granted. Janet Gonzalez-Mena (2001) reports the following conflict scene:

"I just can't do what you want," says the caregiver. "I don't have time with all these other children to care for. Besides," she adds hesitantly, "I don't believe in toilet training a 1-year-old."

"But she's already trained!" the mother says emphatically. "All you have to do is put her on the potty."

"She's not trained—you're trained." The caregiver's voice is still calm and steady, but a red flush is beginning to creep up her neck toward her face.

"You just don't understand!" The mother picks up her daughter and diaper bag and sweeps out the door.

"No, *you're* the one who doesn't understand," mutters the caregiver, busying herself with a pile of dirty dishes precariously stacked on the counter. (pp. 34–35)

Gonzalez-Mena (2001) analyzes this conflict as a conflict between the cultural scripts of independence and interdependence:

If the caregiver defines toilet training as teaching or encouraging the child independently to take care of his or her own toileting needs and her goal is to accomplish this as quickly and painlessly as possible, she'll regard 12 months as too early to start. Children of 12 months need adult help. However, if toilet training is regarded as a reduction of diapers and the method is to form a partnership with the child to do just that, you'll start as soon as you can read the children's signals and "catch them in time." In the first case, the focus is on independence; in the second, it is on interdependence or mutual dependence. (p. 34)

INTERVENING TO REDUCE CROSS-CULTURAL VALUE CONFLICT AND MISUNDERSTANDING

The intervention we present here, as in the rest of the chapter, is from a series of Bridging Cultures projects (e.g., Trumbull, Rothstein-Fisch, & Greenfield, 1999). These are interventions designed to reduce the confusion and conflict, both internal and external, that come from the incompatibilities between collectivistic and individualistic developmental norms in a multicultural society. The intervention we describe here was designed to handle conflicts like the toilet training conflict just presented. Janet Gonzalez-Mena was part of the intervention team; her ethnographic observations, such as the one just presented, were the research base for the intervention itself.

According to the National Association for the Education of Young Children (2005) responding to cultural differences is an important part of developmentally appropriate care. However, as we have seen, appropriateness is determined by cultural beliefs and values. The "Guidelines for Developmentally Appropriate Practice" (Bredekamp & Copple, 1997, p. 12) acknowledge that

“every culture structures and interprets children’s behavior and development” but conclude that “children are capable of learning to function in more than one cultural context simultaneously.” Thus, the default assumption is that, although cultures may vary, infants can be expected to negotiate eating and sleeping arrangements different from what they experience at home. Caregivers might mistake this to mean that because babies can adapt, family routines at home (and implicitly the values and beliefs that underlie them) are not really an issue for them to take on. This is an alternative viewpoint to the one on which we have based our Bridging Cultures intervention.

The following scenario is based on a composite of experiences and observations. It provides another example of how culturally based developmental goals of independence and interdependence can lead to cross-cultural misunderstanding and conflict concerning standards of early care. Most important for present purposes, we describe how this kind of ethnographic knowledge can be used in an intervention to produce more culturally sensitive caregiving attitudes and practices. This particular incident is drawn from the *Bridging Cultures in Early Care and Education Module* (Zepeda, Gonzalez-Mena, Rothstein-Fisch, & Trumbull, in press). The Bridging Cultures project was developed to make caregivers more aware of the individualistic assumptions of professional practice and the more collectivistic assumptions of immigrant and other families from nonmainstream cultures.

The home visitor sits in a small living room near a mother holding a baby. The visitor knows that the baby has some physical challenges and is at risk for developmental delays. While the mother talks to the visitor about some issues going on in her life, the visitor is wiggling a toy in front of the baby. The mother turns the baby around and holds him close so he can’t see or reach the toy. When she hears a noise in the other room, she gets up to check on her older children. The home visitor holds out her arms to take the baby. The mother hands him to her.

The home visitor sits on the floor and holds the baby so he can easily reach any one of several toys she has arranged on a blanket. When the mother returns, the home visitor has the baby lying on the blanket, and she is bent over talking to the baby, who is clutching a soft ball and waving it in the air. “Oh you like that ball! It’s soft,” she says. The mother picks the baby up off the blanket, and the ball falls from his hand. She ignores the ball and takes him back to her chair. As she sits down, the baby reaches for an empty plastic glass on the table beside the chair. The mother puts it out of his reach. She goes back to cuddling

the baby in her arms. The home visitor looks discouraged, and the mother looks puzzled at the expression on the other woman’s face. (Zepeda et al., in press)

In this scenario, the mother remains in close physical contact with her baby and communicates nonverbally with him by holding. She also puts him in a relationship of physical closeness with the visitor. She is communicating the importance of social relationships. In contrast, the home visitor lays the baby down on his back and engages him with verbal labeling around the topic of the toy; she also encourages his manipulation of the toy. The visitor creates a physical separation with the baby and communicates about an object, while encouraging the baby’s agency in relation to the physical world. When the mother reenters the room, she is surprised to see the baby on the floor, perhaps perceived as distancing, and picks him up immediately, with no apparent regard for the ball. Yet it was the baby’s interaction with the object that seemed most important to the home visitor.

This incident provides a further example of cross-cultural value conflict between accepted standards of infant care in the dominant culture and accepted standards of infant care in immigrant cultures. The conflict is potent and fundamental because the home visitor is probably thinking about the baby’s need to interact with objects in order to achieve physical and cognitive goals, whereas the mother may be more concerned about social interactions.

This incident is used as part of the Bridging Cultures curriculum. Participants in the training discuss what they perceive as the goals of the mother and the home visitor. The discussion is intended to lead them to acknowledge the importance of both social relationships (developing social intelligence) and knowledge of objects (developing technological intelligence) and the potential for discussion between the mother and the visitor about their goals. However, if the underlying reasons for the differing developmental goals are not made apparent, each adult may simply disapprove of the other’s behavior, thus undermining an important partnership between parents and caregivers. Through cross-cultural exchange, both styles of communication could be used to socialize children for both technological and social intelligence.

The early childhood Bridging Cultures workshops are based on an extensive body of ethnographic research (e.g., Gonzalez-Mena, 2001). However, the workshops themselves are new, and very little research on their ef-

fects has yet been carried out. One promising indication is that, after a 90-minute workshop, 93% of the participants ($N = 51$) indicated they would change the way they worked with children as a result of their new understanding (Rothstein-Fisch, 2004). When practitioners are open to learning about different cultural values and behavioral options, a new appreciation, and perhaps even successful implementation, of a broader range of practices may be attained.

PARENT-CHILD RELATIONS

Parent-child relations are an important aspect of both child development and child socialization; parents embody and represent the broader cultural context as children learn to become members of their culture. Parents and children become a sort of family microculture with specific norms, customs, and values that reflect a variety of cultural and ethnic norms. In this section, we examine cross-cultural variation in parents' behavior and attitudes toward their children and children's behavior and attitudes toward their parents. The latter is an understudied perspective.

Children's Behavior toward Parents

Consider the following scenario:

A week ago, you went shopping with your mother, and at the register, she realized that she was short \$10. You lent her the money, and after a week, she gives no indication of remembering the loan. What would you do? Why?

In responses to scenarios like this, Suzuki and Greenfield (2002) found an interesting effect. Asian American students, particularly those closer to Asian culture in their acculturative levels and activity preferences, were significantly more likely than European American students to sacrifice certain personal goals for their parents. This finding seems to reflect the collectivistic emphasis on filial piety and respect for parents found in the Confucian worldview of East Asia.

The Confucian value of filial piety deeply influences the desired behavior of children toward their parents. According to Tseng (1973, p. 199), "[Confucius] viewed the parent-child relationship as the foundation from which interpersonal love and trust would grow, and thus interpreted filial piety as the virtue for every person to

follow." Some of the tenets of filial piety are obeying and honoring one's parents, providing for the material and mental well-being of one's aged parents, performing the ceremonial duties of ancestral worship, taking care to avoid harm to one's body, ensuring the continuity of the family line, and in general conducting oneself so as to bring honor and not disgrace to the family name (Ho, 1994, p. 287).

This multidimensional concept of filial piety is believed to be a virtue that everyone must practice, as "the love and affection of a child for his parents, particularly the mother, is the prototype of goodness in interpersonal relationships" (Tseng, 1973, p. 195). From a very young age, children are introduced to these concepts and ideals, and by the time they are teenagers, the extent of filial piety felt among Asians is such that it is not uncommon for Chinese teenagers to hand over entire paychecks to their parents for family use (B. L. Sung, 1985). More recently, researchers have differentiated between different forms of filial piety. For example, filial piety traits can be categorized as authoritarian (suppressing one's wishes and complying with parents' wishes), or reciprocal (emotionally attending to parents out of gratitude), with the former decreasing and the latter increasing in relevance in Chinese society (Yeh & Bedford, 2003).

In the United States, Asian American adolescents also have stronger values and feelings of expectation about assisting, respecting, and supporting their families than do European Americans (Fuligni, Tseng, & Lam, 1999). Greater feelings of family obligation are felt by Latino teens as well (Fuligni et al., 1999). These feelings are strengthened even more during young adulthood (Fuligni & Pedersen, 2002). Suzuki (2000) found that Asian Americans from fifth grade through college, as well as parents of fifth and sixth graders, spoke more favorably about the various components of filial piety—respect, obedience, and eventual care of parents—than did comparable European-American groups.

This pattern is consonant with the fact that traditional European American values are affected by different cultural influences and reflect the importance of individual goals and personal property prominent in the dominant North American worldview. Implicit in this view is a certain personal distance between parent and child; this is consonant with a view of human development that emphasizes the achievement of autonomy by late adolescence. It is also consonant with the predominantly Protestant religious background of the United

States, which stresses each individual's relationship with God rather than family ties and obligations.

In sum, contrasting responses to the scenario manifest and highlight differing models of children's relationships with their parents, models that have deep cultural roots. Given that assimilation to U.S. culture reduced self-sacrifice in Asian Americans in Suzuki and Greenfield's (2002) study, we would expect an even stronger pattern of difference when comparing Asians in Asia with European Americans in the United States.

Many Asian countries (e.g., Japan, China, and Korea) have similar emphases on children's lifelong duties toward their parents (J. S. Choi, 1970; Osako & Liu, 1986; K.-T. Sung, 1990). Some parallel differences emerged when Miller and Bersoff (1995, p. 274) gave subjects in India and the United States the following scenario: "Because of his job, a married son had to live in a city that was a four hour drive from his parents' home. The son made a point of keeping in touch with his parents by either visiting, calling or writing them on a regular basis." The authors note that a typical subject in the United States evaluated "the son's behavior as satisfying in that it enabled him to enhance his relationship with his parents, while still retaining a sense of individual autonomy" (p. 275). A typical Indian subject, in contrast, "focused on the satisfaction associated with fulfilling the obligations of care toward one's parents and of knowing that their welfare needs are being met" (p. 275).

The contrast is, in both scenarios, between a response that values children's obligations to their parents versus one that emphasizes children's autonomy and personal choices concerning their relationship to their parents. In both cases, the dominant cultural response in the United States is for autonomy and choice. Relative to that response, less acculturated Asian Americans emphasized self-sacrifice for parents, while Indians in India emphasized children's obligations to their parents as a positive value.

Parents' Behavior toward Children

In this section, we discuss the other side of the coin, parents' behavior toward their children. Our point is to show that the same two cultural pathways guide parents' behavior toward their children, as they guide children's behavior toward their parents. We will make this point with respect to parental style (discipline), communication, teaching, and patterns of reinforcement. We extrapolate the cultural structuring of parent-

ing through the life span, pointing once again to cultural coherence. Throughout, we explore the impact of cultural dynamics—historical change in demographics or cross-cultural value conflict—on the cultural structuring of parenting behavior.

Styles of Parenting

Baumrind (1967, 1971) offered a now classical formulation of three styles: authoritarian, authoritative, and permissive. Each one defines a core relationship between parents and children; the children that have been studied range from preschool (Baumrind, 1967) to high school age (Dornbusch, Ritter, Leiderman, Roberts, & Fraleigh, 1987). The *authoritative* parent is controlling, demanding, warm, rational, and receptive to the child's communication. The *authoritarian* parent is detached and controlling without exhibiting warmth. The *permissive* parent is noncontrolling, nondemanding, and relatively warm (Baumrind, 1983).

How does parenting style relate to European American parents' goals for their children? Although not generally acknowledged in the developmental literature, Baumrind's typology is closely tied to the normative goals for child development in North America. Authoritative parenting is considered to be the most adaptive style because it is associated with children who are "self-reliant, self-controlled, explorative, and content" (Baumrind, 1983, p. 121). These are the qualities of the independent individual so valued in the cultural model of individualism in countries such as the United States. In the United States, authoritative parenting and relationship closeness are also associated with better school performance among European Americans (Leung, Lau, & Lam, 1998). Interestingly, this is not the case for first-generation Chinese Americans (Chao, 2001a). Thus, authoritative parenting may not be the best model for all cultural contexts.

Cross-Cultural Variability in Styles of Parenting

Authoritative parenting is not the norm in every group. Different ethnic groups within the United States and many Eastern and developing countries have been found to utilize an authoritarian parenting style to a greater degree than do middle-class European American parents in the United States. Authoritarian parenting is more common, for example, in East Asia (Ho, 1994; Kim & Choi, 1994), Africa (Nsamenang & Lamb, 1994; LeVine et al., 1994), and Mexico (Delgado-Gaitan, 1994), as well as in ethnic groups derived from these an-

cestral cultures: Asian Americans (Chao, 1994, 2000, 2001a; Leung et al., 1998), African Americans (Baumrind, 1972), Mexican Americans (Cardona, Nicholson, & Fox, 2000; Delgado-Gaitan, 1994; Reese, Balzano, Gallimore, & Goldenberg, 1995), and Egyptian Canadians (Rudy & Grusec, 2001). (Baumrind's third style, permissive parenting, has not been found to be normative in any identifiable cultural group.)

How does cross-cultural variability in parenting style relate to child behavior and parental goals? Most important in considering cross-cultural variation in parenting styles is the fact that different parental goals can give different meanings and a different emotional context to the same behaviors. Notably, the social and emotional accompaniments of classical authoritarian parenting behavior such as the usage of imperatives may be quite different where the culture has an interdependence-oriented developmental script (Greenfield, 1994). Chao (1994), for example, points out the inadequacy of the notion of authoritarian parenting to describe the Chinese ethnotheory of child socialization. She invokes indigenous Chinese child-rearing ideologies reflected in the concepts of *chiao shun* (training children in the appropriate or expected behaviors) and *guan* (to govern).

For the European American mothers in this study, the word "training" often evoked associations such as "militaristic," "regimented," or "strict" that were interpreted as being very negative aspects of authoritarian parenting. However, although authoritarian parenting was associated with negative effects and images in the United States, the Chinese versions of authoritarianism, *chaio shun* and *guan*, were perceived in a more positive light from within the culture, emphasizing harmonious relations and parental concern (Chao, 1994). Chinese *chiao shun* and *guan* were seen not as punitive or emotionally unsupportive, but rather as associated with rigorous and responsible teaching, high involvement, and physical closeness (Chao, 1994). In fact, in China (and in India), authoritarian parenting styles are associated with maternal valuing of filial piety and academic achievement (Leung et al., 1998; Rao, McHale, & Pearson, 2003).

Another interesting finding indicative of qualitatively different cultural patterning was that, although Chinese American parents were higher on authoritarian parenting than European American parents, they did not differ on the measure of authoritative parenting. In other words, Chinese parents more often subscribed to authoritarian items (sample authoritarian item: "I do not allow my child to question my decisions"); however,

there was no difference between the groups in subscribing to authoritative items (sample authoritative item: "I talk it over and reason with my child when he misbehaves"). In this group, authoritarianism and aspects of authoritativeness such as affection and rational guidance (illustrated in the example) were complementary, not contradictory.

This finding was mirrored by another study of Chinese American parents, which found that they were more directive than but equally as warm as European American parents in their child-rearing behaviors (Jose, Huntsinger, Huntsinger, & Liaw, 2000). A similar result was found in a study of Egyptian Canadians and Anglo-Canadians; Egyptian Canadian parents scored higher on authoritarian parenting, but they did not differ from Anglo-Canadian parents in overall levels of warmth (Rudy & Grusec, 2001).

Besides Chinese Americans, there are other groups in the United States for whom authoritarian parenting is not always associated with the negative child development outcomes (such as discontent, withdrawal, distrust, and lack of instrumental competence) it has for European American children. For example, Baumrind (1972) found that, in lower middle-class African American families, authoritarian parenting was more frequent and seemed to produce different effects on child development than in European American families. Rather than negative outcomes, authoritarian parenting by African Americans was associated with self-assertive, independent behavior in preschool girls. (Baumrind did not have enough information to carry out the same kind of analysis with African American preschool boys.)

This difference in the frequency and effects of authoritarian parenting may be related to different ecological demands of the African American environment. The fact that African Americans have traditionally been on the bottom of society's power and economic hierarchy may have led them to develop obedience in their children through authoritarian directives. Authoritarian parenting can be essential when children live in potentially hazardous conditions where safety is assured only if parental instructions are followed immediately.

A second possibility is that the relative social isolation of African American communities because of slavery, segregation, and discrimination led to more long-term retention of African culture than was the case for voluntary (in Ogbu's, 1994, sense) immigrants. Indeed, according to Sudarkasa (1988, cited in Harrison, Wilson, Pine, Chan, & Buriel, 1990, p. 354),

“Research has documented the persistence of some African cultural patterns among contemporary African American families.” One relevant pattern would be the emphasis on obedience and respect as most important in African child development (LeVine et al., 1994; Nsamenang & Lamb, 1994). On the side of socialization, this pattern is achieved by strictness (Nsamenang & Lamb, 1994) and the use of parental commands as a communication strategy (LeVine et al., 1994). Such a socialization pattern would fit into the rubric of Baumrind’s authoritarian parenting.

Similarly, poor immigrant Latino families bring from Mexico and Central America the developmental goal of respect and the socialization mode of authoritarian parenting to achieve parental respect (Reese et al., 1995; Valdes, 1997).

Parent-Child Communication

Another important aspect of parent-child relations is the styles that parents employ in communicating with their children. Although parents everywhere utilize an array of styles, the emphasis is quite different from culture to culture. Here, we take up several dimensions of this variability, relating each style to parental goals (Sigel, 1985; Sigel et al., 1992) and cultural models of human development.

Nonverbal Communication or Verbalization? The Cultural Role of Empathy, Observation, and Participation. Azuma (1994) notes that Japanese mothers (and nursery school teachers) rely more on empathy and nonverbal communication, whereas mothers in the United States rely more on verbal communication with their children. He sees a connection between the physical closeness of the Japanese mother-child pair (discussed in the infancy section of this chapter) and the development of empathy as a mode of communication.

Azuma (1994) points out that verbalization is necessary when there is greater physical and psychological distance between parent and child. The development of empathy paves the way for learning by osmosis, in which the mother does not need to teach directly; she simply prepares a learning environment and makes suggestions. In turn, the child’s empathy for the mother motivates learning. This tradition survives in the families of third-generation Japanese American immigrants (Schneider, Hieshima, Lee, & Plank, 1994).

Closely related to empathy and learning by osmosis are the use of observation and participation as forms of

parent-child communication and socialization. Whereas verbal instruction is particularly important in school-based learning, observation and coparticipation of learner and teacher are central to the apprentice-style learning that is common in many cultures (Rogoff, 1990, 2003; Rogoff, Paradise, Arauz, Correa-Chavez, & Angelillo, 2003). Often, master and apprentice are parent and child, as in Childs and Greenfield’s (1980; Greenfield, 2004; Greenfield, Maynard, et al., 2003) study of informal learning of weaving in a Maya community of highland Chiapas, Mexico.

Both learning by observation and coparticipation with a parent imply a kind of closeness and empathy between parent and child. For example, in Zinacanteec weaving apprenticeship in Chiapas, Mexico, the teacher would sometimes sit behind the learner, positioned so that the two bodies, the learner’s and the teacher’s, were functioning as one at the loom (Maynard, Greenfield, & Childs, 1999; Greenfield, 2004). Verbal communication and instruction, in contrast, imply using words to bridge the distance through explicitness, thus reducing the need for empathetic communication.

A discourse study by S. H. Choi (1992) reveals a similar pattern of differences between Korean and Canadian mothers interacting with their young children. Comparing middle-class mothers in Korea and Canada, Choi found that Korean mothers and their children manifest a communicative pattern that is relationally attuned to one another in a “fused” state, “where the mothers freely enter their children’s reality and speak for them, merging themselves with the children” (Kagitçibasi, 1996, p. 69). Canadian mothers, in contrast, “withdraw themselves from the children’s reality, so that the child’s reality can remain autonomous” (S. H. Choi, 1992, pp. 119–120).

Effects of Social Change. With an ecological transition from agriculture and subsistence to money and commerce, apprenticeship learning becomes more independent and less under the control of parents. Greenfield and colleagues (Greenfield, 2004; Greenfield, Maynard, et al., 2003) demonstrated this when they studied weaving apprenticeship in a Maya community across two generations. In response to participation in commercial activities, they found a historical shift from reliance on observation of adult models and careful guidance by adult experts (usually the mother) in the generation studied in 1970 to more involvement of the peers in the apprenticeship process, lessened reliance on observation of others weaving, a reduction in teacher

guidance, and more learner independence and initiative in the generation studied in the early 1990s.

Development of Comprehension versus Self-Expression. Authoritarian parenting brings with it an associated style of parent-to-child communication: frequent use of directives and imperatives, with encouragement of obedience and respect (Greenfield, Brazelton, & Childs, 1989; Harkness, 1988; Kagitçibasi, 1996). This style is used where the primary goal of child communication development is comprehension rather than speaking (e.g., Harkness & Super, 1982). An important aspect of the imperative style is the fact that it elicits action rather than verbalization from the child. This style is found in cultures in Africa (Harkness & Super, 1982) and Mexico (Tapia Uribe et al., 1994) and in Latino populations in the United States (Delgado-Gaitan, 1994).

The comprehension skill developed by an imperative style is particularly functional in agrarian societies in which the obedient learning of chores and household skills is a very important socializing experience (e.g., Childs & Greenfield, 1980), with the ultimate goal of developing obedient, respectful, and socially responsible children (Harkness & Super, 1982; Kagitçibasi, 1996; LeVine et al., 1994). This style of interaction is also useful for apprenticeship learning of manual skills, but it is not so functional for school, where verbal expression is much more important than nonverbal action.

On the other hand, more democratic parenting brings with it a communication style in which self-expression and autonomy are encouraged in the child. This parenting style often features a high rate of questions from the parent, particularly “test questions,” in which the answer is already known to the parent (Duranti & Ochs, 1986), as well as parent-child negotiation (cf. Delgado-Gaitan, 1994). Child-initiated questions are also encouraged and accepted. This style is intrinsic to the process of formal education in which the teacher, paradigmatically, asks questions to which he or she already knows the answer and tests children on their verbal expression. An important aspect of the interrogative style is the fact that it elicits verbalization from the child. Such verbal expression is an important part of becoming a formally educated person and is particularly functional and common in commercial and technological societies where academic achievement, autonomy, and creativity are important child development goals. This style is the cultural norm in North America and northern Europe.

Teaching and Learning: The Role of Reinforcement. In societies that put an emphasis on commands in parental communication, there also tends to be little praise used in parent-child communication (e.g., Chen et al., 2000; Childs & Greenfield, 1980). Where schooling comes into play, praise and positive reinforcement take on importance. Duranti and Ochs (1986, p. 229) make the following observation of Samoan children who go to school:

In their primary socialization [home], they learn not to expect praises and compliments for carrying out directed tasks. Children are expected to carry out these tasks for their elders and family. In their secondary socialization [school], they learn to expect recognition and positive assessments, given successful accomplishment of a task. In their primary socialization, Samoan children learn to consider tasks as co-operatively accomplished, as social products. In their secondary socialization, they learn to consider tasks as an individual's work and accomplishment.

Thus, there is a connection between more individualistic child development goals and the use of praise and other positive reinforcers.

Correlatively, there is a connection between a tighter primary in-group and the absence of praise and compliments. Where role-appropriate behavior is expected rather than chosen, positive reinforcement does not make sense. Miller (1995) has described how people do not say “thank you” in India; once you are part of the group, you are completely accepted and expected to fulfill your social roles and obligations. B. B. Whiting and Whiting (1975) noted the lesser need for positive reinforcement where the intrinsic worth of the work is evident, as it is in household tasks and chores.

Teaching and Learning: The Nature of Collaborative Problem Solving. Chavajay and Rogoff (2002) identified two modes of collaborative problem solving between a mother and three related children between 6 and 12 years old (at least two being her own) in a Maya community in Guatemala. One of these modes was shared multiparty engagement, where all four parties simultaneously focused on a single aspect of the task (in this case, a construction task). The other mode was division of labor, in which participants worked on separate aspects of the task. The researchers found that, with increasing maternal schooling, there was a shift from shared engagement in a single aspect of the task to division of labor. In other words, the indigenous mode, consistent with the

community's traditional interdependent orientation (Morelli et al., 1992), involved more interdependent interaction, whereas division of labor, fostered by formal schooling, an influence foreign to Maya culture and an individualizer (Tapia Uribe et al., 1994; Trumbull et al., 1999), involved greater independence of the various members of the cooperating family group.

Cultural Models of Parent-Child Relations: Developmental Goals over the Life Span

There are basically two different cultural models describing parent-child relations over the life span. Without considering both models, we cannot adequately encompass cross-cultural variability in child development, parental behavior, and parent-child relations.

In one model, children are viewed as starting life as dependent on their parents and as achieving increasing independence as they grow older (Greenfield, 1994). In the other model, children are viewed as starting life as asocial creatures and as achieving a concept and practice of social responsibility and interdependence as they grow older (e.g., Ochs & Schieffelin, 1984). Under this model, infants are often indulged, whereas older children are socialized to comprehend, follow, and internalize directives from elders, particularly parents. The developmental outcome of the first model is the independent, individuated self; the developmental outcome of the second model is the interdependent and socially responsible self (Markus & Kitayama, 1991; Raeff et al., 2000).

In the interdependent model found in Japan, the mother-child relationship lasts a lifetime and is seen as the model for all human relationships throughout life (Lebra, 1994). The importance of continued respect up the generational ladder is seen in other cultures that subscribe to this model, such as in Mexico, among Mex-

ican Americans (Delgado-Gaitan, 1994), and in Korea (Kim, 1996).

In contrast, the independent model of family relations is distinguished by the "separateness of the generations and both emotional and material investments channeled toward the child, rather than to the older generation" (Kagitçibasi, 1996, p. 84). As Lebra (1994) points out, in this model, characteristic of the United States, the paradigmatic model of parent-child relations is the rebellious adolescent son who is breaking away from his family of origin.

Cultural Coherence

Again, we find evidence of cultural coherence. This coherence has developmental continuity as well. The two cultural models of infant development and socialization (Table 17.1) continue to be expressed in the parent-child relations of children (Table 17.2).

Ecological Factors and Social Change

The interdependence model is particularly adaptive in poor rural/agrarian societies, where it utilizes a "functionally extended family" to carry out subsistence tasks, including child care (Kagitçibasi, 1996). Due to the high poverty level and agricultural lifestyle, such shared work is highly adaptive for survival (Kagitçibasi, 1996). Indeed, in contemporary China, rural adolescents have a greater sense of family obligation than do urban adolescents (Fuligni & Zhang, 2004).

The interdependence between generations, with the younger ultimately responsible for the security of the older, is particularly adaptive in societies lacking old-age pensions and social security systems (Kagitçibasi, 1996). Conversely, the independence model of family relations is particularly adaptive in industrial, technologi-

TABLE 17.2 Contrasting Cultural Models of Parent-Child Relations

Developmental Goals	Independence	Interdependence
Developmental trajectory	From dependent to independent self	From asocial to socially responsible self
Communication	Verbal emphasis Autonomous self-expression by child Frequent parental questions to child Frequent praise Child negotiation	Nonverbal emphasis (empathy, observation, participation) Child comprehension, mother speaks for child Frequent parental directives to child Infrequent praise Frequent parental directives
Collaborative problem solving	Division of labor	Shared multiparty engagement
Parents helping children	A matter of personal choice except under extreme need	A moral obligation under all circumstances

cal societies, where the unit of economic employment is the individual, not the family. Furthermore, independence and self-reliance are valued in a sociocultural-economic context where intergenerational material dependencies are minimal, and children's loyalty to their elderly parents is not required to support parents in their old age (Kagitçibasi, 1996). With increasing affluence and education, the interdependence model tends to wane as the independence model waxes (Kagitçibasi, 1996).

But the world as a whole is becoming more affluent and formally educated; these are global trends. A cross-cultural Value of Children survey conducted in 1975 and repeated again a generation later indicated a worldwide decline in parents regarding children for their old-age security value and a worldwide increase in parents focusing on their children's development and achievement for its own sake (Kagitçibasi, & Ataca, 2005; Trommsdorff & Nauck, 2005).

IMPLICATIONS FOR PRACTICE: WHAT CAN WE LEARN FROM A CROSS-CULTURAL PERSPECTIVE ON PARENTING STYLES?

In this section, we will draw out implications of the previous section for the practice of developmental researchers, parents, educators, social workers, and clinicians in a multicultural society.

For Researchers: You Can't Take It with You

There is an important methodological lesson here: It is not valid to take the same measuring instrument from one culture to another, with the goal of making a direct cross-cultural comparison. The same behavior may have a different meaning and therefore a different outcome in different cultures (Greenfield, 1997). This is clearly true when looking at the different styles of parental interaction and discipline used by different cultural groups. For example, taking a measure of authoritarian parenting developed in the United States and using it to study parenting styles in China would provide an inaccurate and incomplete perspective on parenting practices there. It is therefore important to explore different methods of research that utilize the ideas and opinions of people native to the society under study.

One way to do this is to encourage the indigenous psychologies approach when studying culture. Kim and

Berry (1993, p. 2) define this approach as "the scientific study of human behavior (or the mind) that is native, that is not transported from other regions, and that is designed for its people." In other words, instead of taking concepts, methods, and measures from one culture and forcing it into the framework of another, it may be more appropriate and more fruitful to work from within the culture to form concepts, methods, and measures that are designed specifically for that environment. If this is done, indigenous concepts (e.g., chiao shun and guan) can be discovered and investigated from a more culturally salient perspective.

For Parents, Educators, Social Workers, and Other Clinicians

Multicultural understanding has direct implications for clinical work with families. Consider the following case (Carolyn McCarty, personal communication, June 1996): A child in an African American family is punished when a younger sibling, under her care, falls off the bed. The older child feels the punishment is unfair and complains of having too much responsibility in the family. The family seeks family therapy for these issues. In this case, armed with unconscious cultural assumptions about the developmental goal and value of independence, the first reaction of the therapist is to blame the parents for "parentifying" the older child; in this framework, parentification is considered pathological. Parentification of a child compromises the autonomy and opportunities for self-actualization that are implicit developmental goals in psychotherapy, itself an outgrowth of an individualistic framework.

However, after some training concerning the two cultural models described earlier, the clinician understood another possibility: that the parents could be developing familial responsibility in the older child by having her take care of the younger child. In accordance with this value system, the older child's punishment makes sense; it helps socialize the child to carry out the familial responsibility associated with child care. Having understood this perspective, the clinician is in a position to explore the issue of culture conflict. Is this situation, in fact, simply a conflict between an older child who has internalized the individualistic notion of fairness and responsibility for self and parents who hold dear the value of familial responsibility? If so, the clinician can now mediate between the two cultures represented by the two generations within the family.

Another implication of the preceding is that professionals (e.g., social workers, counselors, clinical psychologists, pediatricians, and educators) who advise parents on discipline and other parenting practices need to bear in mind that any advice must be relative to a particular set of developmental goals. Often, they may not realize that a particular set of child development goals is implicit in a particular piece of advice on an issue such as discipline. Insofar as members of many ethnic groups in a multicultural society will not share the socially dominant developmental model of the clinician or teacher, practitioners may need to think twice about whether it is appropriate either to ignore or change the parents' developmental goals for their children.

The Problem of Differential Acculturation of Parents and Children

Because parents often acculturate more slowly than children to a host culture (Kim & Choi, 1994), there is a great potential for parent-child conflict when families immigrate from a collectivistic to an individualistic society. Parents may expect respect, but their children have been taught to argue and negotiate (Delgado-Gaitan, 1994). Parents may see strictness as a sign of caring; adolescents may see it as robbing them of autonomy and self-direction (Rohner & Pettengill, 1985). Acculturation differences between parents and adolescents can be related to family conflict; in one study of Indian Americans, adolescents reported less frequent and less intense conflicts within the family if there was no acculturation difference between themselves and their parents (Farver, Narang, & Bhadha, 2002).

Sometimes immigrant parents bring their children, particularly teenagers, to mental health clinics for problem behaviors, such as rebelliousness, that are considered normal for adolescents in the dominant U.S. society (V. Chavira, personal communication, June 1996). When this happens, a clinician may easily assume the perspective of the dominant culture and simply take the side of the child. However, this approach denigrates the parents without understanding the value perspective that has generated their attitudes and behavior. It should be much more helpful if the clinician could accurately diagnose the parent-child problem as a problem of cross-cultural value conflict and differential acculturation. In this way, the perspectives of both parent and child are validated and understood, and a way is opened for compromise and mutual understanding.

BRIDGING CULTURES IN PARENT WORKSHOPS

Parents can also feel alienated from their children as a result of differential acculturation, specifically, the school's success with its individualistic socialization (Raeff et al., 2000). A Bridging Cultures parent workshop process was developed to address this problem. In a true experiment with random assignment, The Bridging Cultures team compared two kinds of six-session parent education workshops with immigrant Latino parents in a large urban elementary school (Esau, Greenfield, Daley, & Tynes, 2004). Parents of children in grades 1 through 4 were randomly assigned to either the district-based "standard" workshop group concentrating on techniques to improve student achievement and school policies or a second kind of workshop group called Bridging Cultures. The Bridging Cultures workshops were designed to make explicit the differences between individualistic culture (the culture of the school) and collectivistic culture (the culture of many immigrant Latinos, as in Table 17.2). We hoped that this process would help Latino immigrants gain a better understanding of their children and the socialization process they were undergoing at school.

After analyzing the group process in the course of the videotaped workshops, we found that we had made an impact in this arena. The parents discovered ways to improve their relationships with their children. They noted an increased awareness of how cultural differences influence their children's development, including the knowledge that the culture of the United States would play a large role in their children's lives. The parents retained the collectivistic values of sharing and helping, while also coming to accept independence, the importance of self-expression in school, respect for children's decisions and choices, and the value of praise and affection. One mother said (translated from Spanish), "When in school they receive merits, then too [I should] tell them, 'Oh my delight, I am so proud of you!'" (Chang, 2003, p. 24).

Parents' own child-rearing methods were validated in the workshops, as they reflected on how they themselves were raised, as well as how they were helping to foster their children's development and learning. They were also encouraged to speak to their children about the different expectations at home and school. Longitudinal research is needed to see whether this kind of cross-cultural understanding can prevent the alienation

between parents and children that often occurs as the schools, representing the dominant culture, become a stronger socializing force than the family, especially as children move into secondary education (Trumbull, Rothstein-Fisch, & Hernandez, 2003).

PEER RELATIONS

Peer relations are the child's first opportunity to take the cultural values and practices learned at home and go forth into a wider world of people who may or may not share these values and practices. This section starts with an overview of different cultural elements that can come into play during peer interaction. We will make inferences from cross-cultural variability in peer behavior in culturally homogenous peer groups to potential intergroup conflict when interacting peers belong to *different* cultural groups. We analyze cultural differences and intergroup peer conflict in a number of different behavioral areas: self-presentation, helping behaviors, competition/cooperation, and conflict resolution.

In several cases, we use adult social-psychological literature to establish developmental end points for peer behavior in different cultures and developmental literature (where available) to see how peer relations develop toward these cultural endpoints. In other words, a cross-cultural perspective on adult behavior is important because adults provide the goals used for child socialization. As a consequence, child behavior grows toward the developmental end points expressed in adult behavior.

Self-Presentation

In many individualistic societies, it is established that people like to perceive themselves as the origin of good effects but not of bad effects (Greenwald, 1980), and the confident attribution of successes to personal ability is commonly practiced (e.g., Mullen & Riordan, 1988). Consequently, self-esteem is a highly desirable quality in these societies. For example, it was found that in the United States, people who scored highest on self-esteem tests (by saying nice things about themselves) also tended to say nice things about themselves when explaining their successes and failures (R. Levine & Uleman, 1979). It appears that self-esteem is somehow correlated with a positive representation of the self.

In collectivistic societies, this tendency to present oneself in a positive light is not as highly valued (Markus

& Kitayama, 1991). Research has shown that Americans tend to self-enhancement, whereas Japanese tend to self-deprecation (Heine, Kitayama, & Lehman, 2001; Heine & Lehman, 1997; Kitayama, Markus, Matsumoto, & Norrasakunkit, 1995, 1997). The effect of self-deprecation among Japanese participants was robust, and carried through to their evaluations of their universities and even family members (Heine & Lehman, 1997). The effect of culture in molding self-presentation, and therefore peer relations, is indeed far-reaching.

This cultural difference in peer relations begins in childhood. In a study conducted on the opinions of second, third, and fifth graders in Japan, students were asked to evaluate a hypothetical peer who was either modest and self-restrained or self-enhancing in commenting on his or her athletic performance (Markus & Kitayama, 1991; Yoshida, Kojo, & Kaku, 1982). Yoshida et al. found that, at all ages, the personality of the person giving the modest comment was perceived much more positively than that of the person giving the self-enhancing comment. A developmental trend was also found: Second graders believed the self-enhancing comment of the hypothetical peer to be true, whereas fifth graders did not. In other words, whereas second graders believed that the self-enhancing peer was truly superb in athletics, fifth graders believed that the modest peer was more competent. Therefore, although the cultural value of restraint and modesty was understood as early as second grade, this value expanded with age to incorporate positive attributes of ability and competence (Markus & Kitayama, 1991). Indeed, behaviors such as the verbal devaluation of oneself and even of one's family members is a norm in many East Asian cultures (Toupin, 1980). Not surprisingly, self-effacing values are also stronger in Asian American than European American youth (Akimoto & Sanbonmatsu, 1999).

Implications for Intergroup Peer Relations

Both modes of self-presentation conform perfectly to their respective cultural goals, but one can see how people from one culture can misinterpret and even decry the preferred self-presentation styles of other cultures. The Asian American tendency to present oneself in a self-effacing manner can be evaluated unfavorably by others (Akimoto & Sanbonmatsu, 1999). In college interview situations, for example, Asian American students can be viewed as uninteresting applicants because of their modesty and desire to fit in rather than stand out. On

the other side, self-enhancing tendencies of European American youth can be seen as undesirable self-aggrandizement (Suzuki, Davis, & Greenfield, *in press*).

Helping Behavior

The desirability of helping others appears to be universal. However, people's perceptions of helping behaviors and when they are appropriate can vary drastically from culture to culture. Some societies view helping as a personal choice; others view this as a moral obligation. For example, children in the United States feel that it is a matter of personal choice, not moral responsibility, to help a friend in moderate or minor need, whereas it is a matter of moral responsibility to help a friend in extreme need or to uphold justice (Miller, Bersoff, & Harwood, 1990). Caring and interpersonal responsiveness are seen as a matter of personal choice based on various factors, such as how much one likes the person needing help (Higgins, Power, & Kohlberg, 1984; Miller & Bersoff, 1992, 1998; Nunner-Winkler, 1984). This value of personal choice is highlighted in individualistic societies, such as the United States, where Miller and colleagues found this pattern of results from second grade to college age.

In societies that value group harmony and cooperation, however, helping behaviors can be perceived at a different level of urgency and obligation. This is particularly true in India, where helping is seen not as a personal choice, but as a moral necessity (Miller, 1994; Miller & Bersoff, 1992; Miller et al., 1990). Virtually all Indians from second grade to college age felt that it was legitimate to punish a person who failed to help a friend, even in minor need. Whether or not the helper liked the person in need had no impact on Indian participants' perceptions of moral responsibility to help others (Miller & Bersoff, 1998).

In another study, Miller (1995) found that most U.S. college students would not inconvenience themselves to help their best friend if he or she had not helped them or others in the past. Although Indian college students agreed with U.S. college students that not helping in the past was undesirable behavior, this history would not deter them from helping their best friend.

Choosing not to help others may be met with harsh disapproval in cultures that value the preservation of group interests. In Cameroon, for example, asserting individual rights and interests over those of the community would cause the Cameroonian to be acting "at the

expense of his or her peace of mind and at great risk of losing the psychological comfort of a feeling of belonging" (Nsamenang, 1987, p. 279). Such a person would be considered deviant under traditional African thinking (Nsamenang, 1987). In the United States, Latinos viewed helping others as more obligatory and personally desirable than did European Americans (Janoff-Bulman & Leggatt, 2002; Raeff et al., 2000). Given these differences, one can imagine how an Indian, Nigerian, or Latino child may be confused and even shocked when a child from another culture may choose not to help a group member in a time of need.

Ecological Factors

J. W. M. Whiting and Whiting (1973/1994, p. 279) put forth the hypothesis that complex societies must suppress altruistic or helping behavior to friends (as well as to family) to maintain the economic order, "a system of open and achievable occupational statuses." Complex technological society requires the egoistic behaviors of self-development; the essence of obtaining a position in the economic system is individual merit, not social or family connections. Based partly on their cross-cultural child observation data in nontechnological small-scale cultures, Whiting and Whiting view the United States, a complex technological society, as occupying an extreme position on the egoistic side of the egoism/altruism dimension.

Play: Cooperation and Competition

Peer games can bring up important cross-cultural differences in the tendency to emphasize cooperation versus competition and in the ways rewards are allocated. These differences can then create difficulties in peer relations in a culturally diverse society.

In Western societies, both cooperation and competition are valued, and children often learn to interact with one another utilizing both concepts. However, children in the United States, for example, are often placed in situations where competition is more likely to be utilized and even encouraged. In the United States, this tendency to be competitive with one another increases with age (Kagan & Madsen, 1972). This developmental trend was clearly depicted in a study by Madsen (1971) that utilized an interpersonal game in which children could either cooperate with one another (and be more likely to receive a prize) or compete with one another (and be less likely to receive a prize). The result showed a

striking effect. In the United States, it was found that younger children (4 to 5 years) were more successful than older children (7 to 8, 10 to 11) in restraining their motivation to compete in order to receive a prize. In older children, the motivation to compete was so strong that it overcame the tendency to act out of mutual self-interest, even when they had the intellectual capacity to act otherwise (Madsen, 1971). In contrast, Mexican children from a small agricultural community behaved cooperatively at the older ages. Small population size may be important because of its role in leading to within-group cohesion.

It is important to note, however, that in-group cooperation is often associated with out-group competition. This was the case for highly cooperative kibbutz children from Israel (Shapira & Madsen, 1969). Israeli kibbutzim are small, collectivistic, agricultural communities with strong in-group ties. Using a game to examine cooperation and competition in peer relations, Shapira and Madsen found that kibbutz children's tendency to cooperate in a game overshadowed their competitive tendencies under different reward conditions. In contrast, Israeli city children would cooperate when there was a group reward, but as soon as rewards were distributed on an individual basis, competition took over.

In kibbutzim, children are prepared from an early age to cooperate and work as a group, and competition is not seen as a socially desirable norm (Shapira & Madsen, 1969). At the time this study was done, kibbutz teachers reported that anticompetitive attitudes are so strong that children sometimes felt ashamed for being consistently at the top of their class (Shapira & Madsen, 1969). Under such cultural norms, it is of no surprise that children in kibbutz communities are much more likely to cooperate than compete with one another in gaming situations. A high level of within-group cooperation was associated with a desire to do better than other groups who had played the game before.

Insofar as an emphasis on cooperation is part of a collectivistic value orientation, it may be that greater differentiation of relations with in-group and out-group members may characterize collectivistic cultures, in comparison with individualistic ones (Triandis, Bondtempo, Villareal, Asai, & Lucca, 1988). In a study comparing Japanese and American students in conflict situations against differing opponents, researchers found that the Japanese participants showed a greater behavioral difference between their interactions with

in-group members and their interactions with out-group members.

Thus, it is too simplistic to say that children from collectivistic cultures are, on average, more cooperative than children from individualistic cultures. Instead, children from more collectivistic cultures are more cooperative with in-groups and more competitive with out-groups. Also, the cross-cultural mean differences are far from absolute. For example, children from more individualistic environments will cooperate when competition is dysfunctional and there are very strong cues for cooperating, for example, group reward (Shapira & Madsen, 1969).

Ecological Factors and Social Change

As with helping behavior, cooperative behavior appears to be more functional and encouraged in small, simple, nontechnological groups with low levels of formal education, and less functional in large, complex, technological groups with high levels of formal education (Graves & Graves, 1978). Therefore, when members of a small, simple, nontechnological group come into contact with members of a large, complex, technological group, competitiveness in peer relations increases, as Madsen and Lancy (1981) found in New Guinea.

The effects of urbanization are confirmed by studies comparing two ecologies in one country. In one such study, Madsen (1967) found that urban Mexican children were much more competitive and less cooperative than rural children from a small, agricultural community in Mexico. This pattern of findings points to the conclusion that the greater cooperation of Mexican immigrants to the United States may be, to a great extent, a function of their rural, agricultural background.

However, urbanization may play its role in reducing cooperation and increasing competition by loosening the strength of in-group ties in an ethnically diverse milieu. This was the conclusion of Madsen and Lancy (1981), who, in a study of 10 sites in New Guinea, found that, when primary group identification could be separated from rural residence, it was by far the most important factor in children's choice between a cooperative and a competitive strategy in a peer game situation. Children who came from ethnic groups that had retained their tribal coherence were more cooperative, even when exposed to urban centers, than were rural children whose groups had less stability and whose traditional way of life had largely disappeared.

Implications for Intergroup Peer Relations

With this in mind, it is apparent that children (as well as adults) with differing cultural backgrounds can easily have differing ideas concerning cooperation and competition. Without proper awareness of such differentiation in viewpoints, one can imagine the possible confusion and misunderstanding that might occur when one child's assumptions about cooperation, competition, and reward allocation fundamentally differs from that of a playmate. This difference can indeed be yet another source of cross-cultural conflict that can occur among children, particularly following immigration from a collectivistic milieu to an individualistic one.

Conflict Resolution

Conflicts among children are inevitable within any culture. It is clear from the earlier descriptions that the potential for conflict (especially culturally based conflict) is even greater between children of differing backgrounds. However, it is ironic to note that acceptable and preferred measures of conflict resolution also differ from culture to culture.

Cultural Bases of Conflict Resolution

In the United States, success, freedom, and justice are "central strands" of culture (Bellah, Madsen, Sullivan, Swindler, & Tipton, 1985). These values are considered individual rights and are treasured concepts, written into the Constitution and worthy of fighting wars for. Under the precepts of these rights and the resulting economic system of capitalism, competition among people is seen as healthy, necessary, and even desirable. Thus, resolution of conflict may be competitive and confrontational, based on the concept that the individual, rather than the collective, has rights that should be actively pursued.

In other societies, however, behavioral ideals lead to different types of desired behavior. For example, Chinese people were found to prefer nonconfrontational approaches to conflict resolution more than Westerners did (Leung, 1988). In fact, there appears to be a strong inverse relationship between the presence of Chinese values and the degree of competitiveness used in handling conflicts (Chiu & Kosinski, 1994), suggesting a strong tie between cultural values and conflict behavior. In general, Toupin (1980) suggests that East Asian cultures share certain norms, including that of deference to

others, absence of verbal aggression, and avoidance of confrontation.

Conflict resolution in West Africa also emphasizes the importance of group harmony. According to Nsamenang (1987, p. 279), West Africans emphasize reconciliation as a means of handling disputes and domestic conflicts in order to "reinforce the spirit of communal life." The preservation of group harmony during conflict resolution is once again crucial in this cultural context. Similarly, college students in Mexico were more likely than students in the United States to prefer conflict resolution styles that emphasize accommodation, collaboration, and concern for the outcome of others (Gabrielidis, Stephan, Ybarra, Pearson, & Villareal, 1997).

Indeed, both the means as well as the goals of conflict resolution vary according to the aspired values and ideals of each culture. We would expect these cultural modes of adult conflict resolution to furnish the developmental goals for the socialization of conflict resolution in children.

Children's Methods of Conflict Resolution Reflect Their Cultural Foundations

In every society, cultural ideals are manifest in the conflict resolution tactics that are encouraged by the adults. According to B. Whiting and Edwards (1988, p. 189), "The manner in which socializers handle children's disputes is one of the ways in which the former transmit their values concerning the legitimate power ascribed to gender and age." That is, through adult intervention, cultural and societal ideals and values are transmitted to the children.

Take, for example, the case of the United States. In American preschools, a child is generally encouraged to use words to "defend oneself from accusations and to seek redress when one feels wronged" (Tobin, Wu, & Davidson, 1989, p. 167). American parents also encourage children to use words to "negotiate disputes or label their emotions" (B. Whiting & Edwards, 1988) when having conflicts with their peers. In a culture that highly values equality, individual rights, and justice, expressing one's personal point of view is very important. By doing so, the hope is that justice can emerge out of learning about each child's individual perspective. Note that the emphasis on verbal dispute resolution reflects the emphasis of European American parents on verbalization.

Individualized attention given to misbehaving children, heralded as an appropriate and effective means of child management in this particular cultural context,

would appear strange in others. In the United States, it is quite common and even desirable for teachers, parents, and children to use negotiation, lobbying, voting, pleading, litigation, encouraging, arbitration, and a variety of other means to resolve conflicts in a "just" or "fair" manner (Tobin et al., 1989). However, such individualized attention given to misbehaving children may not be approved of in more collectivistic cultures.

In the same observational field study, Tobin et al. (1989) observed preschool activities in Japan. Here, teachers were described as being "careful not to isolate a disruptive child from the group by singling him out for punishment or censure or excluding him from a group activity" (p. 43). In a society where group interactions and collectivism are highly valued, such a punishment for misbehavior would be seen as extreme. Given this cultural framework, the Japanese teachers would choose instead to take a more unintrusive approach to conflict resolution. When Hiroki, a misbehaving child, causes a stir among his classmates, the Japanese teacher's response is not to single him out but rather to instruct other children to take care of the problem themselves. This technique is in stark contrast to the American tactic of immediate adult intervention and arbitration.

The philosophy behind this mode of conflict resolution is closely linked to cultural beliefs. In Japan, group interactions are highly salient, and teachers therefore believe that "children learn best to control their behavior when the impetus to change comes spontaneously through interactions with their peers rather than from above" (Lewis, 1984, quoted in Tobin et al., 1989, p. 28). In an interview, the Japanese teacher said that she believed that other classmates' disapproval would have a greater effect on misbehaving children, perhaps more so than would any form of adult intervention. Here we see peer pressure as an effective means of conflict control.

In the United States, in contrast, peer pressure is usually seen not as a means of controlling behavior in a positive way, but as a negative form of conformity and lack of personal freedom. In this context, having children work things out on their own without intervention and assessment by others would be unusual indeed.

Cultural differences in children's conflict resolution have been found between other countries as well. For example, preschoolers in Andalusia, Spain, are more likely to resolve conflicts by reaching an agreement or compromise, whereas Dutch children are more likely to give priority to their individual objectives even at the risk of disrupting the activity (Sanchez Medina, Lozano, &

Goudena, 2001). Perhaps the Andalusian tendency to be more harmonious during conflict is related to the Spanish/Latin American notion of *simpatia*, or "pro-active socioemotional orientation and concern with the social well-being of others" (R. V. Levine, Norenzayan, & Philbrick, 2001, p. 546).

Implications for Intergroup Peer Relations

Conflict is unavoidable in any cultural context. However, the modes of dealing with conflict can differ greatly. Conflict resolution is difficult enough in a homogeneous society where children ascribe to the same cultural scripts and norms. When children from differing backgrounds attempt to reconcile their differences, their task is even further exacerbated by an incongruity between the children's conflict resolution styles. Thus, events such as minor playground altercations can lead to greater schisms in children's perceptions of people from other backgrounds and beliefs.

Implications for Practice

In this section, we deal with the implications of culturally heterogeneous peer groups for educators, counselors, and other clinical practitioners.

Education

Teachers are in the position of interacting with large groups of children of differing backgrounds where cultural differences in interactive style are constantly exposed. When interethnic misunderstandings occur, Quiroz (personal communication, January 1996) observed that the injured party often attributes the behavior of the other group to prejudice and discrimination. This might be especially true when the injured party belongs to a minority ethnicity. An understanding of the cultural reasons for peer behavior has the power to decrease attributions of prejudice and discrimination, thus contributing to improved intergroup peer relations.

How teachers resolve conflicts is often determined by the dominant culture. For example, in their book *Conflict Resolution in the Schools*, Girard and Koch (1996, p. 138) emphasize that teachers should develop their students' negotiation skills so that students can "educate one another about their needs and interests." Another strategy recommended is for teachers to teach students to use "I" messages, such as "I feel _____ when _____ because _____, and I need _____"

(p. 138). These kinds of conflict skills may be appropriate for students from individualistic cultures, where the emphasis is on getting one's own needs met. This is a different style of conflict resolution from consensus building, which is built on "an integrative solution . . . a synthesis and blending of solutions" (p. 137). Consensus building, where points are discussed until the group decides on a common decision, reflects a much more collectivistic orientation (Suina & Smolkin, 1994).

Counselors and Other Clinicians

Child counselors and clinicians should likewise be informed and educated on the effects of culture on child behavior and peer interaction. In this way, they can be better prepared to recognize and accommodate culture in their counseling sessions and diagnoses when children from multicultural environments present with difficulties in peer relations.

School counselors are in a strategic position to help students, teachers, and parents understand culture. In one study, middle school counselors were given a three-session Bridging Cultures training similar to that described earlier. The counselors were able to find many examples of the collectivistic home culture among their largely Latino student population. One counselor noted:

Just today, a female student shared many of her problems that her family has. Problems include poverty, lack of adult supervision and nurturance. She suspects that her mother may be a prostitute. Due to her collectivistic belief she spends all day thinking about ways to possibly solve or improve her home situation for herself and her brothers. That leaves her with no time, energy or motivation to study. (quoted in Geary, 2001, p. 66)

Summary

Differences in peer relations in the areas of self-presentation, helping behavior, play, and conflict resolution organize themselves around what has become a familiar dimension: an idealized cultural model of independent or interdependent functioning. When interacting peers come from home cultures that have different models concerning this dimension, the potential for problematic peer relations arises.

An important source of perceived prejudice and discrimination is failure to understand the cultural values that generate the behavior of others. One can see how differences in cultural value systems have the potential

to cause deep misunderstanding and conflict between children from different cultural backgrounds. Interaction between children is never completely conflict-free, but when children play with other children who share their cultural values, peer interaction can often be smoother, based on similar assumptions of what constitutes fair play, proper methods of conflict resolution, and ideal interactive behaviors.

In a multicultural society such as the United States, children from various cultural backgrounds are given the opportunity to interact with one another. However, interaction alone does not breed awareness of other value systems. There is a tendency for each interactant to see the other's behavior through the implicit lens of his or her own value system. It is therefore important for educators and clinicians to be aware of the potential differences between children to help each child to better understand that children may have different perspectives on proper peer interaction, and that these differences can be acknowledged, respected, and even appreciated.

STUDYING AND INTERVENING IN CROSS-CULTURAL PEER RELATIONS: THE CASE OF MULTIETHNIC HIGH SCHOOL SPORTS TEAMS

In a study of cross-cultural conflict among girls volleyball team members in Los Angeles, players' journals, in combination with ethnographic observation at practices and games, unearthed many instances of peer conflict in which one party assumed an individualistic perspective while the other assumed a collectivistic one (Greenfield, Davis, Suzuki, & Boutakidis, 2002). For example, in a "water bottle incident," a Latina girl drank from a water bottle of a European-American girl, and the latter became quite angry (Kernan & Greenfield, 2005). Journal entries relating to this type of conflict indicated that the girl who drinks from the bottle of another assumes the interdependent value of sharing, whereas the owner of the water bottle assumes the value of personal property, bolstered by a desire not to spread germs (an appeal to the physical world). In a later observation of another team composed entirely of Hispanics and Native Americans in Santa Fe, New Mexico, Greenfield (unpublished field note, 2000) observed that a water bottle was passed around the whole team during a team hud-

dle. Here, in a more homogeneous group in which everyone comes from a collectivistic culture (either New Mexico Hispanic or Pueblo Indian), a subsequent interview indicated that sharing water by the whole team was simply taken for granted. However, given the heterogeneous nature of high school sports teams in Los Angeles, an intervention research project was designed.

The goal of the intervention was to promote greater cross-cultural harmony: If teens could learn about the cultural values of both individualism and collectivism, would it increase their tolerance and understanding of each other? The intervention tried to affect peer-group relations in two multiethnic high school girls varsity basketball teams. The two teams were selected because each one represented a mix of ethnicities: European American, Asian American, Latino American, African American, Native American, and mixed ethnicity. The first analysis examined teams over two seasons. During the first season, baseline data concerning the sources of conflict were obtained (Engle & Greenfield, 2005).

During the second season, three workshops were presented to each team to promote tolerance and understanding of cultural value differences within the framework of independence (individualism) and interdependence (collectivism). The workshops included discussions in large and small groups about individualism and collectivism. The girls also developed skits about conflicts in sports from the perspective of both value systems, with the goal of making implicit values explicit and communicating the notion that each value orientation has its own strengths and weaknesses (Engle & Greenfield, 2005). Pre- and postworkshop questionnaires each included eight action scenarios; four were sports team situations and the other four were home and school situations. Each scenario presented a social dilemma that could be resolved in either a more collectivistic or a more individualistic manner. In addition to choosing their own (collectivistic or individualistic) resolution for the dilemma, respondents were asked if they could imagine someone making the other choice and why. This was meant as a measure of understanding the other cultural perspective. We hypothesized that our intervention would increase this type of cross-cultural understanding. However, we did not find the hoped-for effect.

Instead, we found that the values of individualism and collectivism were situational. The sports team scenarios prompted significantly more collectivistic value choices than did home and school scenarios. In the context of sports-based scenarios, the girls did respond to questions

indicating that they would work together for the good of the team, demonstrating the development of a superordinate group identity that is important for adolescents.

Equally important was the development over time of a team culture. Questionnaire responses were more collectivistic at the end than at the beginning of the season; playing as a team increased collectivism (Engle & Greenfield, 2005).

In sum, the effective intervention was not the workshops, but the experience of playing on a team. Even here, the effect was not what we expected—a greater understanding of another cultural value system—but rather a push toward a collectivistic perspective. The authors conclude that a dynamic model of cultural values systems exists, adapting to contexts over time.

The second analysis examined how young women begin to think of themselves as a team: negotiating problems and creating shared team values (Kernan & Greenfield, 2005). Besides questionnaires, players kept journals throughout the season. The journals supported the questionnaire results: Whatever the starting value orientation expressed in their journals, almost all of the players became more collectivistic during the basketball season. However, there were differences in the rationale depending on value starting point. Over the course of the season, players starting with both value orientations increasingly valued “showing up” for practices and games, but for different reasons. Showing up was valued by the more individualistic team members because of an agreement or contract to do so. In a sense, this perspective emphasizes a task orientation and an explicit contract, features of a more individualistic orientation. This perspective is in contrast to a more collectivistic approach centering on implicit social obligation as a reason to show up. The personal journals supported the questionnaires in showing that cultural values are not static: Family culture interacts with ecological circumstances to create specific cultural practices in specific contexts. However, they also demonstrated that the value starting point, the result of prior socialization, has an impact as well.

In short, the experience of playing together over time made the group more of a team. This recognition of a superordinate peer group—the team—has great potential for bringing peers from different ethnicities and different cultures together for a common goal (Allport, 1958; Gaertner, Dovidio, Nier, Wsard, & Bunker, 1999).

This is an example of a failed intervention. However, the integration of qualitative and quantitative methodology enabled the researchers to understand

other important interpersonal dynamics. At the same time, on a theoretical level, much was learned about the power of the situation to shape a value orientation. This process of shaping values through specific experience indicates the adaptive quality and, by extension, the adaptive origin of cultural value systems.

HOME-SCHOOL RELATIONS

Cultural models of human development and socialization are embodied in infant care practices and parent-child relations (both discussed earlier). These practices and relations then influence the cultural models and behaviors that children bring into their peer relations (previous section). One important institution in which peer relations are forged is the school. Schooling involves more than just peer relations, however. It also involves relations between children and teachers and between parents and teachers. These relationships are the focus of the present section.

By the age of 4 or 5 years, most children venture from their home to enter a brand new environment: school. In a culturally homogeneous situation, this shift between home culture and the culture of the school is a relatively smooth transition, based on shared goals and assumptions (Raeff et al., 2000). In a multicultural situation, the problems are different. Cultural diversity, while being colorful and joyous, can also lead to potential misunderstandings and value conflicts between school personnel and parents. Some of these misunderstandings occur in the context of peer relations at school; here the analysis of the previous section is relevant. Still others occur between parents and teachers or between children and teachers. Such culture-based misunderstandings are the central issue of this section.

In the cross-cultural peer conflicts we analyzed in the preceding section, contrasting cultural values were considered to be on an equal footing. However, in school, this is actually not the case. The power belongs to the dominant culture that is part and parcel of formal education in the United States or any other country.

Bringing a Collectivistic Model of Development to School: The Potential for Home-School Conflict

Raeff et al. (2000) studied conceptions of relationships and areas of cross-cultural value conflict among Euro-

pean American and Latino children, their parents, and their teachers. The study was conducted in two different elementary schools in the Los Angeles area: School 1 served a primarily European American population, and School 2 served a primarily immigrant Latino population. Eight open-ended hypothetical scenarios were constructed based on reported experiences of immigrant families. Four scenarios depicted home-based dilemmas and four were school-based (these scenarios were also used in the sports study discussed in the preceding section). The scenarios were presented to all participants on an individual basis. For example: "It is the end of the school day, and the class is cleaning up. Denise isn't feeling well, and she asks Jasmine to help her with her job for the day, which is cleaning the blackboard. Jasmine isn't sure she will have time to do both jobs. What do you think the teacher should do?" (p. 66).

The results indicate that the overwhelming majority of the responses fell into two categories:

1. Find a third person who will volunteer and will not endanger the helper's own task completion; this was considered an individualistic mode of response.
2. Simply help the sick child with her job; this was considered a collectivistic mode of response.

The teachers (multiethnic in both schools) overwhelmingly made the individualistic choice. European American parents and their children were in tune with the teachers' individualistic model of development. However, the overwhelming majority of immigrant Latino parents made the collectivistic choice: Jasmine should help no matter what. This response was shown to be part of a more general model of development: Across four diverse scenarios, Latino immigrant parents overwhelmingly constructed responses that reflected an underlying collectivistic model of development. As would be expected from this choice, Latino immigrant parents were significantly more collectivistic than their children's teachers; this pattern indicated that the children were being subjected to two different socialization influences, a more collectivistic one at home and a more individualistic one at school.

From the point of view of home-school relations, the Latino parents seemed out of tune with the school's value system, and the teachers were equally out of tune with the Latino parents' value system. This is in sharp contrast to the picture of home-school value harmony

that exists for European American families (Raeff, Greenfield, & Quiroz, 2000).

Children Caught between Home Culture and School Culture

As a consequence of value harmony between their parents and their teachers, European American children are receiving consistent socialization messages at home and at school. The children of Latino immigrants are not. The results reflect these dynamics: Whereas there are no significant differences in the responses of European American children and their parents, there are significant differences between Latino children and their immigrant parents (Raeff et al., 2000).

Indeed, the Latino children are, overall, significantly more individualistic than their parents and significantly more collectivistic than their teachers (Raeff et al., 2000). That is, they are different from both their major socializing agents. Little is known about whether such children have successfully integrated two cultures or are caught in the middle. Although this research was done with a particular population, it is potentially applicable to the children of other collectivistic minorities in the United States.

Schools often reflect aspects of individualism that highlight independence as a goal of development. For example, classroom interactions and activities emphasize individual achievement, children's autonomous choice and initiative, and the development of logicorational rather than social skills (Delgado-Gaitan, 1993, 1994; Reese et al., 1995).

Academic activities are also intrinsically individualistic insofar as evaluations are generally made on the basis of independent work accomplished by individual students (J. W. M. Whiting & B. B. Whiting, 1975/1994) rather than on the basis of group endeavors. This focus on individual achievement and evaluation is a predominant theme in academic settings; indeed, individual achievement and evaluation are the foundation on which most schools are built (Farr & Trumbull, 1997; Trumbull, 2000).

These aspects of school culture often come into direct conflict with the collectivistic orientation toward education favored not only by Latinos, but by many minority and immigrant cultures that emphasize values such as cherishing interpersonal relationships, respecting elders and native traditions, responsibility for others, and cooperation (Blake, 1993, 1994; Delgado-Gaitan, 1993,

1994; Ho, 1994; Kim & Choi, 1994; Suina & Smolkin, 1994). This perspective is antithetical to the school's emphasis on individual achievement.

Individual Achievement from a Collectivistic Perspective

Encouraging children's individual achievements can be seen in some cultures (e.g., Nigeria) as devaluing cooperation (Oloko, 1993, 1994) or group harmony. Research on conferences between immigrant Latino parents and their children's elementary school teachers revealed incidents when the teacher's praise of an individual child's outstanding achievement made a parent feel distinctly uncomfortable (Greenfield, Quiroz, & Raeff, 2000).

These parents seemed to feel most comfortable with a child's school achievement if the academic skill in question could be applied to helping other family members. For example, in one parent-teacher conference, a Latino mother (with a first-grade education) created common ground with the teacher when she responded to a question about her daughter's home reading by telling the teacher that her daughter had been reading to a younger family member.

Written Knowledge from a Collectivistic Perspective

The reliance on textbooks used in many school settings may also be cause for conflict. In some cultures, knowledge is seen as something that is gleaned not from impersonal texts, but from the wisdom and knowledge of relevant others. In the Pueblo Indian worldview, parents and grandparents are seen as the repositories of knowledge, and this fact provides a social connection between the older and younger generations. In cultures such as these, when objects rather than people become the authorities of knowledge, the introduction of resources such as encyclopedias, reference books, and the like is seen to undermine "the very fiber of the connectedness" (Suina, 1991, p. 153) between people. Given this perspective, the school's emphasis on learning through written material may appear to be an impersonal and even undesirable way of acquiring knowledge.

Valdés (1996) in an ethnographic study of 10 immigrant families from Mexico, found that a mother's communication with her son's elementary school teacher "confirmed the school's lack of interest and caring." In this case, the mother had concerns that her

son Saul was eating fish at school, a problem because he was allergic to fish and became sick after eating it, causing him to miss school. She instructed Saul's older brother, 8-year-old Juan, to tell his teacher about this problem. Either the older child failed to deliver the message or the "teacher did not consider it to be her role to pass on the information to the appropriate school personnel" (p. 156). As a result, Saul continued to eat fish and miss school. Valdés concludes that if the mother "had sent a note instead of a message, it might have been that she would have received some response from the teacher or another individual" (p. 156). However, the mother had no way of knowing the greater value of written communication in this instance and assumed that the school had little interest in her child's health.

As this example demonstrates, the problems of home-school communication transcend translation issues. The system of an older child being a knowledgeable, trusted, and responsible care provider of a younger sibling is consistent with the values of collectivistic families. In contrast, the teacher may have believed the older sibling's remarks were unsubstantiated by a formal note and thus discounted entirely. If it were true that the older sibling did not communicate his mother's message to the teacher, then it is possible he had already shifted from his home cultural values to those of the school.

Object Knowledge from a Collectivistic Perspective

Children whose cultural background has emphasized social relations and social knowledge may not understand the privileged position of decontextualized object knowledge in the culture of the school. The following is an example of culture conflict that can occur between teachers and children:

In a Los Angeles prekindergarten class mostly comprised of Hispanic children, the teacher was showing the class a real chicken egg that would be hatching soon. She was explaining the physical properties of the egg, and she asked the children to describe eggs by thinking about the times they had cooked and eaten eggs. One of the children tried three times to talk about how she cooked eggs with her grandmother, but the teacher disregarded these comments in favor of a child who explained how eggs are white and yellow when they are cracked. (Greenfield, Raeff, & Quiroz, 1996, p. 44)

From the Latino point of view, the first child's answer was typical of the associations encouraged in her invisible home culture of interdependence. That is, objects are most meaningful when they mediate social interactions. The child therefore acted on this value of interpersonal relations in answering the teacher's question. The teacher, however, did not recognize this effort and considered the social descriptions of the time the child had eaten eggs as irrelevant; only physical descriptions of these occasions were valued (Greenfield et al., 1996). The teacher did not even see the invisible culture that generated a description of cooking eggs with one's grandmother; the teacher devalued the child's contribution and, implicitly, the value orientation it reflected. Because she did not understand the collectivistic value orientation, she was also unaware that her question was ambiguous in the following way: Children who shared her value orientation would assume that she was interested in the physical properties of the eggs, even though she did not make this point explicit; those children who did not share the teacher's value orientation would make different assumptions.

Assertiveness from a Collectivistic Perspective

In many collectivistic cultures, the value placed on respecting authority may go as far as to undermine the more individualistic styles of learning that require children to articulate and even argue their views with teachers and other elders on a relatively egalitarian basis (Delgado-Gaitan, 1993, 1994; Valdez, 1997). Consider the following cultural ideal for child communicative behavior for many people of Mexican background. According to Delgado-Gaitan (1994, p. 64): "Children are expected to politely greet their elders; they are not supposed to argue with them. In the company of adults, children are to be good listeners and participate in a conversation only when solicited. To raise questions is to be rebellious."

Valdés (1996) found respect to be so central to the families in her ethnographic study that she titled her book *Con respeto*. "Respeto for the mother's role was very much in evidence. . . . When a directive was given, it was followed promptly. If a younger child did not do so, an older sibling soon made certain that the youngster did what he had been told" (p. 120).

A similar view of questioning is found in Japan (Muto, Kubo, & Oshima-Takane, 1980). Given this cultural ideal in child communication, one can imagine the scenario in a U.S. school in which a teacher might falsely

interpret a Mexican American child's culturally defined polite compliance or a Japanese child's absence of questioning as a lack of motivation or intellectual curiosity.

As we saw in the section on parent-child relations, many children from different ethnic groups are raised with the notion of respecting and accepting the opinions of elders without question, and this value may be carried with the children to the school setting. The school's emphasis on rational argumentation can be seen to undermine respect for elders. However, when children with respect for authority are not vocal and adept at logicrational modes of argumentation, they can be subjected to criticism by teachers, who focus on fostering individual assertiveness and opinions.

For example, in a study of fall conferences between immigrant Latino parents and their children's elementary school teachers, we showed that the teacher criticized every single child for not sufficiently expressing his or her views in class (Greenfield, Quiroz, & Raeff, 2000). The teacher was unaware that such behavior would be contrary to the Latino parents' goals for their own children's development.

Implications for Educational Practice

In many collectivistic societies, schools have found ways of integrating indigenous cultural values into the school system. In Japanese and Chinese classrooms, for example, classroom practices that focus the attention of teaching on the class as a whole rather than promoting attention to individual students are common and widely accepted (Stigler & Perry, 1988). This technique might be useful in U.S. classrooms that are homogeneous in the sense of containing only children who come from collectivistic backgrounds. Classrooms for immigrants would be one such example.

Implications for Counseling and Clinical Practice

Conflicts between children's experiences at home versus school could cause some degree of distress to children who are too young to realize that their feeling "different" may be due to culture. Cultural differences can be manifested in a variety of areas (religious restrictions, differences in social interaction, differing customs, foods, and beliefs, unusual parenting styles, etc.), and at an age when children want to fit in with their schoolmates, there is a potential for anxiety when home-school conflict occurs. Counselors and therapists who come into contact with school-age children should be aware of cultural conflicts and their potential to af-

flect children's emotional and psychological well-being. Furthermore, they should be properly trained to deal with these issues.

Summary

By and large, the educational implications of cross-cultural research revolve around a single major theme: the need to recognize that patterns and norms of development and education previously thought to be universal are often specific to European American culture and the culture of the schools. More specifically, immigrant and Native American families often come from collectivistic cultures but must put their children into the highly individualistic institution of the school. On the other hand, members of the dominant culture find relative harmony between their individualistic value framework and that of the school.

The major educational implication of cross-cultural value conflict is for teachers first to acquire an awareness and understanding of the individualistic and collectivistic frameworks and then to encourage mutual understanding and accommodation between the two value frameworks in both children and their parents. This was the foundation of our Bridging Cultures teacher-training intervention, to which we next turn.

EXAMPLE OF A HOME-SCHOOL INTERVENTION: BRIDGING CULTURES FOR TEACHERS

As part of a longitudinal action research project called Bridging Cultures, seven bilingual elementary school teachers serving homogeneous immigrant Latino populations were introduced to the concepts of individualism and collectivism (Rothstein-Fisch, Greenfield, & Trumbull, 1999; Trumbull, Diaz-Meza, Hasan, & Rothstein-Fisch, 2000; Trumbull et al., 1999; Trumbull, Rothstein-Fisch, Greenfield, & Quiroz, 2001). Teachers were selected because they had an interest in multicultural education and they represented all grades from kindergarten through grade 5 in the greater Los Angeles area. Four teachers identified themselves as Latino and three as European American. Teachers attended three workshops designed to acquaint them with the cultural value systems of individualism and collectivism. The teachers completed pre- and postassessments to determine if their problem-solving strategies of home- and

school-based dilemmas (see Raeff et al., 2000) changed as a result of the training. The teachers shifted from a decidedly strong individualistic orientation (independent of ethnicity) to a culturally open perspective that included a mix of individualistic and collectivistic responses (Rothstein-Fisch Trumbull, Quiroz, & Greenfield, 1997).

After the initial training, the teachers met bimonthly along with the researchers to discuss what kinds of changes they were making to their classrooms. They were introduced to ethnographic research methods and were encouraged to become both observers and change agents in their own classrooms. It is important to keep in mind that these changes were always teacher-generated and the researchers were not prescriptive about what changes to make. In addition to these meetings, over a period of 5 years, several classroom observations were made of each teacher and in-depth interviews occurred several times over the course of the project.

Changes in Classroom Management and Assessment

As a result of the training, teachers began using new classroom management strategies (Rothstein-Fisch, Trumbull, & Greenfield, *in press*). Building on their sense of shared responsibility for the group (akin to that of siblings discussed earlier), the students began to control each other's behavior, and very few incidents of poor discipline were ever observed in the classrooms. The teachers allowed students to share resources rather than insisting on personal property (Rothstein-Fisch, Trumbull, Daley, Mercado, & Perez, 2003).

But sharing can be problematic when testing occurs; in a test, helping is called cheating (J. W. M. Whiting & B. B. Whiting, 1994/1973). Therefore, Bridging Cultures teachers created ways to incorporate the cultural tendency for Latino children from immigrant families to want to help and share in the service of test preparation, without compromising individual test taking. In one classroom, children worked together to answer practice test questions, while learning that they would have to take the test individually; in another, they took the test individually but debriefed it in a group. In a third-grade class that was struggling with timed math facts, the teacher brought out a popular motivating device: a star chart to indicate the level of facts mastered by individual students. However, these students were not motivated by individual rewards. They saw the chart as representative

of the whole group, and they decided that the goal was to fill in a whole block of stars. Their idea was to have math buddies to help one another succeed. When it was time for the individual test and a child was successful at the next level of math facts, he or she would ring a bell. This signaled the class to stop and clap for the student who had, through his or her individual achievement, added to the collective class chart (Rothstein-Fisch, Trumbull, Isaac, Daley, & Perez, 2003).

Cross-Cultural Exchange: Parents and Teachers

Drawing from the Bridging Cultures project data, another area of dramatic teacher change centered on teachers' relationship with parents (Trumbull, Rothstein-Fisch, & Hernandez, 2003). These changes revolved around three interrelated themes. First, the teachers increased their psychological proximity to families because of their ability to take parents' perspectives. They also increased their contact through use of a personal and informal style, while still maintaining appropriate roles. Second, the teachers designed new classroom practices that demonstrated their understanding of parents' cultural values; they initiated group parent conferences, successfully increased the number of parent volunteers, and changed their schedules to accommodate family needs. Finally, they explored new roles. As mentioned earlier, they became ethnographers in their own classrooms, allowing them an openness to understanding families; they became more effective advocates for students and families; they explained school culture to parents more explicitly; and they supported parents in taking on new roles at school.

Parents in the Bridging Cultures parent training, described at the end of the section on parent-child relations, also learned to increase harmony with the school. They came to understand teacher behavior better and increased their contact with their children's teachers. The parents in the standard workshops did not increase their contact with their children's teachers.

The standard workshop sessions also resulted in benefits, but these revolved around help with homework and knowledge of school policies. Within the framework of school policies, parents learned about the importance of communicating with school personnel. An example of these two approaches can be seen from the third workshop, when a parent felt disrespected by a teacher. The Bridging Cultures parents viewed the situation through

the lens of cultural differences, resulting in diminished frustration. On the other hand, the standard workshop participants suggested becoming outspoken advocates, talking with the superintendent, writing letters, and even threatening removing the children from the school.

The cultural approach introduces integration and mutual understanding of cultural values into conflict situations, without forcing one side to confront the other. The “standard” approach assumes that everyone holds similar values for child development and that parents should adopt the schools’ methods. In resolving a conflict, the cultural approach completely reconstructs a road of understanding that allows for real reconciliation rather than patching over rough spots. (Chang, 2003, p. 40)

CONCLUSION

Every generalization obscures some things while illuminating others. Cultural variability is no exception. It calls attention to normative cultural patterns at the expense of individual differences. However, individual differences always occur around a culturally defined norm, which also serves as the starting point for historical change. Without knowledge of the norm, individual differences become uninterpretable. In addition, individuation and consequent magnification of individual differences is itself a characteristic of individualistic cultures (Greenfield, 2004). In any case, the primary goal of this chapter has been to contribute to a deeper understanding of culturally variable norms around which individual differences can range. A second goal was to contribute to an understanding of the dynamics of intercultural conflict as these affect development and socialization. A third goal has been to present and evaluate practices and interventions that can alleviate such conflict. Research relevant to the second and third goals is in its infancy. Its social importance provides a motive for much further investigation.

The analysis of cultural variability calls attention to cultures at one point in time, thereby obscuring historical change. We have therefore also tried to show that culture is not static; rather, it is constantly reinventing itself through the addition of new ethnic groups to multicultural societies, through changes in educational practices, through widening effects of the mass media, and through transformations in economy and technology. These sociohistorical changes produce constantly

evolving cultural modes of socialization and human development (Greenfield, 2004; Greenfield, Maynard, et al., 2003; Keller & Lamm, 2005). The dynamics of cultural change and its impact on socialization and development is an area that has been seriously understudied up to now. As cultural change accelerates, it is ripe for research attack.

Cultural History and Multiculturalism

In a diverse society such as the United States, cross-cultural conflict is unavoidable, manifesting itself in interpersonal misunderstandings and altercations. Individuals in every culture must find their own compromise between functioning as an individual and as a member of a group, between independence and interdependence. Some cultures stress one, some the other. Interpersonal differences in this tendency are present in every culture; every culture also has an ideal model of which is more important. Differences in these models and emphases generate cross-cultural differences in many domains of child development. In this chapter, we define domains mainly in terms of socializing influences and social development. They can also be defined in terms of developmental issues, including cognitive development (Greenfield, 2005; Greenfield, Keller, et al., 2003).

Throughout this chapter, cultural models have connected what would otherwise appear to be unrelated cross-cultural differences and, more important, provided an explanation for these differences. The diverse ethnicities that compose the United States and other multicultural societies have their ancestral roots in cultures that have different positions in the cultural complexes of individualism and collectivism. Prior research (Greenfield & Cocking, 1994) has shown that these constructs also generate a historical understanding of the nature of cultural diversity in child development and socialization in diverse societies like the United States.

Although it is clear that such cross-cultural conflicts do exist, it is not enough to simply acknowledge their existence. By educating parents, children, teachers, clinicians, and health care professionals to recognize and deal with cross-cultural difference and conflict, through targeted interventions, children’s social, psychological, and educational needs can be better served. It is hoped that in this increasingly multicultural society, children will learn to prepare for and to appreciate the cultural differences that they will inevitably encounter between

themselves and others. Future research will tell us whether and how this has been accomplished.

One of our main messages for the application of a cultural perspective on human development is the opportunity for cross-cultural exchange in socialization strategies. Cultural differences are a resource for pediatricians, educators, and mental health professionals who work with parents and children. At the same time, there is an important secondary effect of such cross-cultural exchange: No ethnic group feels that they are parenting the "wrong" way; parents from all ethnocultural backgrounds can receive the message that they have something to contribute to the raising of children in a multicultural society. At the same time, the message can go out to members of the dominant culture that, in a changing world, they have much to learn from other cultural modes of socialization and human development. This intercultural learning process is also a ripe domain for future research.

Although fundamentally accepting of wide disparities in economic well-being as an inherent consequence of capitalism, Americans are not inured to economic poverty and its attendant problems. The United States has a long history, dating back to colonial times, of policies, reforms, and interventions ostensibly intended to reduce the incidence and/or ameliorate the human costs of poverty (Demos, 1986; Schlossman, 1976). Most antipoverty efforts have focused on children directly or indirectly through their parents, based on the notion that poverty results from an intergenerational cycle that can best be broken during the victim's childhood (de Lone, 1979). Because of the prevailing ideology among Americans that low motivation, poor choices, and a variety of individual defects are at the core of poverty (Bobo, 2001; Haller, Hollinger, & Raubal, 1990), these efforts primarily have focused on changing poor individuals' putative behavior and characteristics, rather

than altering structural conditions that create poverty and its social ills.

This long-standing pattern notwithstanding, the past 15 years marked a period of policy changes in the United States that increased returns from low-wage work, though they did little to remove structural barriers that disproportionately relegated certain groups to low-wage work in the first place (Greenberg et al., 2002). Most notable is the expansion of the Earned Income Tax Credit (EITC), a provision designed to offset the burden of the Social Security payroll tax, supplement low-wage earnings, and promote work as a viable alternative to welfare (Bos et al., 1999). The EITC helps more families escape poverty than any other government program. In 2002, 4.8 million people, including 2.7 million children, were lifted out of poverty as a result of the additional income provided by the federal EITC. It has also achieved some measure of success in inducing more

single mothers to work (Llobrera & Zahradnik, 2004). Nonetheless, these policy changes have left a significant number of even full-time workers in poverty (U.S. Census Bureau, 2003). In 2002, of 4.9 million poor families with children in which the parents were not elderly or disabled, 66% were families in which at least one parent was working (Llobrera & Zahradnik, 2004). African American and Hispanic individuals, including children, are more likely than their non-Hispanic White counterparts to be poor despite living in full-time working families (Iceland, 1998).

The sharp rise in childhood poverty during the early 1980s and persistently high rates of childhood poverty through the late 1990s generated intense scholarly interest in poor children and families, manifested most strikingly by the publication of numerous edited volumes and special issues of journals devoted to the topic. The issues around which this scholarship coalesced included the effectiveness of various antipoverty programs (Barnett, 1995; Olds & Kitzman, 1993; St. Pierre, Layzer, & Barnes, 1995), the processes that mediate and temper the adverse effects of poverty and economic stress on children's development (e.g., Duncan & Brooks-Gunn, 1997; Huston, Garcia Coll, & McLoyd, 1994; Korbin, 1992), the consequences of the dynamics and context of poverty for children's development (Duncan & Brooks-Gunn, 1997), and the application of research on poor children and families to welfare policy and practice (Danziger & Danziger, 1995). Scholarly interest in these issues remains high (Arnold & Doctoroff, 2003; Bradley & Corwyn, 2002). New to the landscape in recent years is a generation of studies assessing the effects of welfare reform and different welfare and employment policies on child well-being (e.g., Chase-Lansdale et al., 2003; Gennetian et al., 2002, 2004; Gennetian & Miller, 2002; Morris, Bloom, Kemple, & Hendra, 2003; Morris, Huston, Duncan, Crosby, & Bos, 2001). The impetus for these studies was the Personal Responsibility and Work Opportunity Reconciliation Act of 1996, popularly known as PRWORA, and federal waivers granted to states to implement and test welfare reform policies in anticipation of this federal legislation.

The major goal of this chapter is to illuminate the dynamic relation between programs and policies that target poor children and families, on the one hand, and theoretical and empirical work in the field of child development, on the other. The United States is the focal geographic context within which these issues are discussed, but cross-national data are presented to highlight character-

istics distinctive to the United States that shape its antipoverty policies and practices and ultimately affect the economic well-being of its children. Although the centerpiece of this chapter is a discussion of how theoretical and empirical work in the field of child development has influenced policies and programs for poor children, it is important that we underscore two points at the outset to put this discussion in proper perspective.

First, it is our belief that when developmental theory and research have played a role in the formulation of poverty-focused policies and programs, most often it has been a supporting rather than leading role. Political and social forces, not developmental theory and research, typically are the prime movers and wellsprings of social policies and programs directed toward poor children and families. Research often is not a prerequisite and is virtually never a sufficient basis for the formulation and maintenance of such policies and programs. Examples abound of policies directed toward poor families that persisted in the face of strong research evidence that they were not having their desired effect (e.g., Learnfare; Quinn & Magill, 1994). Conversely, in a number of instances, experimental social policies (e.g., negative income tax experiments of the 1960s and early 1970s) shown by research to have salutary effects on poor children's well-being were rejected for universal implementation (Neuback & Roach, 1981; Salkind & Haskins, 1982). Often underlying such divergences between policy decisions and research are ideological and social forces, especially prevailing public sentiments about how the poor should be treated.

In other instances, the enactment of federal policies with the potential to affect massive numbers of poor children has borne remarkably little imprint from child development research and theory. Cases in point are PRWORA and the Family Support Act of 1988, which sought to increase economic self-sufficiency among recipients of Aid to Families with Dependent Children (AFDC) by mandating participation in educational and employment training programs and strengthening enforcement of existing child support provisions. Both laws, like the welfare debate from which they emerged, lacked a clear, consistent focus on children's developmental needs and well-being (Chase-Lansdale & Vinovskis, 1995; Greenberg et al., 2002). Most theories posit structural factors to explain the underutilization of social science research in policymaking (e.g., the political nature of the policymaking process, the paucity of centralized institutions for integrating research-based

knowledge and governmental structures). A more optimistic theory points to communication gaps and limited understanding between social scientists and policymakers, who function in communities that differ in goals, information needs, values, reward systems, and languages. Fortunately, recent years have witnessed growing knowledge and sophistication about effective ways to bridge this gap (Bogenschneider, Olson, Linney, & Mills, 2000).

Delineation of how theoretical and empirical work has sanctioned policies and practices directed toward poor children and families also must be tempered with an appreciation of the often subtle but decided shadows that social and political forces cast on scholarly work itself. The manner in which issues are formulated and, hence, the nature of knowledge generated in the discipline of child development is influenced by sociohistorical context (Riegel, 1972; Wertsch & Youniss, 1987). Scholars in the field of child development, as in any discipline, bring with them predispositions stemming from laws, customs, economic factors, political beliefs, and the prevailing *Zeitgeist*, among other things, that necessarily shape the nature of and conclusions drawn from their research (Youniss, 1990). Their recommendations about courses of action toward children and interventions in the lives of families follow not just from data, but from the interests they bring to their studies. For these reasons, woven into our review of scholarly work that undergirds policies and programs directed toward poor families and children is a discussion of how social and political forces have shaped both of these entities. It represents our attempt to take seriously Youniss's challenge that "an ethically mature development psychology would not deny its debt to social and cultural forces but seek to know them better for itself and the persons it serves" (p. 287).

The chapter is divided into four major sections. We begin with a brief discussion of the official measure of income poverty and its relation to other indicators of economic well-being, such as socioeconomic status. In the second section, we turn our attention to core substantive issues, namely, linkages among theory, research, and programs that seek to reduce poverty and/or its negative effects. Our analysis is limited primarily to three categories of programs that provide an array of educational and social services to poor infants, preschoolers, and/or their parents, specifically early childhood education programs (primarily Head Start and Early Start), parent education and training programs, and pro-

grams that focus on both parent and child and the broader ecology of family life (e.g., two-generation programs). The organizing framework for our discussion is three assumptions on which these categories of programs are premised: (1) that early experience is a critical determinant of the course of development, (2) that parents and the home environment exert primary influence on children's development, and (3) that the broader ecological context of family life impacts parental behavior and, in turn, children's functioning. We review the theoretical and empirical work that prompted and/or sustained these assumptions and provided the intellectual foundation for these antipoverty programs, along with findings from evaluation studies designed to demonstrate the efficacy of these programs. We also consider these programs and their underlying assumptions in light of more recent poverty-focused research. Given the vastness of relevant bodies of research, our review is necessarily selective.

In the third section, we review nonexperimental studies assessing the relation of child functioning to maternal receipt of and transitions off public welfare (AFDC and PRWORA) and studies that used a random assignment design to test the effects of different welfare and employment policies on parental employment, income, family processes, and child well-being. The chapter concludes with a discussion of the implications of extant research for policy and practice. The ideological bases and limitations of existing antipoverty programs are considered in light of social-structural and macroeconomic forces, and suggestions to guide the practices of those working with poor children and families are offered.

CATEGORIES AND DEFINITIONS OF ECONOMIC DEPRIVATION

This chapter encompasses research on multiple categories of economic deprivation, including income poverty, low socioeconomic status, and economic loss. In this section, we discuss how these constructs differ and the potential importance of these differences for children's development and for policy formulation.

Income Poverty

Sound definitions and corresponding measures of poverty are important for a range of "scientific" and po-

litical reasons. They allow comparisons of economic well-being across different groups and across time, identification of individuals, families, and social groups whose most basic needs remain unmet, and assessments of the effects of poverty, policies, and programs on these individuals, families, and social groups (Ruggles, 1990). Most developmental, socialization, intervention, and policy studies relevant to this chapter are concerned with absolute poverty, rather than relative poverty or subjective poverty (see Hagenaars & de Vos, 1988, for a discussion of various definitions of economic poverty).

The most common measure of absolute poverty in these studies is defined by cash income, using the official federal poverty index as a marker. Developed in 1965 by Mollie Orshansky, an economist employed by the Social Security Administration, the federal poverty standard was officially adopted by the government in 1969 during its "War on Poverty" (Haveman, 1987). Cash income was defined as the pretax, posttransfer annual cash income of a family, excluding capital gains or losses. This value was compared with a threshold based on the estimated cost of food multiplied by 3, adjusted to account for economies of scale for larger families and the differing food needs of children under age 18 and adults under and over 65. The estimated cost of food was based on the minimum income a family needed to purchase food delineated in the U.S. Department of Agriculture's (USDA) "thrifty" diet. The food multiplier of 3 was based on a household budget study conducted in 1955 indicating that food typically absorbed about a third of the posttax income of families over a wide range of incomes.

Today, there are well over 100 different poverty thresholds, adjusted annually by the consumer price index so that the purchasing power they represent does not change over time. Hence, they remain close to those calculated with the "thrifty" food plan (Citro & Michael, 1995; Haveman, 1987). Because this index is an absolute dollar amount, not a percent of the median income or a percentile, it is theoretically possible for everyone to be above the poverty threshold.

The official poverty index has several defects and limitations, recognition of which has prompted various corrective efforts in public policy arenas (see McLoyd & Ceballo, 1998, for a discussion). These problems notwithstanding, the official poverty index, or some derivative of it, is widely used in both child-focused research and policy. For example, it has become standard practice among developmental researchers to use

an income-to-needs ratio (calculated as household income/official poverty threshold for household) as an indicator of the degree of poverty or affluence characterizing a household (e.g., Brooks-Gunn, Klebanov, & Liaw, 1995; Gutman, McLoyd, & Toyokawa, 2005; Mistry, Biesanz, Taylor, Burchinal, & Cox, 2004). This ratio tells us how far below or above an individual or family falls relative to the poverty threshold. An income-to-need ratio of 1.0 indicates that a household's income is equal to the poverty threshold, and smaller or larger ratios represent more or less severe poverty (or greater affluence), respectively. Used in this manner, the poverty line becomes a unit of measurement rather than a threshold of need (Hauser & Carr, 1995). An income-to-need ratio has the advantage of being a more sensitive indicator that bears a stronger relation to children's development than does a simple poor/nonpoor dichotomy (Duncan & Brooks-Gunn, 1997). Others define poverty in terms of eligibility for federal or state subsidies to the poor (e.g., reduced-cost or free lunch) or family income cutoffs corresponding to those used to determine eligibility for subsidies.

Low Socioeconomic Status

Another large category of studies pertinent to this chapter focuses on low socioeconomic status (SES) as an indicator of economic deprivation. The term "socioeconomic status" typically is used to signify an individual's, family's, or group's ranking on a hierarchy according to its access to or control over some combination of valued commodities such as wealth, power, and social status (Mueller & Parcel, 1981). Although some dispute exists among social scientists about how SES should be defined or measured, there is considerable agreement that important components of SES include the occupation of the father and/or mother, family income, education, prestige, power, and a certain style of life.

Poverty is not isomorphic with low SES. Unlike SES, poverty is based on an absolute standard or threshold and does not signify relative position. Its marker, cash income, is only one of several components or dimensions of SES and is clearly related to but distinct from occupational status, educational level, prestige, and power. In addition, poverty status is considerably more volatile than SES. During adulthood, income relative to need is more likely to shift markedly from one year to another than SES indicators such as educational attainment and occupational status. Duncan's (1984) examination of

adjacent-year pairs of data from the national, longitudinal Panel Study of Income Dynamics for the period 1969 to 1978 indicated that one-third to one-half of those who were poor in one year were not poor in the next year. One of the important distinctions that emerged from this work is persistent versus transitory poverty (Duncan & Brooks-Gunn, 1997).

These distinctions between poverty and low SES are conceptually important and are viewed as crucial for public-policy discussions (Duncan, Yeung, Brooks-Gunn, & Smith, 1998). Some research has indicated, for example, that poverty and income status have effects on children's development independent of parental education (Duncan & Brooks-Gunn, 1997), although it is not yet known how changes in poverty and income status act synergistically with more stable indicators of SES to influence development (Huston, McLoyd, & Garcia Coll, 1994). Policy analysts regard the SES-income distinction as critical partly on the presumption that it is generally easier to design and implement programs that alter family income (e.g., increasing welfare benefits, tax credits, and minimum wage) than programs that modify family characteristics that mark social class (Duncan et al., 1998).

Also important to bear in mind is that neither poverty as measured by official criteria nor low SES can be assumed to be identical to, or even particularly good proxies for, material hardship. Mayer and Jencks (1988) found, for example, that income-to-needs ratios explained less than a quarter of the variance in householders' reports of material hardship (e.g., spending less for food than the "thrifty" food budget published by the U.S. Department of Agriculture; unmet medical and dental needs; housing problems). This is because poverty and low SES rarely come alone. They often represent a conglomerate of conditions and events that amount to a pervasive rather than a bounded stressor. Scarcity of material resources and services frequently is conjoined to a plethora of undesirable events (e.g., eviction, physical illness, criminal assault) and ongoing conditions (e.g., inadequate housing, poor health care, dangerous neighborhoods, poor diets, environmental toxins) that operate concurrently and often precipitate additional crises (Belle, 1984; Evans, 2004). In short, in the context of limited financial resources, stressors are highly contagious (Makosky, 1982). Traditional measures of poverty and SES, then, may underestimate the direct and indirect effects of material hardship and con-

textual risks on children's development (Ackerman, Brown, & Izard, 2004; Mayer & Jencks, 1988).

Economic Loss

Whereas poverty and low SES are typically conceptualized as ongoing conditions inextricably linked to employment-related factors such as unemployment, underemployment, low wages, and unstable work, another set of studies relevant to our concern here focuses on various events as precipitants of economic deprivation. This research assesses the impact on parents and children of job loss, job demotion, income loss, and economic pressure as experienced by working- and middle-class individuals who characteristically are employed (e.g., Conger, Ge, Elder, Lorenz, & Simons, 1994; Flanagan & Eccles, 1993; McLoyd, 1989, 1990). Although they tend to be overrepresented among poor families, these experiences of economic loss or decline do not necessarily push families into poverty. We review this work to the extent that it helps fill gaps in the poverty literature and, in general, furthers our understanding of the processes by which economic deprivation might influence children's development.

Throughout this chapter, we attempt to maintain distinctions among various categories of economic deprivation, especially poverty and low SES, on the one hand, and economic loss on the other. In our discussion of specific findings, the term is used that most closely approximates the indicator of economic deprivation employed by the researchers. In psychological research published prior to the mid-1980s, the terms "low SES" and "poor" tended to be used interchangeably. Recent research is distinguished by more precise definitions of poverty (e.g., income-to-needs ratios), attention to the multiple dimensions of poverty (e.g., chronicity and contexts of poverty, such as neighborhoods and schools), and a diminution of the tendency to treat poverty as a condition identical to low SES. These conceptual and empirical advances are traceable in large measure to Duncan's (1984) research underscoring the volatility and dynamics of poverty and W. J. Wilson's (1987) seminal analysis of historical changes in the spatial concentration of poverty in inner-city neighborhoods wrought by structural changes in the economy.

The preeminence in research and policy studies of "objective" states of economic deprivation operationalized in terms of the official poverty index, low SES, and

economic loss should not obscure the fact that some of the impact on individuals of economic deprivation and ameliorative policies and practices undoubtedly is subjective. How parents and children perceive and feel about their economic circumstances is driven partly by subjective evaluation of their circumstances in comparison to some reference group. In contexts distinguished by extraordinary affluence and conspicuous consumption, such as the United States, this comparison process can accentuate “feeling poor” among individuals who are poor in an objective sense and can engender “feeling poor” among those who are not (Garbarino, 1992). This subjective state can have direct effects on psychological functioning and mediate as well as moderate the influence of “objective” states of poverty and other forms of economic deprivation (Conger et al., 1994; Garbarino, 1992; McLoyd, Jayaratne, Ceballo, & Borquez, 1994).

BASIC ASSUMPTIONS OF ANTIPOVERTY POLICIES AND PROGRAMS: LINKAGES TO CHILD DEVELOPMENT THEORY AND RESEARCH

Programs that aim to reduce the prevalence of poverty and/or ameliorate the negative effects of poverty on children have informed and been influenced by developmental research, and both have been shaped by common political and social forces. Although a mainstay of these programs is their principal focus on infants and preschoolers, the research that undergirds the programs, and the programs themselves, have grown more complex and sophisticated over time. A historical overview of these programs reveals progressive shifts toward more comprehensive models whose precursors include changing conceptual frameworks and research foci within the field of child development and evidence from evaluation studies of the limitations of previous programs based on more simplistic models.

In this section of the chapter, we consider three major premises that are the bedrock of major antipoverty policies and programs in the United States: (1) that early experience is a critical determinant of the course of development, setting the child on a trajectory toward successful or problematic adaptation; (2) that parents and the home environment exert primary influence on children’s development; and (3) that the broader ecological context of family life impacts parental behavior and,

in turn, children’s functioning. Our primary goal is to illuminate the theoretical and empirical work that gave rise to and/or affirmed these and other guiding assumptions and, hence, helped shape the nature of antipoverty policies and their implementation. Also reviewed are intervention studies that test the efficacy of programs designed to reduce poverty and/or its negative effects. Historical continuities and discontinuities in the nature of policies and programs for the poor are highlighted, with special attention given to antecedents of discontinuities.

Two qualities of research on poor children are reflected in this review. First, basic and intervention research focused on poor children and families are genealogically and conceptually intertwined. Second, issues of race, ethnicity, culture, and racism are prominently and intricately woven throughout the history of research on poor children, because race and poverty are decidedly confounded as a consequence of America’s racial caste system. This confound, however, is not sufficient as an explanation for the fact that the overwhelming majority of basic and intervention studies of poor children focus on African Americans. A few recent studies of the psychological effects, mediators, and moderators of childhood poverty have focused on non-Hispanic White children (e.g., Costello, Compton, Keeler, & Angold, 2003; Evans & English, 2002), but on the whole, these children are scarcely represented in the annals of child development research, despite constituting the plurality of America’s poor children. We speculate about the precursors of this bias and make note of the limitations it poses for the formulation and implementation of national antipoverty policies. More extensive historical accounts of child development research and its relation to practice and social policies directed toward poor children and families can be found elsewhere (Condry, 1983; G. Fein, 1980; Laosa, 1984; Schlossman, 1976; Washington & Bailey, 1995; Weissbourd, 1987; Zigler & Muenchow, 1992).

Early Experience as a Critical Determinant of the Course of Development

The notion that experiences during childhood influence poor children’s ability to meet the expectations of broader, mainstream society and to acquire skills necessary for successful adulthood was implicit in many early policies and practices directed toward the poor. British

colonists, transporting across the Atlantic the attitudes common in England about poverty and its prevention, sought to prevent the development of a pauper class in Boston with the passage of laws mandating parents to provide children with a basic education and marketable skills. Children whose parents did not fulfill these responsibilities, most of whom were indigent, were indentured as servants. The church complemented interventions of the state during the colonial period with efforts to compel parents to rear their children according to religious doctrines and to provide religious instruction to poor children as an antidote to the “temptations of poverty” (Schlossman, 1976).

During the mid- to late nineteenth century, the confluence of industrialization, urbanization, and high rates of immigration sowed urban ghettos populated by the poor and culturally different. Most newcomers of this period were individuals from southern and eastern Europe whose customs, language, and, to a lesser extent, child-rearing practices were unlike those of earlier immigrants from England and western Europe. Plagued by disease, crime, delinquency, and a host of social problems linked to economic exploitation, these urban ghettos were perceived as a threat to the stability of American culture. Large numbers of poor, immigrant women entered the workforce with the new wave of immigration preceding World War I, necessitating out-of-home care of their children. Mainstream, more affluent sectors of the society responded with the introduction into these urban ghettos of three distinct types of interventions: settlement houses, religious missions, and kindergartens. Each was envisioned, in part, as a vehicle of poverty reduction and assimilation of lower-class individuals into mainstream middle-class values, attitudes, and behavior (Braun & Edwards, 1972; Shonkoff & Meisels, 1990). Each had elements of a personal helping strategy that was paradigmatic during the second half of the nineteenth century, namely, “friendly visiting,” in which well-to-do women associated with private relief agencies and charity organizations made home visits to poor families “to provide a mixture of support, scrutiny, and advice” (Halpern, 1988, p. 285).

Settlement houses were established during the late nineteenth century in urban neighborhoods, deemed an “experimental effort” by their most prominent exponent, Jane Addams. Young, college-educated professionals staffed and lived in the houses “not to uplift the masses, but to be neighbors to the poor and restore communications between various parts of society” (Addams, cited

in Weissbord, 1987, p. 44). They “settled and developed services in the neighborhood” (Weissman, cited in Halpern, 1988, p. 286) and aimed to strengthen neighborhood and family life by advocating for and empowering the poor, decreasing ethnic, racial, and cultural conflicts, and increasing understanding among individuals from diverse backgrounds (Weissbord, 1987). Rather than duplicate the services of other family agencies, settlement houses gave priority to linking people with existing services and helping them to utilize them. Settlement workers conducted parent education for immigrant families isolated from traditional sources of child-rearing advice and provided practical assistance with child care, housing, and legal problems. Under the auspices of the settlement movement, nurses also made home visits to care for the sick and to give advice about domestic matters such as child care, diet, and hygiene (Halpern, 1988). Their work and the role of the new social work profession in championing the needs of poor children achieved national attention in the first White House Conference on Children in 1909 (G. Fein, 1980). Many elements of the community work of settlement workers foreshadowed the strategies and goals of today’s parent/family support movement, discussed later in the chapter (Halpern, 1988).

Because missions of Protestant crusaders were largely unsuccessful in modifying the behavior of poor urban adults, attention shifted to young children as instruments of social reform. Subsequent religious missions into poor neighborhoods were intended to “improve the living conditions of families through the lessons the children received in cleanliness, morality, and industriousness” (Ross, 1979, p. 24). The focus on young children continued with the establishment of kindergartens in urban ghettos supported by religious and philanthropic organizations (Braun & Edwards, 1972; Ross, 1979). Espousing the pedagogical philosophy of Froebel, who established the first formal kindergarten classes during the early 1800s in Germany, these kindergartens were grounded in traditional religious values and a belief in the importance of learning through supervised play. However, because of the nature of the social and economic conditions that spawned them, urban kindergartens in the United States sought to satisfy educational and social welfare functions simultaneously. Professional personnel spent mornings as teachers of young children and afternoons as social welfare workers, helping unemployed parents find work, securing health care for children and families, and assisting fam-

ilies in acquiring other needed services. As Braun and Edwards point out, referring to the social welfare functions performed by these employees, "This was the most important contribution of the pioneer kindergartners, as at this period the kindergarten was frequently the only social agency offering a helping hand in the rapidly-increasing slums" (p. 75). This ecologically oriented approach combining educational services to preschoolers and support services to their parents lost ground in the following decades, regaining currency in the late 1970s as interventionists turned their attention to improving the social context of parenthood and children's development (Bronfenbrenner, 1975).

Kindergartens for poor children gave way to nursery schools for middle-class children in the 1930s, which, in turn, served as models for early childhood education programs established in the 1960s to fight poverty. Participation of middle-class families in institutional forms of child care once reserved exclusively for the poor was the result of a confluence of factors operating in the 1930s, including the growing prominence of child development "experts," angst among middle-class parents about their ability to provide a child-rearing environment adequate for positive child development, economic hardship during the Great Depression, pressure on middle-class women to find employment, and the formation of WPA day nurseries (G. Fein, 1980).

Environmentalism as a Cornerstone of Contemporary Antipoverty Programs: The Role of Basic Research

Not until the 1960s was reduction of poverty and its adverse effects formally articulated as federal policy. Initiated by President Lyndon Johnson as a "War on Poverty," this policy and its attendant programs for a "Great Society" were born of a complex configuration of social and political forces operating at the time, including rapid economic growth and the resulting affluence and optimism of Americans, heightened awareness of the high prevalence of poverty in the United States, the struggle for racial equality waged by the civil rights movement, and the emergence of political leaders (i.e., President Johnson, Sargent Shriver) who had notable personal and professional experiences with poor children (Condry, 1983; Laosa, 1984). Educationally oriented early childhood intervention was one of the major categories of antipoverty programs that emerged during this period. Emphasis on "compensatory education" was galvanized by several influential analyses calling attention

to widespread school failure among poor children even in the early years and to the correlation between poverty and low levels of education in the adult population (G. Fein, 1980).

Abundant evidence had accrued prior to the 1960s that lower-class children and children from certain ethnic minority groups performed less well than middle-class White children on indicators of academic achievement and cognitive functioning (e.g., Dreger & Miller, 1960; Shuey, 1958). Performance on IQ tests was elevated to major significance partly because of its significant correlation with school achievement (Deutsch, 1973). Inspired by small-scale, demonstration programs crafted by individual researchers in the early 1960s to study their effects on poor preschool children, for example, S. Gray, Ramsey, and Klaus's Early Training Project, initiated in 1962 (S. Gray, Ramsey, & Klaus, 1983), Head Start was established in 1965 as the first national, publicly funded preschool intervention program (Zigler & Valentine, 1979). Early childhood intervention was premised on a strong environmentalist perspective that called for reducing poverty by equipping poor children with academically relevant cognitive skills during the early years of life, which, in turn, was expected to prevent school failure and, ultimately, low employability, poverty, and economic deprivation. In effect, inadequate cognitive skills were seen as a proximal cause and, therefore, the locus for the prevention of poverty.

This marked a major shift toward environmental, rather than genetic, factors as the prevailing explanation for social class and race differences in academic and cognitive performance and the related notion that intelligence is not fixed (Laosa, 1984). In addition, the optimal time for remediation of these presumed cognitive deficits was thought to be the preschool years. Although attempts at social reforms had historically focused on young children partly because they were perceived to be more malleable than adults, the 1960s marked the transformation of this notion into a "scientific" tenet that undergirded antipoverty policies and programs. It is well-known that these core assumptions on which Head Start was based derived principally from two authoritative books, Hunt's (1961) *Intelligence and Experience* and B. S. Bloom's (1964) *Stability and Change in Human Characteristics* (Zigler & Valentine, 1979).

The notion that early childhood is the critical period for the development of skills required for academic success came under attack in later years as it became clear that early intervention did not inoculate children

against continuing economic disadvantage. Critics argued that because development is continuous, a series of dovetailed programs appropriate for each major stage of development would have more beneficial effects on poor children's development than intervention limited to the preschool years (Zigler & Berman, 1983). Nonetheless, bolstered by research showing positive effects of early education intervention, belief in the singularly potent influence of early experience held sway. Testament to this is the establishment of Early Head Start in 1994 for poor children ages 1 to 3 and the fact that current intervention programs for the poor overwhelmingly focus on infants and preschoolers and/or their parents (Administration for Children and Families [ACF], 2004a). Recent research indicating that early childhood is a period of elevated vulnerability to the impact of poverty (Duncan & Brooks-Gunn, 1997) and growing evidence about the significance of early experience in brain development (Shore, 1997) make the case stronger than ever for enhancing poor children's learning experiences during early childhood (C. T. Ramey & Ramey, 1998).

Cultural Deprivation as a Corollary Premise. The establishment of preschool intervention was also premised on the assumption that the early experiences of poor children are inadequate as a foundation for academic success and upward economic mobility. Recognition of the etiological significance of environment in children's development stimulated a proliferation of studies documenting SES differences in an ever-widening range of cognitive and social variables presumably related to later academic functioning (e.g., Coleman et al., 1966; Deutsch, 1973; Hess & Shipman, 1965). Collectively, these efforts served to build a case for preschool intervention by claiming that poor children were suffering deficiencies that forecast academic failure and, hence, needed remediation (Laosa, 1984). Implicitly contrasting *cultural* with *genetic* to underscore the environment as a determinant of behavior seen as inferior and undesirable (Condry, 1983), poor children were labeled "culturally deprived" and disparities in their behavior as compared to middle-class children were termed "cultural deficits" (e.g., Bernstein, 1961; Hess & Shipman, 1965).

This terminology is a derivative of the "culture of poverty" concept elaborated by Oscar Lewis (1966). Lewis attributed to poor people living in the ghettos of Latin America many of the psychological characteristics

and behaviors that were later conceived as precursors of school failure. Researchers and scholars concerned with the psychological impact of environmental disadvantage during the 1960s borrowed generously from Lewis's writings, applying his culture of poverty notion most consistently and forcefully to inner-city African Americans, although the majority of America's poor were White and lived in rural areas (Condry, 1983). Attempting to explain this peculiarity, J. Patterson (1981, p. 120) noted, referring to poor, inner-city African Americans, "Their comparative visibility, their geographic concentration, and their color made cultural interpretations of poverty more plausible than they might otherwise have been."

Preschool intervention programs established during the 1960s and 1970s, including Head Start and its educational forebearers (e.g., S. Gray & Klaus, 1965), bore the stamp of the cultural deficiency model and drew sustenance from empirical studies conducted under this banner (Laosa, 1984; Zigler & Berman, 1983). Intervention programs of this period varied greatly in terms of their guiding assumptions, curricula, and structure. This diversity aside, common to these programs was the assumption that poor children were suffering deficits that needed remediation by professionals during the preschool years (Laosa, 1984).

Cultural Difference as an Alternative Perspective. By the early to mid-1970s, the concept of cultural deprivation and its companion studies and programs were under scathing attack. They were criticized as perniciously ethnocentric on the grounds that they exalted White middle-class norms as the standard of health, ignored the vast range of intellectual and social competencies possessed by poor children, and blamed poverty on individual characteristics while ignoring social structural contributors to economic deprivation (e.g., Baratz & Baratz, 1970; Cole & Bruner, 1971; Ginsburg, 1972; Sroufe, 1970; Tulkin, 1972). The most vehement and prodigious criticisms were reserved for the notion that poor, African American children are impoverished in their means of verbal expression and that nonstandard vernacular impedes complex abstract thought (Labov, 1970).

This academic discourse, in concert with forces in preschool intervention programs (e.g., parent involvement), played a role in attenuating the pejorative view of the poor that prevailed in preschool intervention programs and shifting priorities to building on the

strengths and cultural experiences that poor children brought to the programs (Zigler, 1985). As we discuss later, criticism of the deficit model eventually tempered the focus on personal behavior as a target of blame. It helped forge a more ecological approach to early childhood intervention, distinguished by a focus on improving the context of child rearing and child development by reducing stressors and increasing social supports (D. Powell, 1988). Nonetheless, the extent to which Head Start and other preschool intervention programs have fully divested themselves of practices rooted in notions of cultural inferiority is still a matter of some debate.

Resilience of Early Intervention as an Antipoverty Policy: The Significance of Evaluation Research

Providing experiences during early life that are presumed to be intellectually stimulating and enriching remains a major cornerstone of antipoverty policies and programs directed toward poor children, although considerable diversity exists in the implementation of this goal (e.g., provision of services directly to parent versus child; home visitation versus center-based education). Head Start is the largest and most enduring exemplar of this antipoverty strategy. It stands as the model for other public, large-scale, non-Head Start preschool education programs established under the auspices of Title I (Chapter I) of the Elementary and Secondary Education Act (Reynolds, 1994, 1995). A multifaceted program that has served more than 22 million children and their families since 1965, Head Start offers a wide range of services that include early childhood education, health screening and referral, mental health services, nutrition education, family support services, and opportunities for parent involvement (ACF, 2004b, 2005b). Head Start programs must adhere to national performance standards but are permitted to adapt components, including the preschool education curriculum, to local needs and resources. Consequently, considerable variation exists among Head Start programs (Zigler & Styfco, 2003).

Currently, Head Start's basic educational component is a center-based preschool program serving children ages 3 to 5. In 2003, the majority (53%) of these children were 4 years old, followed by a large proportion (34%) of 3-year-olds (ACF, 2004b). Head Start serves about 70% of all eligible 4-year-olds but only about 40% of all eligible 3-year-olds (Haskins & Sawhill, 2003). Head Start preschools have an adult:child ratio that

ranges from 1:8 to 1:10 and are gradually shifting away from half-day sessions (U.S. General Accounting Office, 2003), given increased demand due to parents' work schedules. In fact, as of 2003, 54% of Head Start children were served in full-day programs for at least 6 hours daily (Hart & Schumacher, 2004). Most of these programs, however, operate on a 9-month schedule and are not open on weekends. Less than a third of Head Start children (28%) are served for more than 1 year, with most receiving only 1 year or no post-preschool services (Schumacher & Rakpraja, 2003).

In fiscal year 2003, there were 1,670 Head Start grantees (19,200 centers and over 47,000 classrooms) serving more than 909,600 children and their families. Of these children, 31.5% were African American, 28% were Anglo, 31% were Latino, 3% were Native American, and 3% were Asian and Pacific Islander (ACF, 2004b). Federal guidelines require that at least 90% of children enrolled in Head Start programs come from families with incomes at or below the official poverty line and that at least 10% of enrollment consist of children with disabilities. In 2003, nearly three-quarters of families had incomes less than 100% of the federal poverty line, and 21% received Temporary Assistance for Needy Families benefits. Most participating families were single-parent families (56%), and 13% of children had disabilities (Hart & Schumacher, 2004). Head Start receives 80% of its funding from the federal government, with the remaining 20% coming from other sources, usually local, in the form of funds or services (Zigler & Styfco, 2003). Federal expenditures for Head Start have increased by 33% since 1994 and now stand at \$4.66 billion, although a considerable portion of this budget is devoted to evaluation efforts (Reynolds, Wang, & Walberg, 2003).

Evaluations of Head Start's Efficacy. Major landmarks in the evaluation of Head Start include the Westinghouse evaluation (Westinghouse Learning Corporation, 1969), a highly controversial undertaking, followed by the Head Start Evaluation, Synthesis, and Utilization Project, commonly known as the "Synthesis Project" (McKey et al., 1985), the Educational Testing Service (ETS) Head Start Longitudinal Study (Lee, Brooks-Gunn, Schnur, & Liaw, 1990; Schnur, Brooks-Gunn, & Shipman, 1992), and, most recently, the National Head Start Impact Study (ACF, 2005a) mandated by Congress in 1998, when it reauthorized the Head Start program.

Nonexperimental Evaluations. The history of Head Start evaluation is a troubled and contentious one, owing in large measure to the high economic and political stakes attached to the evaluation findings, juxtaposed with the serious methodological problems that have plagued these evaluations (see McLoyd, 1998, for a more detailed discussion of Head Start evaluations). Excluding the National Head Start Impact Study (ACF, 2005a) initiated in 2001, Head Start evaluations have been legitimately criticized for undue focus on cognitive indicators to the neglect of other outcomes that Head Start was designed to improve, nonrepresentativeness of samples, lack of attention to the quality and type of Head Start program in the research design, and lack of systematic attention to moderating and mediating processes.

But the factor that has engendered most consternation is potential selection bias stemming from the non-experimental research designs of these evaluations. Random assignment is the preferred method of evaluation of program effects because it increases confidence that estimated effects are due to program differences rather than to preexisting differences between comparison groups. Until the National Head Start Impact Study (ACF, 2005a), lack of random assignment to treatment and control groups was a major methodological weakness of all evaluations of large-scale preschool programs, including Head Start (Barnett, 1995). Enrollment in basic Head Start programs has never been under experimental control for political reasons, including the fact that the program was instituted on a national, full-scale level rather than as an experimental pilot program. As a consequence, it theoretically was and continues to be open to all poor children (Condry & Lazar, 1982).

With random assignment precluded as an option, researchers conducting evaluation studies of Head Start and other large-scale preschool programs have typically attempted to match treatment and control group children on various familial and demographic characteristics. Strategies include drawing controls from the same neighborhood or elementary school classes attended by enrollees of the program, selecting children from waiting lists comprising those who are eligible but not enrolled in the program, and/or using statistical techniques to control for initial differences. Although preferable to having no comparison group, matching of groups is problematic because it is virtually impossible to rule out the possibility that differences observed between groups of children simply reflect differences that were present prior to the intervention, rather than differ-

ences resulting from the intervention (Barnett, 1995). Indeed, the ETS Head Start Longitudinal Study compellingly demonstrated selection bias in Head Start enrollment, vindicating critics who believed that failure to control for preintervention differences between Head Start and comparison groups posed a significant threat to the validity of several evaluations of Head Start (Schnur et al., 1992).

The ETS study began with the collection of data from children in the spring prior to their possible entry into Head Start, permitting an assessment of preexisting differences between children who enrolled in Head Start and children who were eligible (i.e., poor), but either did not enroll in Head Start or enrolled in a non-Head Start preschool. Preintervention data indicated that children who subsequently enrolled in Head Start were more disadvantaged than their impoverished counterparts. Children destined for Head Start programs, compared to poor children who attended a non-Head Start preschool or attended no preschool, had mothers with fewer years of schooling, were more likely to live in families in which the father was absent, and lived in more crowded homes, even after controlling for race. Mothers of Head Start attendees had lower expectations for their children's achievement, compared to mothers of children who ultimately attended other preschools. Furthermore, prospective Head Start attendees performed less well on measures of cognitive functioning (administered before entry to preschool) than children who ultimately attended other preschool programs, but were similar to children who attended no preschool after controlling for race, site, and family characteristics.

These findings were consonant with long-standing anecdotal evidence that local Head Start staff, faced with an inability to offer Head Start to all eligible children because of limited funds, tend to select the most disadvantaged children for participation in the program (Haskins, 1989). The findings urge strong caution against ignoring the heterogeneity of the poverty population and suggest that "reports of postintervention differences in evaluations of programs like Head Start that lack initial status information, or that use matching techniques, almost certainly have underestimated the efficacy of the preschool intervention experience" (Schnur et al., 1992, p. 416).

Nonexperimental evaluation studies (using both between-group treatment/no treatment designs, and pre-post intragroup longitudinal designs) tend to find positive effects of Head Start on school readiness, reading and mathematics achievement, and social behavior (con-

trolling for background demographic factors). But even with these gains, Head Start children still score below national norms, below children who did not attend Head Start, and below more economically advantaged children. These gains, though educationally meaningful (e.g., effect sizes of approximately .25 or greater, a convention established on the basis of evidence that differences of this size accompany discernible improvement in classroom performance; Cohen & Cohen, 1983), usually fade during the early grade school years (Lee, Brooks-Gunn, & Schnur, 1988; McKey et al., 1985). However, more fine-grained analyses indicate that fade-out did not occur in a number of samples (Barnett, 1995; Zigler & Styfco, 2003). There is also evidence that African American children are more likely than White children to experience significant gains from attending Head Start and that preschool experience, whether Head Start or non-Head Start, boosts their cognitive and analytic functioning, although not to the level of nonpoor children or to parity with national norms (Lee et al., 1988, 1990; McKey et al., 1985).

In 1997, Head Start launched the Family and Child Experiences Survey (FACES), a study of a national random sample of Head Start programs designed to answer questions about child outcomes and program quality. There is no non-Head Start comparison group in FACES, but the use of assessment measures with national norms permits comparisons between the skills of children in the sample and children of the same ages in the norming samples (Zill, Resnick, Kim, O'Donnell, & Sorongon, 2003). Findings from the year 2000 cohort of FACES (2,800 3- and 4-year-old children and their families in 43 different Head Start programs across the United States) mirror those from studies comparing Head Start children to non-Head Start children recruited for the investigation. On average, children entered Head Start with literacy and math skills substantially below national averages. The gap narrowed during the Head Start year, especially with respect to vocabulary knowledge and early writing skills, but despite these gains, Head Start children still fell below national averages when they exited the program. Children who entered Head Start with lower levels of knowledge and skill showed larger gains. Teacher reports indicate that children also showed growth in social skills and declines in hyperactive behavior during the Head Start year (Zill et al., 2003). This study also highlights parental characteristics (e.g., depression) and behavior (engagement in literacy activities at home, involvement in child's schooling) in relation to children's cognitive and socioemotional

functioning, providing clues about factors that may moderate and mediate Head Start effects.

An Experimental Test of Efficacy: National Head Start Impact Study. In 1998, led largely by the U.S. General Accounting Office's concerns about the lack of a rigorous evaluation of Head Start's effectiveness, Congress mandated a national analysis by the Department of Health and Human Services (DHHS) of the impact of Head Start on the families and children the program serves. The evaluation was guided by two principle questions: "What difference does Head Start make to key outcomes of development and learning for low-income children?" and "Under what conditions does Head Start work best and for which children?" (ACF, 2005a).

Aspects of the study design and framework were developed under the direction of an Advisory Committee on Head Start Research and Evaluation chartered by the DHHS secretary. The study design addresses several problems that compromised prior evaluations of Head Start (ACF, 2005a). First, the study used an experimental design with randomized comparison groups (children were randomly assigned to either a group receiving Head Start services or to a control group not receiving program services). Second, sites were selected to maximize representativeness in terms of the range of Head Start characteristics nationwide (i.e., region of the country, race/ethnicity/language, depth of poverty, program length, program options). Sites in heavily saturated Head Start communities, as well as those not complying with Head Start standards or that were new, were excluded from the framework. A multistage sample selection process was completed to select participating Head Start grantee/delegate agencies and children and to maximize similarity in the probability of selection for each (see ACF, 2005a, for specific details of this process). The study was designed to generalize findings to the national program, but the sample overrepresented larger programs and Hispanic/Spanish-speaking children as compared to the national Head Start population (ACF, 2005a). Children (and their parents) will be followed longitudinally through the spring of the first grade year (i.e., 2006; ACF, 2005a).

The evaluation was initiated after refining the full-scale study design through a pilot study. Beginning in fall 2002, data were collected on 2,559 first-time enrolled 3-year-olds and 2,108 newly entering 4-year-olds from 84 nationally representative grantee/delegate agencies and 383 Head Start centers across the United States. Head Start was found to have small to moderate

positive effects on several indicators of child functioning after 1 year of participation in the program, with more positive impacts found among 3-year-olds than 4-year-olds. For both age groups, Head Start positively impacted children's pre-reading and pre-writing skills (based on direct assessments), and their literacy skills (parent report), but had no effect on children's oral comprehension, phonological awareness, or early mathematics skills. Positive impacts on 3-year-olds' vocabulary knowledge were also found. Within the socio-emotional domain, Head Start had no effect on children's social skills, approaches to learning, or social competencies, but it lowered the incidence of parent-reported problem behaviors and hyperactive behavior among 3-year-olds. Finally, among both age groups, Head Start had positive effects on children's access to health care (parent-reported), though positive effects on children's health status (parent-reported) were found only for 3-year-olds. Although the impacts were small to moderate they are nonetheless encouraging when put in context. Families that applied to Head Start but were not accepted were more likely than other low-income families to seek center-based care for their children, highlighting the importance a random-assignment design. Center-based arrangements were the principal form of child care for control families, which means that the Head Start group is being compared to a control group with center-based child care experiences, rather than a "no services" group (ACF, 2005a).

Evaluations of the Efficacy of Model Programs. To the extent that research played a role in the survival of Head Start and other large-scale, publicly funded non-Head Start preschool education programs during the late 1970s and 1980s, major credit goes to research evaluations of small-scale model programs rather than to efficacy studies of Head Start that existed during this period. This is because many of the evaluations of small-scale model intervention programs had methodological advantages that made the evidence they yielded more persuasive, among them random assignment, long follow-ups, and relatively low attrition rates (Barnett, 1995; Consortium for Longitudinal Studies, 1983; Haskins, 1989; Zigler & Styfco, 1994b). In the face of growing threats to downsize and eliminate Head Start due to changing government priorities and the disappointing findings of previous evaluations, the Consortium for Longitudinal Studies was formed in 1975. The Consortium consisted of 11 independent researchers

(and their collaborators) who had initiated model preschool intervention programs for poor children between 1962 and 1972; its expressed purpose was to provide a more definitive answer to the question of whether early education programs were effective in preventing school failure among poor children (Condry, 1983).

As a group, model programs in the Consortium, as well as those not represented in the Consortium (e.g., Carolina Abecedarian Project) were very diverse, varying in terms of curriculum, ages and number of children served, length, and years of operation, among other dimensions. For example, age of entry into these programs ranged from the prenatal and early infancy period to approximately 4 years, with most programs enrolling children between ages 3 and 4. A few were home-based, but the vast majority were center-based with frequent to occasional home visits. Program length during the preschool period varied from about 2 years to 5 years. The curriculum was also highly diversified and based on a range of child development and pedagogical models (e.g., Bank Street, Montessorian, Piagetian, Bereiter-Englemann), but most were primarily cognitive in orientation. The majority of model programs operated during the 1960s and had run their course by the early 1970s (Barnett, 1995; Consortium for Longitudinal Studies, 1983).

The methodological advantages of evaluation studies of model programs noted earlier rendered them more rigorous and sound as tests of the effects of early education intervention. Nonetheless, because model programs typically have lower child-staff ratios, smaller group size, and more highly trained staff than large-scale, public programs such as Head Start, scholars cautioned against assuming that the documented effects of model programs would be produced by ordinary, large-scale preschool programs (Haskins, 1989). Additionally, given the greater comparative demands placed on Head Start programs, as well as growing changes in the Head Start population (e.g., diverse language backgrounds; increased growth in immigrant children; parents who are more likely to be younger, single, and unemployed; new demands experienced due to welfare reform), it is unclear whether comparisons between Head Start and model programs is fair or reasonable (Zigler & Styfco, 2004a).

At the same time, however, studies of large-scale and model programs are best seen as complementary, with both providing unique and important information needed to guide policy formulation and service deliv-

ery. Studies of model programs are often weak on generalizability but strong on internal validity, documenting the effects that can accrue from early childhood education programs implemented under relatively ideal circumstances (Haskins, 1989; Schweinhart, Barnes, & Weikart, 1993). Studies of large-scale programs, on the other hand, are often strong on generalizability in that they provide a close approximation of what effects can be expected to be produced by ordinary, universally available preschool programs. However, they tend to be weak on internal validity (e.g., control of selection bias, uniformity of treatment implementation and test administration, confounding of preschool with other program variations experienced by children after the preschool years).

Consortium for Longitudinal Studies: Pooled Analyses. The 11 research groups composing the Consortium for Longitudinal Studies developed a common protocol for the collection of follow-up data from children in their original treatment and control groups (94% of the original samples were African American children), relocated their samples, collected common data, and submitted the data to an independent group for joint analyses. The studies of programs in the Consortium essentially represented independent tests of the hypothesis that early education has positive effects on poor children's development, the value of which is that chance findings tend to cancel each other out. Common findings across projects increase confidence that effects are reliable (Condry, 1983).

Results from the 11 projects were pooled, in accordance with an elaborate, stringent plan of analysis to identify robust effects (Royce, Darlington, & Murray, 1983; see McLoyd, 1998, for further details about this plan of analysis). The pattern of results from the pooled analyses indicated that (a) children in the programs, compared to those in the control groups, had higher levels of mathematics and reading achievements in the early grades, but these differences disappeared in the later grades, and (b) program participants had lower rates of grade retention and/or placement in special education and were more likely to complete high school than were controls. Data from individual projects suggested that positive effects on school progress were mediated through increased IQ scores at age 6 and through several noncognitive variables such as children's self-esteem, classroom behaviors, and attitudes toward teachers, and mothers' parenting skills, expectations for

their children, self-confidence, and ability to work effectively with teachers and other professionals. However, too few projects measured these hypothetical intervening variables to permit rigorous tests of mediation across studies. Analyses appeared to rule out some competing interpretations of noncognitive pathways, among them, that teachers in public schools may have been more reluctant to place children in special education classes who were known to have attended preschool. If this process operated, they argued, the difference between program and control groups should have been greatest after grade 1 or 2 and to decline thereafter. To the contrary, the difference between the two groups increased as children progressed through the grades and, indeed, did not become statistically significant until grade 7.

The Consortium's success in stoking policymakers' enthusiasm for early childhood intervention and ensuring continued and incremental funding of Head Start has been attributed to three factors: (1) positive and robust findings that concerned specific outcomes the interventions were intended to influence and whose importance and validity were easily understood (e.g., placement in special education classes, grade retention, high school graduation, rather than IQ); (2) cost-benefit analyses of one of the Consortium member studies, the Perry Preschool Project, demonstrating a significant return on the original investment of public dollars (Weber, Foster, & Weikart, 1978); and (3) rapid, broad dissemination of the findings to policymakers. The Consortium's findings were disseminated in policy circles as early as 1977 but did not appear in academic publications until the 1980s (Consortium for Longitudinal Studies, 1983; Darlington, Royce, Snipper, Murray, & Lazar, 1980). Further buttressing Head Start's favored status was additional evidence of long-term positive effects of non-Consortium model programs (e.g., Carolina Abecedarian Project) released after the Consortium's major reports. In the following sections, we highlight program features and findings from two highly prominent model programs whose long-term effects are especially impressive.

Perry Preschool Project. Conducted in Ypsilanti, Michigan, between 1962 and 1967, the Perry Preschool Project (Berrueta-Clement, Schweinhart, Barnett, Epstein, & Weikart, 1984; Schweinhart et al., 1993) is perhaps the most prominent of the model projects and was part of the Consortium. Children who participated in

the program have been followed through ages 39 to 41, the longest follow-up of any early childhood education program. Overall attrition rates for the study are quite low, with only 5% of cases missing across waves (Schweinhart, 2003).

Researchers identified potential participants from a census of the families of students attending the Perry Elementary School in Ypsilanti, referrals by neighborhood groups, and door-to-door canvassing. The sample consisted of 123 low SES families (58 randomly assigned to the treatment group and 65 to the control group) whose children had IQ scores between 70 and 85 but who showed no evidence of organic handicap. All of the families were African American and about half were mother-headed and receiving welfare. Forty percent of parents were unemployed and only 21% of mothers and 11% of fathers had completed high school.

Children entered the program at ages 3 and 4. Those in the treatment group attended 2.5 hour center-based classes five mornings a week from October to May, most (78%) for a period of 2 years. Teacher-child ratio was 1:5–6. The curriculum was guided by Piagetian theory and emphasized children as active learners. Interactions with children were built around a set of active learning key experiences (e.g., creative representation, language, social relations, movement). Teachers made a weekly home visit during the afternoon (with both mother and child present) lasting 90 minutes to involve the mother in the educational process, to enable the mother to provide her child with educational support, and to implement aspects of the center's curriculum in the child's home. Supportive social services such as assistance with housing and nutritional services were not provided.

Evidence from the 14-, 19-, and 27-year-old follow-ups indicated benefits for children's educational performance, with program children having higher literacy and school achievement scores at ages 19 and 14, respectively, and higher educational attainment at age 27 than control children (71% versus 54% completed high school). The strongest effects were found in the areas of economic well-being and crime prevention. At age 27, compared to their control counterparts, (a) program adults had higher earnings (7% versus 29%, respectively, earning more than \$2,000 monthly); (b) program males had better-paying jobs (6% versus 42% earning \$2,000 or more monthly); (c) program females had higher employment rates (55% versus 80%); (d) program adults had received less public welfare as adults,

as indicated by public welfare records and self-reports, although the magnitude of these reductions depended on gender and the time period in question; (e) program participants averaged 2.3 fewer arrests for criminal activity; (f) program males had been married twice as long; and (g) program females were more likely to be married and to have fewer out-of-wedlock births. Effects on economic well-being are less clear in data collected at ages 39 to 41. That is, it is not certain whether these effects lasted into midlife. However, effects on violent crime reduction and time spent in prison were maintained (Schweinhart, 2003, 2004). Cost-benefit analyses of the program indicate significant public benefits per participant (e.g., at the age-27 follow-up, \$7.16 benefits for every \$1 invested). In short, the intervention was an extremely sound economic investment (Barnett & Escobar, 1987; Schweinhart, 2003).

Carolina Abecedarian Project. This project is the most recent vintage of early education model programs and, unlike the Perry Preschool Project, was not part of the Consortium. This center-based program operated between 1972 and 1985 in Chapel Hill, North Carolina (Campbell & Ramey, 1994, 1995; Campbell, Ramey, Pungello, Sparling, & Miller-Johnson, 2002). The program recruited poor families nominated by social welfare departments and prenatal clinics, most of which were African American (98%) and headed by an unmarried mother (mean age = 20 years, with a range from 13 to 44 years; mean IQ = 85) who had not graduated from high school at the time of the child's birth. Fifty-five families were randomly assigned to the experimental group and 54 to the control group.

Children entered the program at 4 months of age, on average, and remained until they entered public kindergarten at age 5. The center operated 8 hours a day, 5 days per week, 50 weeks per year. The caregiver-to-infant ratio was 1:3. Caregiver to child ratios gradually increased to 1:6 as children moved from the nursery into toddler and preschool groupings. The curriculum for infants emphasized cognitive, language, perceptual-motor development, and social and self-help skills. In the later preschool years, emphasis was placed on language development (pragmatic features rather than syntax) and pre-literacy skills. Parents served on the center's advisory board and were offered a series of voluntary classes covering such topics as family nutrition, legal matters, behavior management, and toy making. Supportive social

services were available to families to help solve problems related to housing, food, and transportation.

Cognitive and academic benefits of the Abecedarian program were stronger than those of most other early childhood programs, a fact attributed to the high intensity of the program (full-day, year-round beginning in early infancy) and its long duration (5 years; Campbell et al., 2002). The most recent follow-up (104 of the original 111 individuals) assessed effects on 21-year-olds (Campbell et al., 2002). Findings indicated a long-lasting effect on cognitive outcomes. Program children had significantly higher cognitive test scores from the toddler years to age 21. In addition, their reading and math achievement scores were significantly higher from the primary grades through early adulthood. Compared to control children, program children completed more years of education (14% versus 35%, respectively, attending or graduated from a 4-year college at age 21), had higher employment rates in young adulthood (50% versus 65% employed), and delayed parenthood longer (17.7 versus 19.1 years of age at birth of first child). Twenty-six percent of those in the program group had children as teenagers, compared to 45% in the control group (Campbell et al., 2002). Few studies of model programs have found effects on adolescent parenthood, although there is fairly strong evidence that preschool intervention increases the likelihood that adolescent mothers will complete high school, mediated partly by reducing the likelihood of grade retention and placement in special education (Schweinhart et al., 1993). Unlike findings from the Perry Preschool Project, there were no significant effects on crime prevention in early adulthood, but significant reductions in drug use and smoking were found (Campbell et al., 2002; Schweinhart, 2003). A recent cost-benefit analysis of the Abecedarian program by researchers at the National Institute of Early Education Research indicates significant returns on taxpayer investments (\$4 benefits for every \$1 invested; Masse & Barnett, 2002).

Although we have highlighted findings from model programs, it is noteworthy that long-term effects have also been found for the Chicago Child-Parent Center (CPC) program, a large-scale, public, center-based preschool and school-based intervention for low-income children in Chicago, although the evaluation did not use a random assignment design. A 15-year follow-up indicated that children who participated in the pre-

school intervention had a higher rate of high school completion and lower rates of juvenile arrest, violent arrests, and school dropout, relative to children in the comparison group who participated in alternative early childhood programs (full-day kindergarten). In addition, both preschool and school-age participation were significantly associated with lower rates of grade retention and special education services. These findings are among the strongest evidence to date that large-scale education interventions similar to Head Start and administered through public schools can promote children's long-term success (Reynolds, Temple, Robertson, & Mann, 2001).

Early Head Start. Some of the model programs with the largest or most enduring positive effects began educational intervention earlier in development (i.e., during the first 2 years of life) and continued at least until children entered kindergarten (Campbell & Ramey, 1994; Consortium for Longitudinal Studies, 1983; C. T. Ramey & Ramey, 1998). These findings helped pave the way for the establishment in 1994 of Early Head Start, an intervention for low-income infants and toddlers up to age 3 and their families. The most recent, large-scale, and publicly funded early childhood education program, Early Head Start seeks to enhance children's development and health with a palette of coordinated services, including child care, child development services delivered via home visits, parenting education, health care and referrals, and family support. Depending on community needs, programs provide services via three approaches: center-based, home-based, or a mixed approach. Currently, the program operates in 700 communities and serves more than 60,000 low-income children. It has increasingly received a greater share of the Head Start budget, with its budget for 2003 standing at \$654 million (ACF, 2004a).

When it established Early Head Start in 1994 as part of the Head Start reauthorization legislation, Congress mandated an early evaluation of the new program across sites. The national evaluation, known as the National Early Head Start Research and Evaluation Project, was guided by two overarching goals: to understand the extent to which the Early Head Start intervention was effective for low-income children and families and to understand the specific programs and services that were effective for families and children with different

demographic characteristics and served by programs with diverse characteristics. In short, the evaluation moves beyond the simple question of "What works?" and instead focuses on "What works for whom and under what conditions?"

Beginning in 1995, the evaluation project was carried out in 17 sites selected to represent the Early Head Start programs funded during the first two cycles of the program. Sites were spread across the country, in both urban and rural areas, and initially the research programs were equally divided among center-based, home-based, and mixed approach settings. However, over the course of the evaluation term, the proportion of program approaches changed. A total of 3,001 families across the 17 sites were randomly assigned to participate in Early Head Start ($n = 1,513$) or the control group ($n = 1,488$), yielding groups equivalent on a number of demographic characteristics. Children and families were followed from the time they entered the program until the child was age 3, with assessments done at ages 14, 24, and 36 months.

Findings revealed a number of positive impacts of the program, even though a substantial number of families did not participate for the full eligibility period or at recommended levels. At 36 months, program children, compared to control children, scored higher on standardized measures of cognitive and language development, engaged their parents more, and were less aggressive, less negative toward their parents, and more attentive to objects during play (ACF, 2002). Effects also extended to parental behavior. Compared to control parents, Early Head Start parents provided more stimulating home environments and more support for language and learning. In addition to being more emotionally supportive of the child (observed), they were more likely to read to the children daily and less likely to use physical punishment (self-report). The program also had positive effects on parents' self-sufficiency and on father-child interactions. Program impacts were larger for African American families than White families, families that enrolled during pregnancy, families with a moderate number of risk factors, mixed-approach programs, and programs that achieved full implementation earlier (ACF, 2002). Data collection for a follow-up of children (and families) at entry to kindergarten was recently completed, though at the time of this writing, findings were not available.

Assessing Head Start Policy and Models in Light of Evaluation Findings

It is clear that Head Start is not so potent as to boost enrollees' school readiness and academic competence to the level of nonpoor children, or to parity with national norms. However, findings from the National Head Start Impact Study (ACF, 2005a) bolster confidence that Head Start enhances children's early literacy skills and certain domains of socioemotional functioning and lend support to the claim that the magnitude of Head Start's impact as assessed in nonexperimental studies has been underestimated due to selection bias. This argues in favor of continuing federal support for Head Start, but the argument for seeking ways to improve Head Start's efficacy is equally strong. Head Start quality has been observed to be consistently good over time, as indicated by child-adult ratio, teacher-child interactions, and classroom activities and materials (Zill et al., 2003). Nonetheless, the findings from the FACES 2000 (Zill et al., 2003) assessment of children's functioning when they exited Head Start are clearly regarded among some government officials as disappointing and grounds for substantive changes within Head Start (U.S. Department of Health and Human Services, 2003).

Head Start's basic model has remained largely intact, and until recently, this adherence seemed justified because numerous researchers had looked for, but not found, strong, consistent evidence that program, child, or family characteristics moderate to any significant degree the long-term impact of model or large-scale preschool interventions (McKey et al., 1985; Royce et al., 1983). However, findings from FACES 2000 (Zill et al., 2003) invite reconsideration of this conclusion, and along with findings from evaluations of small-scale model programs, suggest ways that Head Start might be modified to achieve larger impacts on children's competence. This study found that several program and classroom characteristics within Head Start were associated with greater gains in children's cognitive and socioemotional functioning, including use of an integrated curriculum (programs using the High/Scope curriculum versus programs using other curricula), provision of full-day classes, higher educational credentials of teachers (i.e., bachelor or associate degrees), and higher teacher salaries. It is of considerable interest whether these findings will be replicated in the National Head Start Impact Study.

Two large-scale federal initiatives are under way to assess the effectiveness of different early childhood curricula and early childhood interventions and programs in preparing children for school (U.S. Department of Education's Preschool Curriculum Evaluation Research Program; Interagency Early Childhood Research Initiative). Additional experimental studies focusing partly on curriculum issues are being conducted by the Head Start Quality Research Consortium, in keeping with Head Start's tradition of implementing demonstration projects both within and outside its basic core program to ascertain more effective ways of serving poor children and families (U.S. Department of Health and Human Services, 2003; Zigler & Styfco, 1994a). These collective efforts, along with lessons learned from state-level experimentation with new strategies for coordinating early childhood programs and enhancing children's school readiness, are expected to strengthen Head Start and result in stronger and more seamless early childhood systems in the United States (U.S. Department of Health and Human Services, 2003).

The shift in Head Start preschools away from half-day sessions to full-day programs (U.S. General Accounting Office, 2003) is consistent with the aforementioned finding from the FACES study (Zill et al., 2003) and with the pattern found in model programs of larger and more enduring effects on children's cognitive and academic functioning when programs are more intensive (Campbell et al., 2002; C. T. Ramey & Ramey, 1998). This shift has the additional advantage of being more practical for poor women who are working or participating in job programs. The numbers of such women have increased markedly in response to welfare reform (Greenberg et al., 2002). Undoubtedly, many of these mothers were forced to place their children in informal, unregulated child care of much lower quality than that provided in Head Start centers because Head Start preschools offered only half-day sessions or had no slots available. As of 2003, 54% of Head Start children were served in full-day programs for at least 6 hours daily, but most centers operate on a 9-month school year, with most open 5 days or fewer per week (Hart & Schumacher, 2004).

Research findings also buttress Head Start's prevailing practice of providing 1 rather than 2 years of Head Start for most children who participate in the program. Taken together, longitudinal studies of model programs and large-scale public programs such as the Chicago

Child-Parent Centers provide little evidence that a 2nd year of preschool intervention confers enduring, educationally meaningful academic advantages beyond a single year (Consortium for Longitudinal Studies, 1983; Reynolds, 1995; Sprigle & Schaefer, 1985). A 2nd year may reinforce the school readiness skills that children have learned during the 1st year, but its unique contribution to the acquisition of academic skills is modest at best and decidedly less than that of the 1st year (Reynolds, 1995). Research findings provide a much stronger case for providing 1 year of publicly funded preschool intervention for all poor children (30% of 4-year-olds and 70% of 3-year-olds eligible for Head Start are currently not served by Head Start), in lieu of 2 years for a smaller number of poor children. Findings from the National Head Start Impact Study (ACF, 2005a) will allow a more rigorous consideration of all of the issues mentioned here.

Effectiveness of Follow-Through Services into Elementary School: Findings in Search of Policy.

Paradoxically, although 2 years of preschool may not be markedly more advantageous than 1 year in increasing poor children's cognitive functioning and school achievement, comparisons of treatment effects between and within studies suggest that programs of even longer duration may be optimal (Fuerst & Fuerst, 1993; Madden, Slavin, Karweit, Dolan, & Wasik, 1993; Reynolds, 1995). Consequently, some have advocated for a continuation of Head Start intervention services into the primary grades as a strategy to prevent fade-out (Reynolds, 2003). It was precisely this rationale that led to the creation of Head Start/Follow Through in 1967. Despite original intentions, Follow Through never became a national program, and initial emphasis on comprehensive services was supplanted with a primary focus on innovative curricula. In the early 1990s, it operated in only 40 schools, and few evaluations of its effectiveness exist (Zigler & Muenchow, 1992). However, the Follow Through concept was revamped in 1991 with the National Head Start/Public School Early Childhood Demonstration Transition Project. This project followed Head Start graduates in 31 programs from kindergarten through third grade. Children and parents were introduced to the new school environment and provided comprehensive services and support. Parental involvement was heavily emphasized.

Although evaluations of the Transition Project are incomplete, preliminary findings provide some evidence that the program enhanced children's school transition (S. L. Ramey, Ramey, & Lanzi, 2004; Reynolds, 2003). Also encouraging is the fact that although children initially performed below national norms, by the end of the second and third grades, they performed at essentially the national average in reading and math. Additionally, results of similar transitional programs, most notably the Chicago Child-Parent Centers, lend support to the value of such extended interventions (Reynolds, 2003; Zigler & Styfco, 2003).

No specific plans currently exist for expansion of follow-through services to the larger Head Start population. Direct delivery of educational services to the child and significant changes in the child's learning environment, especially in the school context, appear to be prerequisites for effective follow-on interventions (Barnett, 1995). Follow-on services for children that are parent-mediated (e.g., programs that focus on increasing parent involvement in the child's schooling through home curriculum activities for the parent) and based primarily in the home setting have not been found effective (C. T. Ramey & Ramey, 1998; see McLoyd, 1998, for a more detailed discussion of this issue).

Individual Differences in Program Benefits.

There continues to be keen interest in determining whether certain child and family characteristics moderate program effects, in part, because understanding this issue would be the basis for better targeting of early interventions. According to C. T. Ramey and his colleagues (C. T. Ramey, Ramey, & Lanzi, 1998), individual differences in how much children benefit from participation in diverse early interventions tend to be related to aspects of children's initial risk condition. Extrapolating from this generalization, within-group differences in poor children's level of disadvantage or risk for dysfunctional development are likely linked to the individual differences in the benefits they accrue from participating in early education interventions. C. T. Ramey et al. used data from former Head Start children at entry to kindergarten to explore the usefulness of cluster analyses to distinguish among poor families. The analyses identified six major family types on the basis of correlation coefficients among 13 widely used indicators of family characteristics (e.g., maternal education, mother's employment and AFDC status, presence of parenting assistance in the home, maternal age at time of child's entry to kinder-

garten). These clusters or family types were systematically related to children's receptive language, special education placement, and social competence. Identification of risk levels or typologies among poor children prior to entry to Head Start, using this or other procedures, lays the foundation for addressing the question regarding what intervention works best for whom.

To date, questions about what child and family characteristics moderate program effects have not been fully explored in the National Head Start Impact Study (ACF, 2005a), but an initial examination of sources of variation in program impacts indicated that Head Start effects on cognitive competence were larger for children whose primary language was English (as compared to Spanish), for African American and Hispanic children (as compared to non-Hispanic White children), and for children whose primary caregiver had lower levels of depressive symptoms at baseline. Other evaluations of the effects of preschool interventions on poor children point to both child sex and race/ethnicity as moderators of program effects. We discuss these findings below.

Attenuated Gains among African American Boys? A conspicuous number of higher-quality studies (of model programs and large-scale, public programs) serving African American children report stronger intervention and follow-on effects on girls' school competence, school progress, and socioemotional functioning than boys', although program findings by sex interactions have not necessarily been statistically significant. Boys often benefited substantially less from programs than did girls, despite bringing equivalent and, in some instances, superior intellectual abilities to the program. These studies also suggest that sex is a more probable moderator of long-term rather than immediate effects, with gender differences becoming progressively larger over time in some instances (Consortium for Longitudinal Studies, 1983; Fuerst & Fuerst, 1993; Schweinhart et al., 1993).

Researchers have offered several explanations for these differences, but ascertaining which ones are most credible is difficult because longitudinal studies have not tracked the school, family, and broader social experiences of boys and girls in relation to the preschool experience. Explanations centering on post-preschool factors appear more plausible than those centering on the programs themselves because gender differences in immediate effects typically are not found. A combination of gender and racial stereotypes may condition teachers and school staff to more readily ignore or to

respond less positively to improvement in school competence among African American boys. Attention may be directed toward boys' conduct at the expense of their academic competence (Jackson, 1999; Schweinhart et al., 1993).

Perhaps poor African American boys, compared to their female counterparts, confront more barriers to academic achievement and/or barriers that are more impervious to preschool intervention. Gender-related barriers may include an indifferent, if not hostile, school climate, peer pressure against school achievement, belief that academic competence is not masculine, low expectations of achievement among parents and teachers, and early school failure (Graham, Taylor, & Hudley, 1998; Jackson, 1999; Kunjufu, 1986; Osborne, 1997). These analyses suggest that African American boys may need follow-through services uniquely tailored to the challenges that confront them in elementary school.

The conditions and underlying processes that encourage divergence between boys and girls in their long-term response to preschool education are intriguing issues. Given the increasingly bleak status of a substantial segment of the African American male population (Gibbs, 1988), few issues are more deserving of systematic study.

Race as a Moderating Variable? The ETS study of Head Start's efficacy (Lee et al., 1988), as well as more recent evidence from the Early Head Start evaluation (ACF, 2002) and the National Head Start Impact Study (ACF, 2005a) raise the possibility that programs have larger positive impacts on African American children than White children, apparently because of differences in risk exposure and related differences in cognitive performance at the point of preintervention. In the ETS study, children who started out lowest gained the most. African American children were relatively more disadvantaged demographically than White children in the preintervention year and scored significantly lower on all four measures of cognitive functioning (Lee et al., 1988).

In terms of comparative risk, it also bears repeating that African American children are more likely than White children to experience poverty that is both persistent and extreme (income below one-half of the poverty threshold), factors that predict lower levels of cognitive functioning (Duncan & Brooks-Gunn, 1997). In addition, the differential impact of poverty by childhood stage reported by Duncan and his colleagues (i.e., poverty during first 5 years is more detrimental to educational attainment than poverty during middle child-

hood and adolescence) is especially pronounced among African American children (Duncan et al., 1998). Hence, African American children may experience greater benefits from Head Start than White children because they are more vulnerable to the elevated effects of poverty during early childhood as compared to subsequent developmental periods. Other intervention studies of poor children and families have found the greatest relative gains among those at highest risk (C. T. Ramey & Ramey, 1998), although Halpern (2000), in his review of a broad range of early childhood intervention programs for low-income children and families, concluded that research is equivocal and ultimately inconclusive as to whether relatively higher- or lower-risk populations benefit more from participation in early childhood intervention.

In contrast to the ETS findings, Currie and Thomas's (1995) analysis of data from the National Longitudinal Study of Youth (NLSY) child sample revealed no race differences in initial gains from Head Start. However, significant race disparities were found in the rate at which gains dissipated, with White children retaining the benefits of Head Start on the Peabody Picture Vocabulary Test (PPVT) much longer than African American children. By age 10, African American children had lost any gains on the PPVT derived from Head Start, whereas 10-year-old White Head Start enrollees retained a gain of 5 percentile points. Currie and Thomas also found race differences in the impact of Head Start on grade retention. Whereas Head Start reduced the probability of grade retention among White children by 47% compared to their siblings who did not attend preschool, it was unrelated to grade retention among African American children. At least part of the race difference in rate of dissipation may reflect differences in the quality of schools that African American and White children attended once they left Head Start. Curiously, no evidence of a similar race effect in the dissipation of positive effects was found among children who attended non-Head Start preschools. Currie and Thomas's findings conflict not only with the race differences found in other prominent studies of the effects of Head Start and Early Head Start (ACF, 2002, 2005a; Lee et al., 1988), but also with reports of long-term positive effects of other large-scale preschool intervention programs on African American children's cognitive functioning and school progress (e.g., Reynolds, 1994).

What explains these discrepancies is unclear, but it is notable that unlike most studies of preschool effects, Currie and Thomas (1995) used siblings (rather than

nonsiblings) of Head Start enrollees who had not attended Head Start as a comparison group (as a strategy to control for family background effects). Another important consideration may be their questionable creation of a "White" comparison group of Head Start children. They combined White non-Latino and Latino children into a single White group and estimated fixed-effects models using this grouping (Barnett, 2004). A reanalysis of the fixed-effects models by Barnett and Camilli (2000) indicated that there was no justification for treating the White non-Latino and Latino children as a single population given their differences in test scores and program participation rates. Additionally, their reanalysis indicated identical short- and long-term effects for White non-Latino and African American children, as well as a fade-out for both groups.

Effects of Preschool Intervention on Whites and Other Ethnic Groups? The discussion about race as a moderator of preschool effects points up a related gap in the research literature, namely, inadequate study of the impact of preschool education on White children and children from other ethnic groups. Studies of preschool effects reveal a preoccupation with African American children (Barnett, 1995). African American children are greatly overrepresented in the population of poor children, but the fact remains that poor White children vastly outnumber poor African American children in an absolute sense. Over the course of Head Start's existence, African American children have constituted from about one-third to two-fifths of its enrollment and Latino children from about one-fifth to one-third (Hart & Schumacher, 2004; National Center for Education Statistics, 1995). Historically, a large percentage of the early growth of Head Start centers occurred in poor, African American communities. Taking account of their rates of enrollment, however, African American children are overrepresented in studies of Head Start effects, whereas White and Latino children are underrepresented.

Model programs provide virtually no insight into the effects of preschool interventions on children from ethnically diverse populations, because with the exception of a few studies of preschool programs that targeted Latino children (Andrews et al., 1982; Johnson & Breckenridge, 1982), they have focused almost exclusively on African American children (see McLoyd, 1998, for a discussion of considerations that led to the racial makeup of model programs). Whatever its underlying cause, this bias has had at least two unfortunate consequences. First, we know little about the utility of Head Start and

preschool education generally for poor White children. The most rigorous evaluations of Head Start (ACF, 2002, 2005a; Lee et al., 1988) raise cautions against generalizing findings based on African American children to White children. Second, it feeds the stereotype of African Americans as invariably poor and economically dependent, while furthering the tendency to render poor White children and families invisible in the field of child development research. Given the changing demographics of the current Head Start population (Zigler & Styfco, 2004a), an understanding of the experiences of all children and families served by the program is essential.

Parents and the Home Environment as Determinants of Development

A second major assumption that undergirds antipoverty programs is that parents and the home environment they afford exert major influence on the course of children's development. During the 1960s, rapid growth in research evidence lending support to this assumption, along with other forces, propelled interest in parent education as a form and a major component of early childhood intervention (Clarke-Stewart & Apfel, 1978; D. Powell, 1988). Parent education programs and, to a lesser extent, opportunities for parent involvement in early education interventions were conceived as strategies to alter poor children's outcomes indirectly by increasing parents' knowledge of the principles of child development and, ultimately, modifying parental behavior.

Parent education as an indirect strategy to influence children's development has a long history in America, dating back to the early 1800s (for historical reviews, see G. Fein, 1980; Halpern, 1988; Schlossman, 1976). Parent education programs proliferated during the 1950s, but their clientele was almost exclusively middle class (Brim, 1959). Parent education rose to prominence again during the late 1960s and 1970s, but in ways that distinguished it from its predecessors. First, it was now a strategy that targeted principally poor families, on the grounds that enhancing parents' child-rearing skills would, in turn, improve children's ability to effect a successful transition from home to school, to benefit from schooling, and to maximize cognitive gains accrued from preschool education (Chilman, 1973; Clarke-Stewart & Apfel, 1978; D. Powell, 1988). Characterized by a focus on mothers of infants and preschoolers as primary recipients of services, parent education programs marked an evolving direction in early childhood intervention from an almost exclusive focus on children to

one that gave major consideration to the roles of parents, the home environment, and parent-child interaction in poor children's development. This trend was strengthened by rising rates of single-parent households, unmarried teenage mothers, divorce, unemployment, and economic instability and increased public awareness of child abuse and neglect, all of which evoked concern that the child-nurturing capacities of American families were in decline (D. Powell, 1988).

Research-Based Antecedents

The reincarnation of parent education during the late 1960s was also different from its predecessors in that it had much deeper foundations in empirical child development research (Clarke-Stewart & Apfel, 1978). Proponents cited popular ideas such as "parents are a child's first and most important teacher" (Clarke-Stewart & Apfel, 1978, p. 48) and "every child needs—and has a right to have—trained parents" (Bell, 1975, p. 272), but they relied heavily on a diverse set of research findings from child development research to support their cause. First, the disappointing findings from early evaluations of the effects of Head Start were interpreted by some advocates as evidence that prevention of cognitive deficits required intervention even before preschool and, relatedly, that the source of cognitive deficits resided somewhere in the home (Clarke-Stewart & Apfel, 1978). Second, a major boost for parent training programs came from Bronfenbrenner's (1975) synthesis of findings from early education interventions, wherein he concluded that early education interventions produce greater and more enduring benefits in children the more involved their parents are. Although Bronfenbrenner's conclusion spoke more directly to the enhanced efficacy of family-centered interventions involving parents and their children, it was viewed as support for the narrower concept of parent education as well. What was more, data indicated that the positive effects of interventions involving parents diffused to younger siblings (e.g., S. Gray & Klaus, 1970), making such programs highly cost-effective.

Third, proponents pointed to a panoply of interview and laboratory studies demonstrating the relation of children's cognitive functioning to countless indicators of mothers' knowledge of child development, child-rearing attitudes, and child-rearing practices (e.g., level of maternal stimulation of child, such as playing, talking, and elaborating the child's activities; provision of appropriate play materials; abstractness of the mother's speech; promptness of the mother's responsiveness to

the infant's distress signals; use of consistent, firm discipline accompanied by frequent approval). Also contributing to the credibility of parent training was evidence that parents' behavior could be modified by brief interventions (see Clarke-Stewart & Apfel, 1978, for a review of these studies).

A fourth and critical set of studies on which advocates of parent education relied focused on social class differences in children's home and family environment (Clarke-Stewart & Apfel, 1978). One line of work documented SES differences in child-rearing practices (e.g., teaching strategies, maternal speech patterns, influence techniques). On the basis of parent-child correlational data or developmental theory, this research inferred that these differences accounted for social class variation in children's cognitive and academic functioning (e.g., Bee, Egeren, Streissguth, Nyman, & Leckie, 1969; Bernstein, 1961; Deutsch, 1973; Hess & Shipman, 1965; Kamii & Radin, 1967). In a related line of work, poverty, low levels of maternal education, and other indicators of low social status were identified as predictors of both lower cognitive/academic functioning in children and lower levels of various indicators of maternal behavior associated with children's cognitive and academic functioning (e.g., verbal and cognitive stimulation in home environment, emotional support of child, positive reinforcement). Children with higher levels of cognitive and academic competence tended to have mothers who were more accepting, affectionate, and egalitarian, less commanding, threatening, and punishing, and more consistent and rewarding in their interactions, and these were the very dimensions of child rearing that distinguished lower-class from middle-class mothers (Bradley & Caldwell, 1976; Clarke-Stewart & Apfel, 1978; Deutsch, 1973).

In general, the view of lower-class patterns of child rearing painted by 1960s-era research generally was one of wholesale inadequacy (e.g., Bee et al., 1969; Hess & Shipman, 1965; Kamii & Radin, 1967). The culture of poverty notion that held sway during the 1960s and 1970s led inexorably to interpretations of SES differences that disparaged lower-class patterns of child rearing (Bernstein, 1961; Lewis, 1966). These differences were conceptualized as antecedents of retarded cognitive, linguistic, and socioemotional development and, in turn, as a major pathway by which poverty is perpetuated from one generation to the next. A natural extension of these arguments was the assertion that poor parents needed training for their child-rearing role more

than parents from more affluent backgrounds (Baratz & Baratz, 1970; Laosa, 1984).

The foundation on which 1970s-era parent education for poor mothers rested was not nearly as sound as proponents made it out to be. First, much of the research on parental effects on children's development was based on White, middle-class families and, hence, of uncertain generalizability to poor families. Second, serious methodological biases against poor parents (e.g., assessments in university laboratories; use of measures normed for middle-class individuals) and race-SES confounds limited interpretations of many of the research findings and their applicability to policy. Third, as an intervention that targeted participants principally on the basis of SES, especially during the early stages of the movement, parent education ignored the considerable heterogeneity that existed among lower-class parents. Typically, modal behavior of parents, like children's, is the same at different SES levels, and heterogeneity within social class typically is greater than variation between social classes. Hence, SES is, at best, an extremely crude proxy of presumed differences in parental behavior and home environment (Clarke-Stewart & Apfel, 1978).

As the parent education movement gained momentum, a number of programs began to target specific groups at high risk for parenting difficulties, such as pregnant adolescents, adolescent mothers, and women identified as drug users or potential child abusers (e.g., Field, Widmayer, Stringer, & Ignatoff, 1980). In the main, though, the eligibility criterion for most programs was simply low SES. Heightened appreciation in subsequent years of the heterogeneity within groups of poor individuals prompted studies of parenting practices, home environment, and extrafamilial factors as sources of psychological resilience and academic competence, rather than problematic development, in poor minority children (e.g., Baldwin, Baldwin, & Cole, 1990; Gutman & McLoyd, 2000).

Recent research on parenting and home environmental factors as determinants of cognitive functioning in poor children diverges from 1960s-era research in that it tends to (a) emphasize social structural rather than cultural deficiencies as causal factors in poverty, (b) focus on income poverty rather than social class, and (c) directly assess provision of stimulating experiences in the home as a mediator of the relation between family income and children's development. Another striking difference is that contemporary researchers tend to

interpret links between family income and home environment within an investment model (i.e., the notion that income is associated with children's development because it enables families to invest in the human capital of their children by purchasing materials, experiences, and services that benefit the child's development and well-being), rather than within a cultural deficit model (e.g., Linver, Brooks-Gunn, & Kohen, 2002). In short, they

assume a direct link between income and home-based stimulation rather than an indirect one mediated through parenting knowledge and attitudes.

Recent research demonstrates that the provision of cognitively stimulating experiences in the home (e.g., presence of cognitively stimulating toys, reading to child, helping children learn numbers, alphabet) is a strong mediator of the relation between family income and young children's cognitive functioning (Duncan, Brooks-Gunn, & Klebanov, 1994; Klebanov, Brooks-Gunn, McCarton, & McCormick, 1998; Linver et al., 2002), although it appears to play a smaller role in mediating the effects of *across-time, within-family income changes* than mediating the effects of average income (Dearing, McCartney, & Taylor, 2001). Other variables, such as maternal sensitivity, appear to play a much weaker role in mediating the link between family income and children's cognitive functioning (Mistry et al., 2004). Further, these studies have yielded strong, consistent evidence that the relationship between family income and quality of home environment is nonlinear, such that the home environments of children in low-income households are particularly sensitive to income and income changes. Data indicate that the quality of children's home environment, like IQ scores, decreases as families' income-to-need ratios decline and as duration of poverty increases, and further, that improvements in family income have the strongest effects on the quality of children's home environment if children were born poor (versus not born poor) or spent more time in poverty (Dubow & Ippolito, 1994; Garrett, Ng'andu & Ferron, 1994).

In response to concerns that the reported income-home environment link and the home environment-child functioning link are spurious (i.e., that they reflect unmeasured individual differences or omitted variables related to income, income changes, home environment, and child outcome), researchers have used longitudinal fixed effects models to control for stable omitted differences between individuals (e.g., mother and child cognitive

abilities) by comparing individuals to themselves over time, which holds these characteristics constant. Studies using this more rigorous test have also found nonlinear relationships. This work indicates that household income is positively related to children's cognitive functioning and the level of cognitive stimulation in children's home environment and, more important, that over-time improvements and reductions in family income (a) have much stronger impacts on the home environments of low-income children than those of middle-income children (Votruba-Drzal, 2003) and (b) bear a strong relationship to young children's cognitive functioning in the expected direction if they are poor, but are of little consequence if the child is not poor (Dearing et al., 2001).

Taken together, recent research makes a stronger case for family income supplements than for parent education as a strategy to promote poor children's cognitive functioning (a) because of the investment model that guides these investigations; (b) because studies have shown that the link between income and home learning environment remains robust after applying various statistical techniques to control for maternal, household, and child characteristics (Votruba-Drzal, 2003); and (c) because investigators have not tested differences in parenting knowledge and attitudes either as a mediator of the income-home environment link or as a direct contributor to income-related disparities in children's cognitive functioning. However, there are data from poor families indicating that maternal knowledge of child development indirectly influences poor children's cognitive test scores through maternal supportiveness (Wacharasin, Barnard, & Spieker, 2003).

Evaluations of the Efficacy of Parent Education Programs

In this chapter, we use the terms "parent education" and "parent training" interchangeably, while acknowledging that differences exist in their meanings. Parent education tends to be regarded as the more general term, whereas parent training is thought of as one category of parent education, distinguished by a process that includes a component devoted to teaching specific skills (Dembo, Sweitzer, & Lauritzen, 1985). Although parent education programs vary in their goals, a large proportion of them generally seek to increase parents' knowledge of child development, enhance the child's home learning environment, and ultimately improve children's cognitive functioning and school success. Another large

category of parent education programs is designed to improve parent-child communication, help parents use effective discipline methods, and foster children's social competence.

The past 2 decades brought a stunning panoply of parent education programs and evaluations of their efficacy (C. Smith, Perou, & Lesesne, 2002). The overwhelming diversity among parent education programs makes it hazardous to compare effects across programs and sites. Parallel with the proliferation of programs has been a growing tendency to embed parent education within broader family support programs or as a component of comprehensive intervention programs for low-income families (Brooks-Gunn, Berlin, & Fuligni, 2000; C. Smith et al., 2002). In terms of assessment, the thorny problem this creates is sorting out the unique effects of parent education *per se* from other program components such as parent support and social services, because these multifaceted programs invariably are not structured to set apart the impact of the parent education component. Some of the largest and best-evaluated interventions are of this nature, such as the Parent and Child Development Centers and the Comprehensive Child Development Program (Morley, Dornbusch, & Seer, 1993; D. Powell, 1982; St. Pierre & Layzer, 1999). On the other hand, some scholars argue that efforts to dissect multifaceted programs into their constituents are misguided because it is the sum of the parts and the synergistic processes operating among program components that often account for their success (Olds & Kitzman, 1990).

Another challenge for those interested in the effects of parenting education on low-income parents and children generally derives from the correlation that poverty and low income bear to numerous other demographic and family characteristics that are increasingly the criteria for inclusion in parent education programs. For example, a growing number of programs target teen mothers, parents with limited English proficiency, and parents with limited formal education. These programs may serve parents from socioeconomically diverse backgrounds, and in evaluations of their efficacy, SES/poverty status may be controlled rather than examined as a potential moderator of program effects (e.g., Baker, Piotrkowski, Brooks-Gunn, 1999). More precise targeting of parent education programs on the basis of demographic or family criteria other than poverty that place children at risk for poor cognitive, school, or behavioral outcomes may, in the long run, prove cost-effective. However, compared to programs

that specifically target poor or low-income parents, these programs may have comparatively high attrition rates because they incorporate fewer or less effective incentives to curb dropout and low attendance rates or are implemented in ways incompatible with the life circumstances of low-income participants (Gomby, Culross, & Behrman, 1999). Poor and low-income parents are more likely to drop out of or have low levels of involvement in parent training programs, compared to their more advantaged counterparts (e.g., Baker et al., 1999; F. Frankel & Simmons, 1992), a finding that may suggest the need for incentives that are more responsive to the resource needs of poor and low-income parents (e.g., transportation, child care; R. B. Wolfe & Hirsch, 2003).

Most parent education programs that were initiated during the 1970s and that focused primarily on low-income parents emphasized enhancing children's cognitive performance (Clarke-Stewart & Apfel, 1978; Morley et al., 1993; Olds & Kitzman, 1993). Recent years have brought a broader focus that includes fostering social competence and preventing conduct problems in low-income children, partly in response to growing recognition of the role of social skills in early academic success (e.g., Webster-Stratton, 1998). Diverse strategies have been employed to achieve these goals, as reflected in the vast array of dimensions on which parent education and training programs differ. These dimensions include focus (parent-child dyad versus parent alone), method of instruction (one-to-one versus group discussion, toy demonstration and modeling), setting (home- versus center-based), frequency of contact, duration of the program, existence of a predetermined curriculum, and staff credentials (e.g., professional versus paraprofessionals). Content may include information about various milestones in child development, physical and emotional development, and parenting techniques. In programs seeking to enhance cognitive functioning, children generally range in age from young infants to 5-year-olds, though more emphasis is given to the first 3 years of life. Those concerned with children's social competence tend to involve parents of children representing a broader age range. A large number of programs with an evaluation component have focused on African American mothers (e.g., Morley et al., 1993; Olds & Kitzman, 1993; D. Powell, 1982).

The vast majority of parent education and training programs do not include an evaluation component. Among those that do, a variety of methodological prob-

lems exist that make it difficult to assess their effects and to determine what aspects or kinds of programs are most effective. Parenting programs (or programs with parent education components) evaluated in rigorous randomized trials were rare in the 1970s and 1980s and remain so (Clarke-Stewart & Apfel, 1978; Dembo et al., 1985; Gomby et al., 1999). Moreover, the advantages of a true random control group is likely lost in some studies because control and experimental groups live in close proximity and the curriculum may be diffused from program mothers and children to control mothers and children. Other common threats to the validity of evaluations of these programs include repeated testing of children with the same instrument, use of nonstandardized and culturally biased measures and measures with unknown psychometric properties, and subject attrition. Few evaluations have included long-term follow-ups or gone beyond demonstrating the overall effectiveness of the program to systematically investigate either processes through which change is effected or factors that moderate overall effectiveness (Clarke-Stewart & Apfel, 1978; Gomby et al., 1999).

Effects on Children. Despite these myriad methodological limitations, existing research supports the general conclusion that well-administered parent education programs can produce immediate effects on low-income children's cognitive functioning (for detailed reviews of these studies, see Clarke-Stewart & Apfel, 1978; Halpern, 1990b; Morley et al., 1993). When cognitive gains have been found among program children, compared to control children, they have been modest and are usually maintained for 1 or 2 years and then gradually fade. In a meta-analysis of the effects of 13 programs that offered parent education either alone or in combination with other intervention services to mothers/parents of children under 3 years of age, Morley et al. found an overall positive effect on children's intellectual functioning that tended to persist for a year or so. Analysis of the effects of parent education alone, unmixed with other interventions, yielded similar findings. In general, though, interventions that rely solely on parent-mediated routes to increase children's cognitive competencies (e.g., parent education that involves only the parent) produce less positive and enduring effects than interventions that provide direct learning experiences to children (C. Ramey, Ramey, Gaines, & Blair, 1995; Wasik, Ramey, Bryant, & Sparling, 1990).

Parenting programs also have been found to enhance low-income children's social competence, though reliance on parent reports is a major limitation in most studies (e.g., Myers et al., 1992). In one of the most rigorously evaluated parenting programs of this genre that used a random assignment design, Head Start children whose mother participated in an 8- to 9-week parenting program (weekly parent group meetings of 8 to 16 parents for 2 hours, once a week) were found to exhibit significantly fewer conduct problems, less noncompliance, less negative affect, and more positive affect (as assessed by home observations and teacher report) than Head Start control children. Most of these improvements were maintained 1 year later (Webster-Stratton, 1998).

Considerably less consensus exists about the degree to which the effectiveness of parent education programs on children's development is moderated by program characteristics such as duration, intensity, location, format, focal child's age at the inception of the intervention, and curriculum content. It is difficult to assess the independent contribution of these program characteristics because they tend to be confounded within and across programs. Several studies have found no difference in the effects of programs lasting 1 versus 2 years, or 2 versus 3 years, but when differences are found, they tend to favor longer programs, the latter tending to produce more enduring rather than larger gains (Clarke-Stewart & Apfel, 1978; Morley et al., 1993). There is suggestive evidence that a more intense program schedule may result in increased benefits, but most studies have confounded intensity with other potentially critical variables. In one of the higher-quality studies of this issue, C. Powell and Grantham-McGregor (1989) varied the frequency with which community health aides provided psychosocial stimulation to infants and toddlers and demonstrated these techniques to their mothers during a 2-year period. At the end of the 1st and the 2nd years, children who were visited biweekly had higher intellectual functioning than those who were visited monthly or not at all. The pattern of scores indicated that the 1st year of biweekly home visiting increased intellectual functioning, whereas the 2nd year served to maintain this benefit or reinforce the skills that children had learned during the 1st year, a pattern reminiscent of that found in studies of the effects of 2 versus 1 year of center-based intervention (e.g., Reynolds, 1995).

Data do not point to any optimal age during the first 5 years of the child's life for initiating parent education.

Studies that systematically vary by about a year the age of the child at the inception of parent education tend to find no significant age-related difference in immediate effects. Beginning at a younger age may be better in the long run (Clarke-Stewart & Apfel, 1978), though there may be no significant advantage to beginning prior to the child's 12th month of life (Morley et al., 1993). Discrepancies in findings regarding the relative effectiveness of different formats (e.g., home-based versus group/center-based), along with cultural insensitivity of programs for ethnic minorities, acknowledgment of individual differences among parents, and evidence that exact replication of model programs was not possible because of the need to adapt programs to local circumstances have led to a shift in the parent education field to matching program content and methods to the needs and characteristics of parents (D. Powell, 1988).

Effects on Maternal Behavior and Attitudes. A number of parent training programs have been found to positively affect low-income mothers' parenting behavior and attitudes. Effects include use of more complex speech, greater provision of stimulating activities in the home environment, less authoritarian child-rearing attitudes, greater discipline competence, greater use of praise and less harsh critical behavior, greater involvement in the child's education, and increased confidence and perceived efficacy in the role of parent (Clarke-Stewart & Apfel, 1978; Duggan et al., 1999; Morley et al., 1993; Webster-Stratton, 1998; R. B. Wolfe & Hirsch, 2003). Too few long-term studies have been conducted to know whether these maternal effects persist well beyond the end of the programs. Overall, though, parent education programs have stronger immediate effects on mothers' attitudes and behavior and on the quality of the home environment than on children's cognitive functioning (Clarke-Stewart & Apfel, 1978; Morley et al., 1993). An even finer-grained distinction may be warranted, in that some interventions with parent education components have been more effective in modifying parental attitudes and self-reports of behavior than observed home environment or mother-child interaction (Duggan et al., 1999). Because evaluation studies have not assessed the relationship between changes in maternal and child behavior over time, it remains unclear whether gains in children's cognitive and social functioning are indeed caused by increased parental knowledge and changes in parental behavior

and attitudes (Clarke-Stewart & Apfel, 1978; Shonkoff & Phillips, 2000).

Parent Participation/Involvement in Early Childhood Interventions

During the mid- to late 1970s, emphasis on parent education in a narrow sense began to give way to the broader concepts of parent participation and involvement, whereby professionals, in effect, were to do things “with rather than to parents in early intervention programs” (D. Powell, 1988, p. 11). This realignment of parent-professional relations, seen by some as more rhetorical than substantive, was the product of several forces, including (a) provisions for parent participation in federal legislation establishing programs for the poor, such as the Economic Opportunity Act of 1964, which called for “maximum feasible participation” for individuals served by Community Action Programs (CAP), the umbrella entity under which Head Start was implemented; (b) the civil rights movement, which sought institutional change and empowerment of the poor partly by pressing for poor people’s involvement in decisions that affected them; (c) criticisms of the deficit model; and (d) growing concern about professional meddling in private family matters (Halpern, 1988; D. Powell, 1988).

Although not without strong resistance from those who perceived Head Start parents as deficient in educational and parenting skills and as a primary source of their children’s “cultural deficits,” parent involvement (and parenting education) ultimately was incorporated as a central component of the Head Start model (Zigler & Muenchow, 1992). By the early 1970s, provisions for parent participation and decision making in Head Start had been clearly enunciated and spanned a wide array of possibilities (e.g., participation in the classroom as paid employees, volunteers, or observers; educational activities for parents which they helped to develop; leading and serving on committees that make decisions about budgetary matters, curriculum development, health services, program goals, and implementation of program services; G. Fein, 1980; Parker, Piotrkowski, Horn, & Greene, 1995). Parent involvement continues to be a salient feature of Head Start. Head Start parents are significantly more involved in school-based activities (e.g., volunteering in child’s classroom, going on class trips with child) and conference with teachers and school administrators more frequently than parents whose children attend comprehensive day care centers (Fantuzzo, Tighe, & Childs, 2000), although the two groups do not

differ in behaviors that actively promote a learning environment at home for the child.

Parent Participation/Involvement as an Enhancer of Preschool Effects

The legitimacy of parent participation/involvement in preschool interventions increased exponentially following Bronfenbrenner’s (1975) conclusion, noted previously, that increased parent involvement enhanced the efficacy of early childhood interventions. Advocates pointed to two potential pathways by which this effect is produced. First, it was asserted that helping parents understand and manage their children’s developmental needs helps consolidate and maintain the benefits of early education, given parents’ uniquely salient and enduring presence in the child’s life. Second, involving parents in the planning, implementation, and assessment of programs was thought to enhance programs’ sensitivity to the needs of children and, hence, boost positive effects (White, Taylor, & Moss, 1992).

In subsequent reviews of research bearing on parental participation/involvement as a moderator of the effects of early childhood intervention, researchers have noted limitations in Bronfenbrenner’s (1975) analysis (e.g., the sample of programs was small, ages and frequency of home visits were confounded) and concluded that existing research provides no compelling evidence of an enhancing effect of parental participation/involvement (Clarke-Stewart & Apfel, 1978; White et al., 1992). Clarke-Stewart and Apfel identified a number of studies reporting evidence of stronger effects in mother-child programs than programs that focused only on the child. However, they found equally strong evidence that children’s cognitive gains were not dependent on their mother’s level of participation/involvement in the program. Moreover, they cited studies in which child-focused programs were more effective than mother-child programs in producing gains in children’s test competence and school skills. Clarke-Stewart and Apfel’s conclusion of an overall null effect, based on a traditional review of the literature, foreshadowed similar findings from a meta-analysis published several years later (White et al., 1992).

Taken together, extant investigations yield no consistent evidence that parent participation/involvement enhances the immediate or long-term effects of early intervention on children’s development. This may be due to a lack of consensus about the definition of parent participation/involvement. Parent participation/involvement

ment has evolved into a broad and highly diffuse concept whose operationalizations encompass highly disparate activities, including teaching parents specific skills to assist them in becoming more effective socializers of their children, exchanging information between parents and professionals, participation of parents in the planning and implementation of programs, assisting parents in accessing community resources, and providing emotional and social support to family members (White et al., 1992). Failure to find an enhancing effect of parent participation/involvement also may be due to insufficient attention to a range of parent behaviors across different settings and populations, inadequate implementation of parent participation/involvement components of intervention programs, and poorly designed research (Reynolds, 1992; White et al., 1992).

The most obvious limitation to drawing firm conclusions about the impact of parental participation/involvement, however, is the remarkably sparse number of studies that have been designed expressly to investigate this issue. A strong, venerable presumption exists that parental involvement in child-directed educational efforts, however defined and measured, is desirable (G. Fein, 1980; Reynolds, 1992). Low priority may be given to conducting empirical tests of this assumption because it is so prevalent and held with such certitude. Even if parent participation/involvement does not enhance children's gains from early intervention, this in no way negates its potential importance as a means to achieve other laudable goals (e.g., enhancing poor parents' political power and sense of efficacy).

Although apparently not a robust moderator of effects, parent involvement has been found to mediate preschool effects. In his longitudinal study of children enrolled in a large-scale preschool intervention program similar to Head Start, Reynolds (1991) found that parental involvement mediated the effect of preschool intervention on reading and mathematics achievement during the first 2 years of primary school and the effect of children's achievement motivation during kindergarten on academic achievement in first grade.

Ecological Influences on Parenting and Child Development

Intervention strategies that aim to prevent and ameliorate the negative effects of poverty on children's development traditionally have concentrated on providing direct educational experiences to children and modify-

ing the parenting practices and home environment to which poor children are subject, without major regard for contextual, extrafamilial factors impinging on parents and their children. This perspective and its implicit disavowal of the need to change contextual factors and social systems has always had its critics, though they typically have been a minority voice (Chilman, 1973). During the late 1960s and early 1970s, a handful of demonstration models evinced some degree of departure from this traditional approach (Andrews et al., 1982). In addition to parent education and educational experiences for preschoolers, they offered social services to the entire family and attempted to remediate extrafamilial obstacles to optimal parent and child functioning (Halpern, 1988).

It was not until the 1980s, however, that an ecological perspective achieved notable currency in early childhood intervention. At the heart of this shift was increased appreciation of stress, social support, and broader contextual factors as determinants of parenting behavior, on the one hand, and as conditioners of parents' and children's ability to profit from an intervention program, on the other (Bronfenbrenner, 1975; Chilman, 1973; Halpern, 1984). An overarching goal is improvement of the social and economic context of parenting and children's development. Ecologically sensitive intervention is a highly diverse genre, but a few common denominators distinguish programs in this category. They tend to be expansive in focus (i.e., family-focused rather than child- or parent-focused) and offer a broad complement of services. Emphasis is given to prevention rather than treatment as a cost-effective approach to human service delivery. In addition, these programs claim espousal of a nondeficit orientation dedicated to building on families' strengths rather than simply remediating their weaknesses, though questions exist about whether this is a substantive change or a public relations maneuver (D. Powell, 1988).

A multiplicity of strategies are employed to increase supports and reduce stressors at multiple levels of proximity to the parent, child, and entire family (e.g., psychological, sociological, economic, home, neighborhood, workplace). These include direct provision of emotional support to parents and other family members, facilitation of peer support and social networks, assistance of family members in gaining access to and using educational, health, and social services in the community, reinforcement of links between families and both formal and informal sources of support, and mediation between

the family and more distal bureaucracies to help families obtain needed services. Considerable variation exists across programs, however, in the degree of emphasis given to each of these services (Halpern, 1990b; Kagan, Powell, Weissbord, & Zigler, 1987).

As a form and component of early childhood intervention, parent education also broadened its focus to include ecological factors. By the early 1980s, many parent education programs sought to improve parent functioning via provision of social support to parents, not just dissemination of information about child rearing and the principles of child development. D. Powell (1988) identified two variants of the family/parent support approach that emerged during this period. In the first, the assumption is that parents lack confidence in their child-rearing beliefs and practices. Rather than attempting to modify parental behavior and attitudes in accord with some ideal notion of what a parent should do with children, these programs provide validation and affirmation of the parent's existing child-rearing beliefs and behaviors on the assumption that this alone is sufficient to enhance parental behavior and attitudes. Such programs attempt to replicate some elements of informal support systems traditionally available through networks of friends and family. In the second variant, programs provide social support as a means to increase parents' receptivity to expert information and advice, on the grounds that high levels of stressors and low support inhibit parents' ability to attend to the curriculum content of parent education programs.

The trend toward more ecological approaches to poverty-focused early childhood intervention is part of a broader "family support" movement that surged during the 1980s. Family support programs share the characteristics, emphasis, and perspectives of ecologically sensitive early childhood intervention programs but are distinctive in one major regard. They are committed to universal (rather than means-tested) access to family support services on the grounds that economic and social changes have created widespread support needs that transcend social class and economic boundaries (e.g., increases in costs of living that necessitate two paychecks to maintain a middle-class standard of living; increased geographic mobility that has reduced the availability of extended family members for provision of myriad kinds of support; increase in divorce and single-parent families). Head Start, especially its demonstration models, laid the foundation for the principles underlying the family support movement (Kagan et al., 1987).

The late 1970s and 1980s also brought a broadening of the developmental outcomes considered in both basic and intervention research. With the burgeoning of intervention programs during the late 1960s and early 1970s, several scholars questioned the preoccupation with cognitive enrichment. They asserted that socioemotional factors (e.g., impulsivity, noncompliance) contributed as much to school failure as the lack of academic skills and, hence, that studied attention should be extended to socioemotional functioning and the overall development of poor children and their parents (Chilman, 1973; Zigler & Berman, 1983). Interest in the impact of early interventions on children's socioemotional functioning exploded during the 1980s, strengthened by rising rates of crime, violence, and antisocial behavior among youth; the growing availability of longitudinal data on preschool intervention effects during late adolescence and early adulthood, when antisocial behavior tends to peak (e.g., Berrueta-Clement et al., 1984; Johnson, 1988); and advances in the measurement of socioemotional functioning. Gains in cognitive functioning continue to be regarded as critical indicators of the efficacy of early childhood interventions, but they no longer eclipse a focus on socioemotional outcomes.

In the following section, we discuss conceptual and empirical work that triggered and sustained the evolution toward more ecologically oriented approaches in early childhood intervention for poor children and families. We then turn to an appraisal of different categories of interventions whose content reflects some of the hallmarks of this approach.

Precursors of an Ecological Approach to Early Childhood Intervention

A confluence of factors have been credited for the evolving direction of early childhood intervention toward a more ecological approach (Bronfenbrenner, 1987; Halpern, 1990a; D. Powell, 1988), among them: (a) prominent model programs developed in the late 1960s that exemplified and documented positive effects of ecologically oriented intervention (Andrews et al., 1982; Seitz, Rosenbaum, & Apfel, 1985); (b) Bronfenbrenner's (1975) assertion that ecological intervention and parenting support are essential to effecting positive change in the course of poor children's development and his subsequent elaboration of an ecological model of human development (Bronfenbrenner, 1979); (c) empirical evidence that family processes, including parenting

behavior, and children's development can be undermined by stressful events and conditions, including those that occur in extrafamilial settings; (d) empirical evidence that the availability and provision of social support from immediate family members, and persons outside the immediate family such as kin, friends, and neighbors, can enhance psychological functioning and parenting behavior under ordinary and stressful conditions; and (e) persistent criticisms of the deficit model and evidence of its negative effects. We discuss each of these factors, although this is not to suggest that individual interventionists are cognizant necessarily of how these factors have shaped their efforts. Indeed, although the work reviewed here provides strong underpinnings for the policies and practices governing ecologically oriented intervention, its contributions to some of the basic concepts underlying these programs and to some of the programs themselves often have gone unrecognized (Bronfenbrenner, 1987).

Early, Prominent Demonstration Models. Research findings on SES differences in parenting practices and the relations between parenting practices and child development, discussed previously, were widely disseminated among policymakers during the mid-1960s by a cadre of pediatricians, developmental psychologists, and other social scientists. These dissemination efforts, along with the disappointing findings of the Westinghouse evaluation, prompted the Office of Economic Opportunity, and later the Office of Child Development and its successor, the Administration for Children, Youth, and Families, to launch several experimental demonstration projects focused on early parenting in poor families (Halpern, 1988). They included the Parent and Child Centers (PCCs), followed by the Parent and Child Development Centers (PCDCs), and later, the Child and Family Resource Programs (CFRPs). Carefully conceived, implemented, and evaluated to enhance the probability of replication if they proved effective (all were randomized trials), these programs are rightly credited as forerunners of the current family/parent support movement and the source of some of the best evidence about the conditions of effective parent education and support (Halpern, 1988; Zigler & Freedman, 1987).

The PCCs, established in 1967 as the first Head Start experimental programs designed to serve very young children (infants to 3-year-olds) and their families, were multipurpose family centers (about 33 were

established) that provided parent education, health, and social services. Whereas center-based Head Start was seen as remedial, the PCCs reached poor children during the earliest years of life and, hence, were regarded as preventive. This initiative was envisioned as a nationwide program, but its expansion was prevented by shifting political forces and bureaucratic reorganization (Halpern, 1988).

In 1970, three PCCs (located in Birmingham, Houston, and New Orleans) were selected to become experimental Parent and Child Development Centers. Their general purpose was to define the goals of parent-infant intervention, develop different approaches to meet these goals, and establish appropriate evaluation strategies. The centers adopted different methods of program delivery (i.e., in Birmingham, a step system of increasing maternal responsibility for program work, culminating in staff positions; in New Orleans, involvement of paraprofessionals from the community; in Houston, a year of home visits, followed by a year of center programs for both mother and child), but all served families with children from birth to 3 and were developed and implemented within a common framework that emphasized the role of parents in children's development. Core components in all the centers were (a) a comprehensive curriculum for mothers consisting of information on child development and child-rearing practices, home management, nutrition and health, mothers' personal development, and government and community resources (e.g., community colleges) and how to use them; (b) a simultaneous program for the children of these women (ranging in age from 2 to 12 months at the time of entry into the program); and (c) extensive supportive services for participating families, including transportation, some meals, family health and social services, peer support groups, and a small, daily stipend. The programs varied in the amount of weekly participation expected and ended when the child was 36 months of age (Andrews et al., 1982).

Evaluations of short-term effects showed that program children scored higher than control children on the Stanford-Binet, although this difference reached statistical significance in only two of the three sites. In general, immediate effects of the PCDC intervention were stronger for mothers than their children. At graduation, program mothers in all three PCDCs showed more positive maternal behavior than controls in videotaped interactions with their children (e.g., giving child praise and emotional support, being affectionate and accepting,

encouraging child's verbal communications, participating actively in child's activities, greater use of language to inform rather than restrict and control child; Andrews et al., 1982). In a follow-up of children in the Houston PCDC when they were in grades 2 through 5, 5 to 8 years after program completion, positive effects were found for children's academic and socioemotional functioning. Compared to the control group, program children scored significantly better on standardized achievement tests and were reliably more considerate of others, less hostile, restless, impulsive, and obstinate, and less likely to be involved in fights (Johnson, 1988). However, a subsequent comprehensive follow-up of all three PCDC samples found no residual program effects on a number of child and family variables (Halpern, 1990b). Efforts to replicate the centers on a broad scale were abandoned, despite evidence of their short-term efficacy, because of budgetary pressures and concerns about their costliness and generalizability (G. Fein, 1980; Halpern, 1988).

The Child and Family Resource Program, initiated in 1973 and funded through 1983, had as its core a 2-year program of bimonthly to monthly home visits for families with infants from birth to 3. Its distinguishing features were (a) an emphasis on parent support and education (e.g., information on prevention and identification of child abuse, domestic management, use of community services), including helping parents resolve serious family problems (e.g., poor health, substandard housing, alcoholism); (b) stress on developmental continuity by providing services before birth and continuing them into elementary school; (c) coordination of comprehensive social services provided directly and via referrals; and (d) an attempt to individualize services through needs assessment and goal setting with each family. Referrals for adult education, literacy, and job training were made by case managers as needed, but this was not a strong component of the program. Each of the 11 local programs was linked to Head Start centers, where 3- to 5-year-olds in the program attended preschool. Once children began elementary school, staff personnel maintained contact with parents to maximize their involvement in their child's academic progress (St. Pierre et al., 1995; Zigler & Freedman, 1987).

Effects of the program on children were much weaker than those produced by the PCDCs, probably because children received fewer direct services and only uneven attention was given to parent-child interaction. The CFRP had no significant effect on children's Bayley scores or on several other measures of development,

health, and behavior. However, the program had significant, positive effects on parenting behavior, feelings of efficacy, and perceived ability to control events. Rate of maternal employment and training, but not household income, also favored program mothers, though this difference was modest (St. Pierre et al., 1995).

Bronfenbrenner's Analyses. In his analysis of the effectiveness of early intervention, Bronfenbrenner (1975) selected for special attention the famous Skeels (1966) experiment and the extremely invasive and controversial Milwaukee Project (Garber, 1988) to illustrate the potential of ecological interventions to promote cognitive functioning. He noted:

[The] "enabling act" took the form in both instances, of a major transformation of the environment for the child and the persons principally responsible for his care and development. . . . The essence of the strategy [of ecological intervention] is a primary focus neither on the child nor his parent nor even the dyad or the family as a system. Rather, the aim is to effect changes in the context in which the family lives; these changes in turn enable the mother, the parents, and the family as a whole to exercise the functioning necessary for the child's development. . . . The need for ecological intervention arises when the . . . prerequisites [for the family to perform its child-rearing functions] are not met by the environment in which the child and his family live. This is precisely the situation which obtains for many, if not most, disadvantaged families. Under these circumstances no direct form of intervention aimed at enhancing the child's development or his parents' childrearing skills is likely to have much impact. Conversely, once the environmental prerequisites are met, the direct forms of intervention may no longer seem as necessary. (pp. 584-585)

Bronfenbrenner noted further that ecological intervention is rarely carried out because it "almost invariably requires institutional change" (p. 586).

He continued his theme concerning the importance of the family's ecology on children's development in a subsequent analysis focusing on basic research. Drawing on a theoretically convergent body of research, Bronfenbrenner (1979) argued compellingly that children's development is influenced not only by the family system, but by systems well removed from the family's control, among them, parents' workplace, neighborhoods, schools, available health and day care services, and macroeconomic forces that result in stressors such as parental unemployment and job and income loss. He

exhorted researchers to take seriously the potency of the family's ecology by undertaking multilayered, contextual, and more process-oriented analyses of family relations and children's development. Two scholarly contributions were pivotal in sustaining interest in ecological influences, namely Ogbu's (1981) cultural-ecological model, underscoring the potency of extrafamilial forces on the socialization and development of poor African American children, and W. J. Wilson's (1987) historical analyses of changes in the economic character of inner-city neighborhoods and his speculations about the implications of these changes for social norms and children's development (e.g., Brooks-Gunn, Duncan, Klebanov, & Sealand, 1993).

Research on Relations among Stressors, Parenting, and Adult Psychological Functioning. A rich body of research produced during the 1970s and 1980s provided compelling support for the contention that undesirable events and conditions compromised adults' mental health and hence, their parenting behavior and that social support lessened these compromising effects. In the following sections, we highlight some of the most prominent research documenting these relations.

Adverse Events/Conditions as Determinants of Parenting. A considerable amount of research documenting the effects of undesirable life events and chronic conditions on both adult psychological functioning and parenting focused on economic stressors, prompted in part by the economic downturns of the late 1970s and early 1980s (McLoyd, 1989). The most influential work published during this period concerned economic hardship as experienced during the Great Depression of the 1930s. In that research, Elder and his colleagues (Elder, 1974; Elder, Liker, & Cross, 1984) found that fathers who lost jobs and sustained heavy financial loss became irritable, tense, and explosive, which in turn increased their tendency to be punitive and arbitrary in the discipline of their children. These fathering behaviors were predictive of temper tantrums, irritability, and negativity in young children, especially boys, and of moodiness and hypersensitivity, feelings of inadequacy, and lowered aspirations in adolescent girls.

Elder et al.'s (1984) basic causal pathway linking economic loss and economic hardship more generally to the child through the parent's behavior has been replicated in several studies of ethnically diverse contemporary families (Conger et al., 1993; Gutman et al., in press; Lempers, Clark-Lempers, & Simon, 1989). In

Lemper et al.'s study of White working- and middle-class families, for example, economic loss led to higher rates of adolescent delinquency and drug use by increasing inconsistent and punitive discipline by parents.

Further corroboration of the link between economic loss and parenting comes from studies of child abusers and investigations of the relationship between the status of an economy (e.g., unemployment rate, inflation rate) and rates of child abuse. These investigations are consistent in showing that child abuse occurs more frequently during periods of undesirable economic change and in families experiencing economic decline (i.e., job and income loss) than in families with stable resources (Parke & Collmer, 1975). Negative life events and daily hassles more generally were also found to predict lower-quality parenting (e.g., less responsive, more restrictive, and punitive parenting; for example, Gersten, Langner, Eisenberg, & Simcha-Fagan, 1977; G. Patterson, 1988). Adverse events/conditions were also linked to the quality of the home learning environment. Reminiscent of the inverse relationship found between children's IQ and number of risk factors (Sameroff, Seifer, Barocas, Zax, & Greenspan, 1987), Brooks-Gunn et al. (1995), for example, found that as the number of risk factors experienced by the parents increased (e.g., incidence of stressful life events, parental unemployment), the less stimulating the preschooler's home environment.

Psychological Distress as a Mediator of the Adversity-Parenting Link. Several studies conducted during the late 1970s and 1980s yielded direct as well as indirect evidence that psychological distress mediates the link between negative life events/conditions and harsh, inconsistent parenting. This mediational process was clearly demonstrated in work on economic hardship precipitated by parental job and income loss (Conger et al., 1993; Elder, 1974; Lempers et al., 1989) and was thought to operate more generally across a range of stressors. Two types of evidence are relevant to this proposition: research linking adverse events/conditions to adult psychological functioning and investigations documenting an association between parents' psychological functioning and parenting behavior.

A plethora of studies reported strong positive relationships between negative life events/conditions and psychological distress in adults, as indicated by depression, anxiety, hostility, somatic complaints, eating and sleeping problems, and low self-regard (e.g., Kessler & Neighbors, 1986; Liem & Liem, 1978). Parenthetically, several studies conducted during this period found a

strong link between negative life events/conditions and psychological distress (including school adjustment problems) in children (e.g., Sandler & Block, 1979; Sterling, Cowen, Weissberg, Lotyczewski, & Boike, 1985). Complementing these studies of adults was evidence linking fluctuations in unemployment rates to aggregate-level indices of psychological distress (e.g., admissions to psychiatric hospitals; Horwitz, 1984). Research demonstrated cogently that these are true effects and not simply selective factors that lead to job loss or unemployment (e.g., Kessler, House, & Turner, 1987).

Turning to the second line of research, enormous amounts of data were generated during the 1980s about how parents' affective states condition the quality of parent-child interaction. These data, most from mothers of infants and preschoolers, directly tied negative psychological states in the parent (e.g., depressive symptoms, as well as clinical depression) to greater parental punitiveness, inconsistency, and unresponsiveness, less reliance on reasoning and loss of privileges in disciplining the child, more negative perceptions of the child, and greater use of conflict-resolution strategies that require little effort, such as dropping initial demands when the child is resistant or enforcing obedience unilaterally rather than negotiating with the child (Downey & Coyne, 1990; McLoyd, 1990). The relationship between psychological distress and parenting is robust, for it has been found to exist in samples of poor individuals where the range of scores is generally more restricted (Crockenberg, 1987; Zelkowitz, 1982).

Parallels between Correlates of Poverty and Correlates of Adverse Events/Conditions. By the mid-1980s, the inverse relationship between SES (and poverty) and various forms of psychological distress was well established. In addition, enough data existed to conclude that the poor's increased exposure to negative life events and chronic conditions was a major cause underlying this relationship (Liem & Liem, 1978). Researchers documented that poor and low SES individuals were more likely than economically advantaged counterparts to be confronted with an unremitting succession of negative life events (e.g., eviction, physical illness, criminal assault, catastrophes resulting from substandard housing) in the context of chronically stressful life conditions outside personal control, such as inadequate housing and dangerous neighborhoods. It was also clear from research that psychological impairment was more severe when negative conditions and events were not under the

control of the individual, a condition more common for the poor (Liem & Liem, 1978). Ongoing stressful conditions associated with poverty and low SES, such as inadequate housing and shortfalls of money, were found to be more debilitating than acute crises and negative events (e.g., Makosky, 1982). In some studies, after chronic stressors were controlled, the effects of life events on psychological distress were diminished to borderline significance (e.g., Gersten et al., 1977; Pearlin, Lieberman, Menaghan, & Mullan, 1981).

If poverty and low SES are markers for a conglomerate of negative life events and chronic stressors and are predictive of higher levels of psychological distress, they should predict child-rearing behaviors and attitudes similar to those linked to specific negative life events, undesirable conditions, and psychological distress as discussed earlier. Abundant evidence accumulated over 3 decades confirms this expectation. These studies found that mothers who are poor or from low SES backgrounds, compared to their economically advantaged counterparts, are more likely to use power-assertive techniques in disciplinary encounters and are generally less supportive of their children. They value obedience more, are less likely to use reasoning, and are more likely to use physical punishment as a means of disciplining and controlling the child. Lower-class parents also are more likely to issue commands without explanation, less likely to consult the child about his or her wishes, and less likely to reward the child verbally for desirable behavior. In addition, poverty has been associated with diminished expression of affection and lesser responsiveness to the socioemotional needs explicitly expressed by the child (Gecas, 1979; Hess, 1970).

Parallels between poverty and low SES, on the one hand, and specific negative life events, undesirable conditions, and psychological distress, on the other, also were found for child abuse. Poverty, like job and income loss, is a significant predictor of child abuse (e.g., Garbarino, 1976). Indeed, it is the single most prevalent characteristic of abusing parents, although it is indisputable that only a small proportion of poor parents are even alleged to abuse their children (Pelton, 1989). Several kinds of data generated during the late 1970s and 1980s contradicted the claim that the relationship between poverty and abuse is spurious because of greater public scrutiny of the poor and resulting bias in detection and reporting. First, although greater public awareness and new reporting laws resulted in a significant

increase in official reporting in recent years, the socio-economic pattern of these reports has not changed (Pelton, 1989). Second, child abuse is related to degrees of poverty even within the lower class, which admittedly is more open to public scrutiny; abusing parents tend to be the poorest of the poor (Wolock & Horowitz, 1979). Third, the most severe injuries occur in the poorest families, even among the reported cases (Pelton, 1989).

In sum, research conducted during the 1970s and 1980s yielded a trove of evidence that poor and low SES individuals are more likely than their economically advantaged counterparts to experience negative life events, undesirable chronic conditions, and psychological distress and that these factors are conducive to less nurturant and more punitive parenting. In addition, the findings of several studies lend support to the hypothesis that child-rearing practices associated with poverty and low SES are partly a function of higher levels of psychological distress brought on by elevated exposure to negative life events and undesirable chronic conditions (McLoyd, 1990). These data, with their clear implications for practice, commanded the attention of the early childhood intervention field. They suggested that in some cases, stressors and their attendant psychological distress can override knowledge of the principles of child development as a determinant of parenting and that removal or amelioration of acute and chronic stressors can be highly effective as a strategy to improve parenting, and presumably child functioning. The multidimensionality of poverty and the conglomeration of acute and chronic stressors experienced by the poor accented the poor's need for a broad range of concrete services. These factors also suggested that service delivery should be integrative in approach (e.g., collaboration among individual service providers and clients in developing intervention and evaluation plans; close proximity of service delivery sites) so that it is not yet another source of stress.

Research on Social Support as a Contributor to Positive Psychological and Maternal Functioning. Empirical research on social support as a determinant of adults' psychological well-being, family functioning, and parenting behavior, as well as ecological models of the determinants of parenting (Belsky, 1984) and family coping patterns (Barbarin, 1983), were powerful stimulants of interventionists' interest in the social context of parenting. Several of the interpersonal-level strategies chosen to promote poor children's development indi-

rectly through the parent (e.g., peer support, strengthening self-help networks, reinforcing links between families and sources of support) are rooted in this vast literature. They also have been informed by qualitative research that developed methods for professionals to identify and recruit natural helpers in social networks, to collaborate in the matching of needs and resources in neighborhoods, and to link with formal agencies as needed (Watson & Collins, 1982).

The first set of findings from empirical research that proved to be highly significant to the field of early childhood intervention concerned the role of social support as a buffer against the negative effects of stress. Inspired by Caplan's (1974) thesis that social support is a protection against pathology, several studies were published during the late 1970s and thereafter indicating that social support buffered psychological distress among individuals under stress, including unemployed adults (e.g., Kessler et al., 1987) and mothers on welfare (e.g., Zur-Szapiro & Longfellow, 1982). A second set of studies documented naturally occurring patterns of informal help seeking (e.g., Cowen, 1982) and poor African Americans' heavy reliance on kinship ties and social networks for primary support and mutual aid (Barbarin, 1983; Stack, 1974).

A third set of studies based on low-income as well as economically advantaged families demonstrated the salutary effects of various forms of social support on parents' behavior toward their children (main effect, rather than a buffering effect). Emotional support (i.e., companionship, expressions of affection, availability of a confidant) and parenting support (e.g., assistance with child care), for example, were linked to improved mental health in mothers, increases in maternal sensitivity and nurturance, and decreases in coercive discipline (Crnic & Greenberg, 1987; Zur-Szapiro & Longfellow, 1982). Parenting support was also linked to increases in the mother's ability to give effective directions to the child and her effectiveness in getting the child to conform to rules (Weinraub & Wolf, 1983).

Indirect evidence of the salutary effects of social support emerged from the research literature on child abuse as well. Studies reported that parents who abused their children, compared to nonabusing parents, were more isolated from formal and informal support networks, less likely to have a relative living nearby, and usually had lived in their neighborhood for a shorter period (Gelles, 1980). This research suggested that in addition to indirectly preventing child maltreatment by

enhancing parents' psychological functioning, members of parents' social networks directly inhibit child abuse by purposive intervention. Network embeddedness increases detection of child abuse, and a strong sense of obligation fosters direct intervention in the interest of the child (E. P. Martin & Martin, 1978). Sometime later, studies documented that children accrued benefits from naturally occurring social support systems (e.g., Cowen, Wyman, Work, & Parker, 1990). For example, researchers found that availability of child care support to the primary caregiver distinguished stress-resilient from stress-affected children (Cowen et al., 1990). Increased parenting or emotional support, and more nurturant parenting behavior as a result, may explain why emotional adjustment in poor African American children living in mother/grandmother families is almost as high as that of children living in mother/father families, and significantly higher than that of children living alone with the mother (Kellam, Ensminger, & Turner, 1977). In general, though, the bulk of the evidence suggests that parents' social networks have more indirect than direct effects on the child through their effects on the mother (M. Wilson, 1989).

Although the research literature provided incontrovertible evidence that social support enhances psychological and maternal functioning, it also sounded a number of cautionary notes that merit careful attention from those formulating and implementing programs that rely on the creation and strengthening of social support systems for families under stress. First, the protective effects of social support vary by context and circumstance. Support relationships exert a more positive influence on emotional and parental functioning when psychological distress is relatively low (Crockenberg, 1987), during times of major life transitions (Crnic & Greenberg, 1987), and when the source of stress is an event rather than a chronic condition such as persistent poverty or economic hardship (Dressler, 1985). Second, support from individuals who are also major sources of distress reduces the effectiveness of the support (Belle, 1982; Crockenberg, 1987). Likewise, embeddedness in an extended family network, though generally providing economic and psychological benefits, is not without its psychological and material costs. These costs include feeling burdened by obligations to the extended family, feeling exploited by those who want more than they need or deserve, disagreement concerning the need for and/or use of aid, and disapproval by extended family members of potential marital partners and child-rearing practices and decisions (Stack, 1974). Hence, although parent/

family support was greeted with enthusiasm and high hopes as a balm for the problems of the poor, the research literature sounded some sobering notes that called for, at the very least, guarded optimism.

Persistent Criticisms and Negative Effects of the Deficit Model. Criticism of the deficit model on which early childhood intervention was premised continued relentlessly through the 1970s and 1980s, although the nature and practice implications of these criticisms varied (Bronfenbrenner, 1987; Halpern, 1988; Laosa, 1989; Washington, 1985). To the extent that early childhood intervention in general has been torn away from its deficit-based moorings—an issue of some debate still—the variant that was most potent in forging this change argued that "failures" in the social environment, not personal deficiencies, were responsible for the problems of the poor. Its effect was to direct attention to the social ecology of poor families, rather than the individual, as the primary target for transformation (D. Powell, 1988).

This perspective, combined with the notion of empowerment of poor parents, is the essence of the compensatory model of helping articulated by Brickman and his colleagues (1982). The core tenet of this model is that people are not blamed for their problems but are held responsible for solving the problems by compelling an unwilling social environment to yield needed resources. People are seen and see themselves as having to compensate, via effort, ingenuity, and collaboration with others, among other strategies, for the hardships and obstacles imposed on them. Likewise, people who help others under the assumptions of this model see themselves as compensating by providing assistance and opportunities that the recipients deserve, but somehow do not have. However, the responsibility for using the help and determining whether the help is successful is seen to lie with the recipients. This ideological perspective is embodied in Jesse Jackson's repeated assertion to urban, economically distressed African Americans, "'You are not responsible for being down, but you are responsible for getting up'" and "'Both tears and sweat are wet and salty, but they render a different result. Tears will get you sympathy, but sweat will get you change'" (quoted in Brickman et al., 1982, p. 372).

An evolving orientation toward transformation of the environment, rather than the individual, was also a product of growing awareness of the ill effects of the deficit or person-blame model. In contrast to the beneficial effects of emotional support from family and friends, several investigations found use of community/neighborhood ser-

vices to have no enhancing effect on the psychological well-being and parenting behavior of adolescent mothers (e.g., Colletta & Lee, 1983; Crockenberg, 1987). In fact, in one study, adolescent mothers were more dissatisfied with professionals than any other group of helpers. Health professionals were often seen as unsympathetic, impatient, disapproving, uninformative, and offering parenting advice that contradicted that of family members or other professionals. In essence, they provided these mothers little, if any, emotional, informational, or instrumental support and, hence, had no salutary effect on their mental health or parenting (Crockenberg, 1987).

Evidence that attribution biases moderated the impact of economic hardship on adults' psychological functioning also served notice of the dysfunctionality of person-blame attributions. For example, researchers found that men who held themselves responsible for their loss of income or a job (e.g., Buss & Redburn, 1983; Cohn, 1978) and poor African American women who blamed themselves for being on welfare (Goodban, 1985) had more psychological and physical health problems than those who did not blame themselves for their economic difficulties. Extrapolating from these findings, professional helpers who covertly and overtly heap blame on poor parents for their difficult circumstances essentially compromise their avowed mission, because such attributions, reflected in behaviors and attitudes, render them less effective in ameliorating psychological and parenting problems.

Evaluations of Ecologically Oriented Interventions

The research just discussed helped illuminate the ecology of poor families and the multidimensionality of family poverty. As such, it increased understanding of the pathways by which poverty influences children's development and expanded the focal targets of change to include concrete conditions, social circumstances, and other features of the ecology. It also nurtured an appreciation of the heterogeneity of the poverty population and, hence, a tendency toward developing programs for distinct subgroups within the poverty population. In Schorr's (1989) qualitative evaluation of a broad cross-section of programs for poor children and families, whose services spanned the gamut from health, social services, and family support to education, programs judged to be most effective in increasing positive outcomes for poor children were all predicated on an ecological model. Specifically, they typically offered a broad spectrum of coherent, easy-to-use services (rec-

ognizing that social and emotional support and help with concrete problems such as food and housing are often prerequisites to a family's ability to make use of other interventions such as parenting education); provided help to parents as adults so they could make good use of services for their children; and allowed staff members to exercise discretion, redefine their roles, and cross traditional professional and bureaucratic boundaries to respond to clients' needs. Given these characteristics, Schorr's conclusion that many highly successful interventions are "unstandardized and idiosyncratic" (p. 268) is not surprising.

In the sections that follow, we focus attention on the effects of two categories of ecologically oriented interventions that proliferated during the 1980s and 1990s: home visitation programs and two-generation programs. They are but a small sampling of a variety of ecologically oriented programs for poor children and families, but are of special interest because of their comparatively strong research designs and because several have been subject to intensive evaluation.

Home Visitation Programs. As noted previously, home visitation programs date back at least to the second half of the nineteenth century, when well-to-do women associated with private relief agencies and charity organizations made home visits to poor families "to provide a mixture of support, scrutiny, and advice" (Halpern, 1988, p. 285). This helping strategy was revitalized during the late 1970s and 1980s, when several home visitation programs were erected to promote positive functioning in poor mothers and children and prevent several problems associated with poverty. In 1989, the federal government responded to the growing popularity of these programs by authorizing funding of home visitation for pregnant women and infants, by which time a number of state governments had begun supporting maternal and child home visitation programs with Medicaid dollars (Olds & Kitzman, 1990). Home visitation programs are of particular interest because they permit within- and across-study comparisons of the relative effectiveness of programs that are more or less ecological in their approach.

Effects on Maternal Teaching and Children's Cognitive Development. Several studies exist of randomized trials with poor families that aimed to promote cognitively stimulating mother-child interaction and, in turn, children's cognitive development either through parent education alone (e.g., Scarr & McCartney,

1988) or a combination of parent education and social support (Barnard, Magyary, Sumner, & Booth, 1988; Olds, Henderson, Chamberlin, & Tatelbaum, 1986a). Both types of interventions have produced positive effects on maternal parenting and teaching behaviors and on children's cognitive functioning. In general, though, programs that address the broader ecology of the family by providing parent education as well as social support (e.g., help locating needed community resources; establishing a therapeutic alliance between mother and nurse home visitor) produce stronger and more enduring effects on mothers' parenting and teaching behavior and children's cognitive functioning than programs that provide parent education only, or parent education combined with minimal social support (e.g., referrals without establishment of a therapeutic alliance; Olds & Kitzman, 1993; Schorr, 1989). Note that in this schema, provision of parenting education is the distinguishing feature of the ecological approach, with social support provided in both categories of programs. Across-program comparisons also suggest that home visitation programs that target poor families at particularly high risk of parenting problems (e.g., unmarried adolescent mothers living alone with child; drug-addicted mothers) are generally more effective than those focusing on heterogeneous groups of poor children and families (for a more detailed review of efficacy studies of these programs, see Olds & Kitzman, 1990, 1993).

Sweet and Applebaum's (2004) recent meta-analysis of the efficacy of 60 home visiting programs for families with young children points to the advantages to children of programs that target specific populations. Although their analysis is not constrained to the poverty population, 55% of the programs represented in their meta-analysis targeted low-income families. Sweet and Applebaum found that programs that targeted specific populations (e.g., families with a low birthweight child, families with low income, and teenage mothers) had stronger effects on children's cognitive functioning than programs in which families were universally enrolled. Effects on children's cognition outcomes were also larger when families were visited by professionals (as compared to families visited by nonprofessionals), were visited more frequently, and had more hours of visits. However, findings for child outcomes did not necessarily mirror findings for parenting behavior. For example, programs that targeted specific populations had stronger effects on children's

cognitive functioning than programs in which families were universally enrolled, but for parenting behavior, the effect was reversed. That is, effect sizes for parenting behavior were significantly larger when families were universally enrolled than when families were targeted in some way. Moreover, programs that targeted low-income families were less successful in enhancing parenting behavior than programs not targeting low-income families.

Sweet and Applebaum's (2004) meta-analysis also reaffirms the challenge of fostering maternal and child functioning in the same program. Programs in which maternal life enhancement was a primary goal produced larger effects on parenting behavior (i.e., programs in which maternal social support and maternal self-help were primary objectives) but smaller effects on children's cognitive functioning (i.e., programs in which maternal self-sufficiency and maternal self-help were primary objectives) than programs in which these goals were not primary. This finding echoes earlier syntheses of extant research suggesting that interventions that rely solely on parent-mediated routes to increase children's cognitive competencies produce less positive and enduring effects than interventions that provide direct learning experiences to children (C. Ramey et al., 1995; Wasik et al., 1990).

Effects on Child Maltreatment. The public institution charged with protecting the welfare of dependent, neglected, and abused children is the public child welfare system. In response to criticism that child welfare agencies devote insufficient effort to placement prevention and provide care of questionable quality to children who have been removed from their own home, the Adoption Assistance and Child Welfare Act was passed in 1980. It mandated that a certain portion of funding of child welfare agencies must be allocated to services intended to reduce the need for placement of children in foster care, reunify families, and find adoptive families for those children who cannot return home. Family-centered, home-based service programs are among the options available to meet these requirements. These programs focus on the family system, not just the mother, and its social and physical context as the target for change. They typically provide counseling and concrete services such as homemakers and day care. Unfortunately, very few well-designed studies exist of the effectiveness of this approach versus more traditional approaches in preventing child placement. Existing eval-

uations tend to be seriously flawed (e.g., lack of comparison or control groups, inadequate descriptions of service activities; H. Frankel, 1988).

One of the higher-quality studies of the effectiveness of different approaches to prevention of child abuse and placement used a design reminiscent of the one employed by Olds et al. (1986a) in their study of intervention effects on preterm delivery and low birthweight. D. A. Wolfe, Edwards, Manion, and Koverola (1988) assessed the relative effects of support services alone versus parent education combined with support services on the parenting behavior of mothers who were under supervision from a child protective service agency because public health nurses suspected that a child living in the home was at high risk of maltreatment. In addition to receiving standard agency services (e.g., informal discussion of topics related to health and family, social activities, periodic home visits from caseworkers), mothers in the parent education intervention received didactic instruction and exposure to modeling and rehearsals procedures to increase positive child management skills (e.g., rewarding compliance, using more praise and less criticism, giving concise demands). Results indicated that, in comparison to mothers who received only standard agency services, mothers in the parent education intervention had more positive attitudes and feelings about parenting and reported less depressive symptomatology, though the two groups did not differ on their child-rearing methods as assessed by home observation. One year following treatment, caseworkers rated mothers in the parent intervention group as managing their children significantly better and at lower risk for maltreating the child than mothers in the comparison group.

These findings are in general accord with those from a randomized trial of nurse home visitation of primiparas mothers who were either teenagers, unmarried, or of low SES (Olds, Henderson, Chamberlin, & Tatelbaum, 1986b). One group received home visits once every 2 weeks during pregnancy. For a second group, home visits continued with decreasing frequency until the child was 2 years of age. During these visits, nurses provided mothers with information about infants' development and socioemotional and cognitive needs (e.g., crying behavior and its meaning; infant's need for progressively more complex motor, social, and intellectual experiences), encouraged involvement of relatives and friends in child care and support of the mother, and connected families with community health and human ser-

vice agencies. Among poor, unmarried teenage mothers, those who were visited by a nurse had fewer instances of verified child abuse and neglect during the first 2 years of the child's life, reported less conflict with and scolding of their 6-month-old infants, and were observed in their home to restrict and punish their children (10- and 22-month-olds) less frequently and to provide more appropriate play materials, compared to those who received either no services or only free transportation to medical offices for prenatal and well-child care. In addition, during the 2nd year of life, regardless of the family's risk status, babies of nurse-visited women were seen in the emergency room less frequently and were seen by physicians less frequently for accidents and poisoning. However, differences in rates of maltreatment did not persist during the 2-year period after the program ended.

Notwithstanding the short-term positive findings from these two studies, randomized trials of programs designed to prevent child maltreatment generally do not demonstrate overall decreases in maltreatment, as evidenced by state child protective services records (Olds & Kitzman, 1990, 1993). Some have found differences that are suggestive of a reduction in maltreatment, such as lower rates of severe diaper rash (Hardy & Streett, 1989) or decreased use of medical services associated with child abuse and neglect (e.g., hospitalizations for serious injury; J. Gray, Cutler, Dean, & Kempe, 1979; Hardy & Streett, 1989). In their detailed review of these randomized trials, Olds and Kitzman (1993) detected no clear pattern in findings as a function of program characteristics (e.g., comprehensiveness, intensity), but noted that two of the programs that produced positive effects in a subsample of women or on at least some variables associated with abuse and neglect employed especially well-trained home visitors who remained through the course of the study. Sweet and Applebaum's (2004) meta-analysis yields additional insights about this general issue. They found that programs were more effective in preventing or reducing the incidence of child abuse if prevention of child abuse was a primary objective of the program, if the home visitors were paraprofessionals rather than professionals, and if low-income families as well as families at risk of child abuse or neglect were targeted. Surprisingly, programs that had maternal social support as a primary goal were less effective in lowering the potential for child abuse than programs not listing this as a primary goal.

Effects on Preterm Delivery and Low Birthweight.

During the 1980s, rapid growth occurred in home visiting programs to prevent preterm delivery and low birthweight and to improve the health and development of preterm or low birthweight infants and their parents. Most of these programs focused on poor, unmarried adolescents and young adult women, and many combined health education, parent education, and various forms of instrumental and emotional support (e.g., Olds et al., 1986a).

The immediate precipitant of these programs was a burgeoning body of research suggesting that poverty adversely affects children's cognitive development partly by impairing their physical health status at birth and restricting their ability to overcome perinatal complications. Numerous studies had found that poor children were overrepresented in premature samples due partly to substandard or total lack of prenatal care and inadequate nutrition. Evidence also existed that poor children were more likely to be exposed prenatally to illegal drugs as well as to legal drugs such as nicotine and alcohol and that such exposure increased perinatal complications such as prematurity, low birthweight, small head circumference, and severe respiratory problems. These complications were found to be risk factors for delayed cognitive development, especially in poor children. In particular, research indicated that poor children were less able than affluent children to overcome the problems created by perinatal complications, apparently because they grow up in circumstances marked by fewer social, educational, and material resources (Escalona, 1984; Werner & Smith, 1977).

Olds and Kitzman (1990) contrasted the effects of four home visiting prenatal programs (all randomized trials) on birthweight and length of gestation, three of which adopted a narrow "social support" model, in contrast to an "ecological" approach followed in the fourth program. The three programs exemplifying a social support model assumed that high rates of preterm delivery and low birthweight among poor women are caused by high rates of psychosocial stress in the absence of social support. To test this assumption, home visitors in the three programs provided various kinds of social support (e.g., serving as a confidant; providing concrete assistance such as help with transportation and child care; facilitating women's use of community services; helping women with their relationships with family members and friends; involving family members and friends in

child care and support of the mother), but actively avoided teaching about health-related behaviors or provided such information only on request. In contrast, a fourth program followed a broader "ecological" model, integrating social support with education about health-related behaviors such as smoking, alcohol consumption, nonprescription drug use, and managing the complications of pregnancy. Note that in this across-study comparison, health education, rather than social support, is the distinguishing feature of the approach labeled ecological, as provision of social support to improve the broader context of women's pregnancy is a common denominator of the programs.

Only the ecological program had a discernible positive effect on birthweight and length of gestation, and the effect was concentrated among women who smoked or who were very young (less than 17 years) at the time of program entry (Olds et al., 1986a). This pattern of findings suggests that programs are more likely to be effective if they are more comprehensive in their approach and target women with specific risks for preterm delivery or low birthweight (e.g., smoking, alcohol, illicit drug use). However, more corroborating evidence is needed given that the subsample in which effects were identified in the Olds et al. study was quite small and that no similar effects were found in a subsequent evaluation of a prenatal home visiting program that also combined social support with education (Villar et al., 1992). Moreover, Olds et al.'s prenatal home visitation program had no enduring effects on maternal and child functioning (e.g., cognitive performance), despite nurses' attempts to establish a close working relationship with families and their success in improving women's health-related behaviors, the psychosocial conditions of pregnancy, and the health status of babies born to smokers and young adolescents.

Overall, home visiting prenatal programs of varying levels of comprehensiveness generally have not produced significant reductions in preterm delivery or low birthweight or reliable improvement in utilization of routine prenatal services. Even if successful in improving pregnancy outcomes, prenatal home visitation does not appear sufficient to promote long-term maternal and child functioning (Olds & Kitzman, 1993). This pattern of negative findings may be due to insufficient intensity or poor program implementation, but is more likely attributable to failure of most of these programs to concentrate directly on elimination of known behavioral

antecedents of poor pregnancy outcomes (e.g., smoking; for a fuller discussion of these issues and a detailed review of the effects of prenatal home visiting programs, see Olds & Kitzman, 1990, 1993).

Two-Generation Programs. The most recent genre of antipoverty programs, labeled “two-generation” programs, is distinguished by a combination of services for children and a more omnibus parent component that provides parenting education and social support, but gives greater emphasis than most of its predecessors to adult education, literacy training, and other job skills training intended to help parents become economically sufficient. Ancillary services such as transportation, meals, and child care are typically provided so that parents can participate in these activities. The child-focused component of these programs usually includes educational day care or preschool education, although the intensity of child-focused services of this category of programs varies tremendously (S. Smith, 1995).

Two-generation programs, most of which began in the early 1990s, owe their emergence partly to growing recognition that early childhood education programs and other unigeneration programs are not sufficiently broad to address the multidimensional aspects of family poverty (St. Pierre et al., 1995). Among the specific arguments that have laid the groundwork for more omnibus programs are that (a) parenting programs may improve parenting skills, but children cannot wait to accrue the benefits of such programs because some critical aspects of their development occur on their own timetable; (b) early childhood education programs can confer enhanced cognitive and socioemotional skills, but high-quality parenting can increase the prospects that these skills will translate into school success; and (c) neither child-focused nor parent-focused programs alone provide interventions sufficiently expansive to address the multiplicity of problems and needs that poor families face (e.g., unemployment, limited literacy, and job skills) and to significantly improve the economic status of poor families (Lerner, Halpern, & Harkavy, 1992; St. Pierre et al., 1995). These arguments, taken together, have been sufficiently cogent to forge this new category of interventions into the ranks of an already complex array of programs designed to serve poor children and families (S. Smith, 1995; St. Pierre et al., 1995).

Several two-generation programs were part of Head Start, among them the Comprehensive Child Development Program (CCDP) and the Head Start Family Service Centers (FSCs; S. Smith & Zaslow, 1995). One of the earliest of these programs, the Child and Family Resource Program, described previously, operated from 1973 to 1983 as a Head Start demonstration project. These programs are in keeping with Head Start’s long-standing tradition of implementing demonstration projects both within and outside its basic core program to ascertain more effective ways of serving poor children and families (Zigler & Styfco, 1994a). Well-known two-generation program models that are not part of Head Start include Even Start Family Literacy Program (St. Pierre & Swartz, 1995), Avance Parent-Child Education Program (Walker, Rodriguez, Johnson, & Cortez, 1995), and New Chance (Bos, Polit, & Quint, 1997).

A description of CCDP is presented here to exemplify the approach that characterizes most two-generation programs. Initiated in 1990, CCDP was a national demonstration program that aimed to enhance parents’ progress toward economic self-sufficiency by increasing the scope, duration, and intensity of services, while maintaining the services to children provided by Head Start’s basic program. It operated in both rural and urban areas and provided integrated, comprehensive, and continuous support services to more than 4,440 low-income families with a newborn child for up to 5 years. On average, families were enrolled in CCDP for 3.3 years. Parents and other adult members of the family received prenatal care, parenting education, health care, adult education, job training, and other supports as needed, such as treatment for mental health problems and substance abuse. Adult literacy education, employment counseling, and job training and placement were typically provided through linkages and referrals to community colleges and other local educational institutions. Job linkages were also made with employers and agencies. CCDP was not conceived as a home visiting program, but the program used home visits as the primary means of delivering early child education and case management (St. Pierre et al., 1999). CCDP provided relatively low-intensive services to children from birth through age 3, using biweekly home visits that usually lasted about 30 minutes. These home visits focused on educating parents in infant and child development and parenting skills, rather than working directly with children. A parent who was present for every session, then, received a maximum of

13 hours of parenting education in a year. By 4 or 5 years of age, at least half of the children in CCDP had enrolled in center-based early childhood education (Head Start); the remainder continued to receive early childhood education by means of parenting education (St. Pierre et al., 1999).

In addition to a stronger focus on adult services, several features of CCDP were intended to improve on Head Start's capacity to deliver two-generation services. These included (a) broader eligibility requirements (e.g., a family could remain in the program even if its income rose above the poverty threshold at any time during the program's 5-year period); (b) provision of services to all members of a participating family, broadly defined to include any children of the primary caregiver under age 18 in the household and any family member residing in the household having major responsibility for the care of the focal child; (c) provision of services to a parent of the focal child who resided outside the household; and (d) expanded and stronger provisions for ensuring that families could gain access to needed services. The impact evaluation was conducted in 21 of the original 24 CCDP project sites (Parker et al., 1995; St. Pierre et al., 1999).

All six of the two-generation programs cited here have been evaluated via randomized trials (St. Pierre et al., 1995; St. Pierre, Layzer, & Barnes, 1996). In general, the findings of these evaluations have been disappointing.

Effects on Children. Efficacy studies indicate that two-generation programs have only small or no effects on children's cognitive development, verbal skills, and school readiness. For example, 5 years after the program began, CCDP had no meaningful impact on children's cognitive or socioemotional functioning or physical health, or on birth outcomes for children born subsequent to the focus children. It also had no important differential effects on various subgroups of participants (e.g., children of teenage mothers versus older mothers; children of mothers who entered CCDP with high school diplomas versus children of mothers who entered without high school diplomas; St. Pierre et al., 1999). Neither Avance nor CFRP had an effect on Bayley scores. Even Start produced a significant gain in children's school readiness skills 9 months after entry to the program, but this difference dissipated once children in the control group began school (St. Pierre et al., 1996). At follow-up,

no effects were found for cognitive functioning, social skills, school progress (e.g., percentage of children in special education), or parent reports of child literacy (Ricciuti, St. Pierre, Lee, Parsad, & Rimdzius, 2004). Similarly, at the 3.5-year follow-up, New Chance had no effect on children's cognitive functioning or school readiness and, in fact, increased children's behavioral problems and reduced positive behavior, as reported by the mothers. Negative impacts on children's socioemotional functioning were concentrated among women who were at high risk of clinical depression at random assignment (Bos et al., 1997).

Effects on Mothers. Two-generation programs have stronger effects on parents than on children, although even when effects are found, they are quite modest. Several have produced positive short-term effects on parenting attitudes and behavior. For example, at the end of the 1st year of participation in the Avance program, program mothers compared to control group mothers had a stronger belief in their ability to determine the nature of their children's educational experiences, provided their children a more educationally stimulating home environment, and interacted in a more positive and stimulating manner with their children during videotaped play sessions (e.g., affect, vocalization, contingent praise, initiation of social interaction with child, time spent teaching child; Walker et al., 1995). Other significant changes in parents' attitudes and behavior resulting from participation in these programs include less authoritarian child-rearing attitudes, more emotional support and nurturance of the child (CCDP, CFRP, New Chance), higher expectations for the child's success, increased time spent with the child (CCDP), and increased presence of reading materials in the home (Even Start; St. Pierre et al., 1995, 1996). However, most of these effects did not persist. For example, 5 years after it began, CCDP had no statistically significant impact on mothers' parenting attitudes and beliefs, the quality of parent-child interaction, or the child's home learning environment (St. Pierre et al., 1999). Even Start had no effects on parent reports of parent-child reading, literacy resources in the home, or parent participation in the child's school (Ricciuti et al., 2004). Likewise, at the 3.5-year follow-up, New Chance had no effects on children's home learning environment or mothers' use of harsh discipline, although positive effects in the home environment persisted among mothers who were not at risk of clinical depression at baseline

(Bos et al., 1997). Evaluations generally find relatively high levels of depressive symptomatology in both program and control group mothers, but no evidence that programs are effective in reducing depressive symptoms or increasing mothers' self-esteem or use of social supports (Bos et al., 1997; St. Pierre et al., 1995, 1999; Walker et al., 1995).

Of particular significance to any assessment of two-generation programs is whether programs affect parents' educational attainment, employment status, household income, and use of welfare benefits. Effects appear modest at best and tend to be restricted to educational attainment. Evaluations of Even Start, New Chance, and Avance indicated that program mothers, compared to control group mothers, were significantly more likely to attain a GED certificate, but this educational advancement was not accompanied by positive effects on standardized tests of adult literacy (Bos et al., 1997; Ricciuti et al., 2004; St. Pierre et al., 1995, 1996). New Chance had no effects on women's fertility, fertility-related behavior, contraceptive use, or physical health status (Bos et al., 1997). None of the studies that measured annual household income (or average hourly wage among those employed) found positive effects (Even Start, New Chance, CCDP, CFRP, FSC), and only CFRP increased rates of employment. In general, two-generation programs did not affect use of federal benefits such as AFDC and food stamps, or actually increased participants' use of such benefits by heightening awareness of their availability or by rendering more families eligible for them by virtue of increased participation in educational classes (e.g., CCDP, CFRP, New Chance; Bos et al., 1997; St. Pierre et al., 1995, 1996; Swartz et al., 1995).

The primary reasons for the disappointing pattern of findings from two-generation studies are thought to be insufficient intensity of services to both mothers and children and/or incorrect assumptions about the most appropriate intervention strategies (e.g., assumption that what poor families need most is a case manager to help guide and negotiate as they navigate services in the community; assumption that changing parent behavior is an effective means to promote children's development), rather than poor implementation (Bos et al., 1997; St. Pierre et al., 1999). It is also possible that these studies did not follow mothers long enough to capture longer-term impacts on maternal employment, a factor that may explain why a more favorable picture of employ-

ment effects emerged from evaluations of pre-1990 interventions that provided a combination of services to children and their parents (Banasich, Brooks-Gunn, & Clewell, 1992).

WELFARE AND EMPLOYMENT TRANSITIONS, WELFARE REFORM POLICY, AND THE WELL-BEING OF POOR CHILDREN

Evelia, a Puerto Rican single mother of four, lived in a low-income neighborhood in Milwaukee, Wisconsin and had an income at or below 150% of the poverty line. In the spring of 1998, Evelia worked the second shift (3–11 P.M.) as a casual employee of the U.S. postal service. During that time she either kept her 3-year-old daughter at home with her three older children (the oldest was 13 at that time) or with nearby relatives while she worked in the evening, checking in on them time-to-time by telephone. She did have some concerns leaving her youngest with her other children and she did occasionally consider looking for a child care center or in-home care provider at night for her daughter to ensure adult supervision. But she never looked for one. Evelia did not believe her children would be safe in a formal care center and she also believed that it would be difficult to find a center that would be open as late as she needed it to be.

Things changed in January 1999 when Evelia started working the day shift (7 A.M.–4 P.M.). Evelia's nearby family members were either unreliable or unavailable during the day at the time. Without available family support, she had no alternative but to place her daughter in a day care center. She called the local agency in charge of dispensing Wisconsin Shares for her area to find out what she needed to have in order to receive subsidized care. She was informed that she simply needed to come into the office and fill out a form. However, when Evelia arrived at the office she discovered that she needed a number of additional pieces of information regarding her employment, income, and so on, before she could sign up for the program. Evelia would end up spending an entire day, losing an entire day's wages, running around so that she could enroll her daughter in the subsidy program. She enrolled her daughter in a day care center, but Evelia continued to feel ambivalent. She worried that her daughter might get sick or get lice from other children. Sometimes she felt that her daughter might be healthier in the care of trusted relatives. After a few months of this arrangement, however, Evelia was thrilled with her child's experiences in the day care center. Evelia believed her daughter had really learned a great

deal in the day care center in just a short amount of time—lessons she could never have provided at home. Evelia even remarked that her daughter would be the smartest of all her children as a result of having been placed in a formal care setting. (Lowe & Weisner, 2004, p. 144)

Questions about how best to reduce child poverty and enhance the well-being of poor children were not central in congressional debates that culminated in the 1996 federal welfare reform law (PRWORA). Rather, these debates centered on promoting devolution from the federal to the state level, reducing government spending, promoting parental responsibility, requiring work and imposing time limits on welfare receipt, and strategies for reducing out-of-wedlock births (Greenberg et al., 2002). The law that emerged from these debates voided the long-standing principle of federal entitlement to assistance for poor children and adults alike (i.e., AFDC). More specifically, PRWORA (a) replaced AFDC and several related programs with state block grants known as Temporary Assistance for Needy Families (TANF); (b) mandated that recipients of public assistance be working within 2 years of the time they start to receive assistance; (c) lowered to 12 months the age-of-child criterion for exempting parents' work requirements (in prior provisions, mothers of children under 3 years old were exempt from mandatory work-related activities); (d) imposed a 5-year lifetime limit on assistance in the form of cash aid, work slots, and noncash aid such as vouchers to poor children and families, regardless of whether parents can find employment; and (e) required states to have a certain proportion of their welfare caseloads meet work requirements (Greenberg et al., 2002). The law granted states numerous options and discretionary powers, for example, the option to require work of parents with children under 12 months of age, to impose caps so that payments do not increase if recipients have additional children, and to require recipients of public assistance to be working sooner than 2 years from the time they start to receive assistance (Morris et al., 2001; Zaslow, McGroder, & Moore, 2000).

PRWORA's core goals are to reduce long-term welfare dependency, increase employment-based self-support, encourage marriage, and discourage out-of-wedlock childbearing, not directly enhance the well-being of poor children. Nonetheless, advocates of welfare reform foresaw many benefits redounding to children indirectly through increased parental employment (i.e., role models of disciplined work behavior,

more structured daily routines, increases in parents' self-esteem and sense of control) and higher family income—presumed consequences of welfare reform. Opponents, however, predicted a host of detrimental consequences for child well-being, among them, increases in the rate and depth of childhood poverty because of loss of welfare benefits without compensating increases in earnings, placements in low-quality child care, increases in unsupervised time, and decreases in responsive parenting brought on by excessive demands and attendant emotional distress (Chase-Lansdale et al., 2003; Morris et al., 2001). Evelia's case provides a glimpse of the complicated set of factors that may influence how children fare under welfare reform, including the mother's employment circumstances (e.g., work schedule), type and quality of child care, changes and instability in these factors, and the compatibility of employment circumstances and child care arrangements with the mother's values and preferences.

Although sweeping in its changes, PRWORA was the denouement of a more gradual process begun during the 1960s to push welfare recipients to higher levels of employment-based self-support (Morris et al., 2001). Congress passed a law in 1967 requiring AFDC recipients with no preschool children to register for activities, but states did not make serious efforts to enforce work requirements until the early 1980s. The Family Support Act of 1988 sought to increase economic self-sufficiency among recipients of AFDC by mandating participation in educational and employment training programs and strengthening enforcement of existing child support provisions. States' efforts to promote employment and reduce welfare gained full momentum during the mid- to late 1980s, and by the early 1990s, a large number of states had been granted waivers of AFDC rules to experiment with changes in welfare provisions (Morris et al., 2001). States' receipt of waivers from the federal government to experiment with changes in welfare provisions was conditional on use of a random assignment design and evaluation of the program (Gennetian & Morris, 2003). States mixed and matched several kinds of welfare and employment policies, and the resulting diversity of programs provided an opportunity to assess the comparative effects of different program features on child well-being. Because these experimental programs anticipated key elements of the federal law, they offer important lessons about the potential effects on children of welfare reform policies legislated after PRWORA (Morris et al., 2003). In the following, we discuss the

findings from some of the evaluations that the Manpower Demonstration Research Corporation (MDRC) conducted under these waivers. It is too soon to know if and how the findings from these programs will influence welfare policies.

Experimental Tests of Welfare and Employment Policies: Two Synthesis Projects

The core dependent variables in the evaluations of these programs were parents' economic outcomes, but some states expanded the focus to include child well-being on the grounds that programs might affect children indirectly as a consequence of their potential to alter important aspects of children's lives. In some sense, this decision harkened back to the historical roots of welfare programs, which were to protect the well-being of children growing up in poor, especially single-parent households (Zaslow et al., 2000). At the time these programs were designed (early to mid-1990s), extant research provided only a limited basis for making predictions about how and through what pathways these programs might affect children. Hence, rather than test specific predictions, most studies with a child-focused component set out to explore in a general sense whether the programs had positive, negative, or no effects on children or whether the program affected only children in certain subgroups (Zaslow et al., 2000). However, some studies (e.g., those testing effects of income supplements) were guided by a well-articulated conceptual framework, accompanied by hypotheses about effects as well as mediators of those effects (e.g., Bos et al., 1999).

Two recent syntheses of the findings of these experiments have significantly advanced our understanding of the potential implications of different welfare policies for children's well-being. These projects are products of the Next Generation Project, a collaboration among researchers at MDRC and several universities devoted to an examination of the effects of welfare, antipoverty, and employment policies on children and families. In this section, we discuss the findings from these two synthesis projects, as well as findings published subsequent to the completion of the synthesis projects about the effects of certain programs that were included in the synthesis. To illustrate some of the processes through which various welfare and employment policies influenced family life and child well-being, we present selected case studies from ethnographies that

were carried out in conjunction with some of these individual projects (e.g., New Hope).

Preschoolers and Elementary School-Age Children

In the first syntheses, Morris et al. (2001) examined the findings from five large-scale studies that together assessed the effects on preschoolers and elementary school-age children of 11 different employment-based welfare and antipoverty programs aimed primarily at single-parent families. They classified these programs on the basis of three features: earnings supplements, mandatory employment services, and time limits on welfare receipt. Four of the programs—Minnesota Family Investment Program (MFIP), the Self-Sufficiency Project (SSP), the New Hope Program, and Florida's Family Transition Program (FTP)—offered *earnings supplements* to compensate for some of the shortcomings of the labor market and to make work more financially rewarding, either by providing working families cash benefits or by increasing the earnings disregard, that is, the amount of earnings that were not counted as income in calculating the amount of a family's welfare benefit (Bos et al., 1999; Gennetian & Morris, 2003; Huston et al., 2001, in press; Morris et al., 2003; Morris & Michalopoulos, 2003). Earnings disregards allowed welfare recipient to keep more of their welfare dollars as their earnings increased, whereas under AFDC, welfare recipients experienced sharp reductions in welfare dollars as their earnings rose. For example, in MFIP, working families continued to receive supplemental benefits until their income reached approximately 140% of the poverty level (Gennetian & Morris, 2003).

These programs differed in a number of respects, however. Some made earnings supplements contingent on full-time employment (at least 30 hours/week; SSP, New Hope, Full MFIP), whereas others provided earnings supplements for any amount of work (MFIP Incentives Only). MFIP Incentives Only was created as a contrast to Full MFIP to help disentangle the effects of MFIP's two components: financial incentives and mandatory employment and training services. Single-parent families in MFIP Incentives Only received MFIP benefits and earnings disregards for part-time as well as full-time work but were not subject to mandatory employment and training services. Some programs provided supplements within the welfare system by raising the earnings disregard, whereas others did so outside of the welfare system (SSP, New Hope). Some programs included additional components, but provision of supplements was the sole feature

that the four programs in this category shared. In the New Hope Program, for example, parents who worked full time were eligible for wage supplements sufficient to raise family income above the poverty threshold as well as subsidies for child care and health insurance. In addition, project representatives provided advice and services to participants, and community service jobs were available to people who could not find employment in the unsubsidized labor market (Bos et al., 1999).

Six of the programs provided *mandatory employment services* (e.g., education, training, or immediate job search) in which parents were required to participate in order to receive cash welfare benefits (Atlanta Job Search First, Atlanta Education First, Grand Rapids Job Search First, Grand Rapids Education First, Riverside Job Search First, Riverside Education First, all of which were part of the National Evaluation of Welfare-to-Work Strategies). These programs were generally successful in increasing employment rates but did not provide earnings supplements or institute time limits on family's eligibility for welfare benefits. Each of the three sites (Atlanta, Grand Rapids, Riverside) operated both a program emphasizing job search as a first activity (labor force attachment approach) and a program emphasizing basic education as a first activity (human capital development approach). In the former program, participants usually attended a "job club" that lasted 1 to 3 weeks, and those who were unsuccessful in their job search were then enrolled in short-term adult basic education, vocational training, or work experience. Education First programs initially placed participants in education and training programs to increase knowledge and skills before they attempted to transition into employment. They are founded on the view that welfare recipients should raise their skill levels before searching for work so they can obtain jobs with higher wages and more fringe benefits (D. Bloom & Michalopoulos, 2001; Zaslow et al., 2000).

One of the programs (FTP) put *time limits* on families' eligibility for welfare benefits. Receipt of cash assistance was limited to 24 or 36 months (depending on parents' level of disadvantage) in any 60-month period. Time limits were combined with mandatory employment services and a small earnings supplement in the form of an enhanced earnings disregard (Morris et al., 2003).

In all of these studies, parents were randomly assigned to either a program group, which had access to

the new services and benefits and was subject to the new rules, or a control group, which received welfare benefits and were subject to rules governing welfare receipt that existed in the locale where the study was conducted. In most instances, control group members were eligible for cash assistance through AFDC. Children were assessed 2 to 4 years after random assignment and ranged in age from approximately 5 to 12 years at the time of assessment. For the synthesis of child effects, Morris et al. (2001) focused on a subset of measures that were similar across studies; fortunately, these measures represented a wide range of outcomes for children that might be affected by welfare policies. Too few of the studies of these experimental programs assess children under age 3 for conclusions to be drawn about this age group.

Pattern of Effects. Morris et al.'s (2001) synthesis identified a clear-cut pattern of effects. Programs that included earnings supplements increased both parental employment and income. Moreover, these programs had modest, positive effects on a range of behaviors, with effect sizes averaging about .15. All of these programs had positive effects on children's school achievement, and some also reduced behavior problems, increased positive social behavior, and/or improved children's overall health. For example, at 24 months post-random assignment, the New Hope Program had strong positive effects on boys' academic achievement, classroom behavior skills, positive social behavior (e.g., compliance, social competence, sensitivity), and problem behaviors, as reported by teachers (who were given no information about children's participation in New Hope or other interventions), and on boys' own expectations for advanced education and occupational aspirations (though there were not corresponding program effects for girls; Huston et al., 2001).

Subsequent to Morris et al.'s (2001) synthesis, findings regarding the longer-term impact of New Hope became available. A follow-up conducted 60 months after random assignment, when the children were 6 to 16 years old, indicated that New Hope's effects on boys' school achievement, motivation, and social behavior persisted. In comparison to impacts measured 2 years after program onset, effects on school achievement were robust, but effects on social behavior were reduced (Huston et al., in press). The effects of New Hope on child outcomes are particularly persuasive because they appeared on measures obtained from multiple sources.

Measures obtained from parents, who were the most likely to be affected by their knowledge of the New Hope treatment and the evaluation design, showed fewer treatment differences than did measures completed by teachers and children.

The one program included in Morris et al.'s (2001) synthesis that combined mandatory employment services and earning supplements (Full MFIP) increased full-time employment among parents but tended to have no impact on children's outcomes beyond those positive effects (i.e., higher academic performance, higher engagement in school, increases in positive interactions with peers, fewer behavioral problems) found when the program was implemented with earnings supplements alone (i.e., MFIP Incentives Only). It is notable, however, that adding mandatory employment services to MFIP (as compared to MFIP Incentives Only) significantly reduced children's positive behavior, especially their social competence and autonomy (Gennetian & Miller, 2002; Gennetian & Morris, 2003). Overall, programs with mandatory employment services successfully increased parental employment rates and reduced welfare receipt, but generally left family income unchanged because participants lost welfare benefits as their earnings increased. These programs had few effects on children, and the effects found were mixed in direction. The pattern of effects among these programs appeared to be more closely linked to particular sites than to program characteristics (Morris et al., 2001; Zaslow et al., 2000).

The program with time limits produced an increase in parental employment and a modest increase in income but had no consistent pattern of effect on child outcomes. Because this program was combined with mandatory employment services and a small earnings supplement, it is impossible to sort out the impact of time limits (Morris et al., 2001). A recent study of the impact of Connecticut's Job First program found that generous earnings disregards can both increase family income and improve children's outcomes, even when such disregards are combined with a short time limit (i.e., a cumulative total of 21 months of cash assistance receipt). Parents in the program group, compared to those in the control group, reported that their children had fewer internalizing and externalizing problem behaviors and more positive behaviors with peers, although there were no effects on parents' reports of children's performance and engagement in school or on

teacher reports of children's achievement and behavior in school (Gennetian & Morris, 2003).

Mediating Processes. All of the earnings supplement programs had in common one result, an increase in employment and income, but no one mechanism appeared to be responsible for the beneficial effects of these programs on children. Within the corpus of relevant studies, none of the outcomes considered to be possible mediators of effects (i.e., family relations, child care, parental well-being, parenting practices) was affected across all programs (Morris et al., 2001). Full MFIP and MFIP Incentives Only increased marriage among long-term welfare recipients, but SSP and New Hope had no effects on marriage rates (Bos et al., 1999; Gennetian & Miller, 2002; Morris & Michalopoulos, 2000).

Some programs increased the use of formal and stable child care and children's participation in afterschool activities (New Hope, SSP, Full MFIP), though others did not (MFIP Incentives Only; Gennetian & Miller, 2002; Huston et al., 2001; Morris et al., 2001; Morris & Michalopoulos, 2003). For example, at 24 months post-random assignment, children ages 3 to 12 in the New Hope Program had spent almost twice as many months in center-based care (for preschool and school-age children) and more than twice as many months in school-based extended day care than had control group children. Moreover, among the 9- to 12-year-olds, program group children spent more time in adult-supervised, organized afterschool activities (e.g., lessons, sports, clubs, youth groups) than did control children (Huston et al., 2001). Although evaluations of welfare and employment programs do not provide information on the quality of child care children received, there is some evidence that center-based care, on average, is more likely than home-based care to enhance cognitive, academic, and social skills (Lamb, 1997). Likewise, extended day care for elementary school children has been linked to higher school achievement; this appears to be due partly to tutoring and help with homework received by children in this setting (Pierce, Hamm, & Vandell, 1999; Posner & Vandell, 1999). The case of Evelia, presented at the beginning of this section, provides an example of how center day care may foster children's academic readiness, even when such a child care arrangement was selected as a last resort and is at odds with the mother's original preference. Lynnette's case, presented next, illustrates how an adult-supervised,

afterschool program can benefit children's school performance and make it easier for parents to maintain full-time employment. Although a control group parent in the New Hope study, Lynnette's situation could apply to many program group families as well.

Lynnette, an African American woman, lives with Mark, her fiancé, and her fiancé's younger brother. Lynnette worries about who is caring for her 6-year-old son, Mark, while she is at work. She specifically focused on supplemental or after-school care as having helped her maintain full-time employment. Lynnette took college courses for 1 year and then dropped out. Her employment history has been sporadic and varied—she has worked at Kinko's and Burger King and as a nanny-babysitter. Recently, she was hired full time by the trucking firm for which she had been temping. She works in the accounting department. As a single mother returning to work after the birth of her son, she had no choice but to leave him in the care of someone else. Before Mark entered school, she relied on a network of close friends and family to care for him while she worked. She said that she never considered putting him in a child care program since, from her perspective, "it doesn't matter what you call it, it's still 'stranger care.'" Similarly, now that her son is in first grade she does not think that organizations that provide after-school programs are safe for children. "Boys and girls, that all there is—no supervision." However, last year, when Mark was in kindergarten his school instituted an after-school program, run by teachers whom Lynnette knew, in the school library. Consequently, Lynnette was comfortable leaving her son in what she considered a familiar and well-supervised program. The program focused on school skills as well as play activities. Her only complaint about the program was they did not offer the children a snack. Lynnette was disappointed that the program was terminated for lack of funding after a few months. Lynnette said that while Mark was attending the after-school program he mastered the alphabet and then learned to read, which put him ahead of most students in his class. Even a year later Mark says that he is doing well in school. As he had put it, "I am better than everyone else." His mother explained that he has scored higher on the school district reading tests than any other student in his class. (Bos et al., 1999, p. 201)

Parents' psychological functioning, child-rearing practices, and children's home environment were thought to be key pathways through which earnings supplement programs would impact children, but programs had few effects on these factors (Gennetian & Miller, 2002; Huston et al., 2001; Morris et al., 2001). Some programs improved parents' psychological functioning (e.g., fewer

symptoms of depression, less parental stress, greater sense of agency; Gennetian & Miller, 2002; Huston et al., 2001), but others did not, and SSP actually increased depressive symptomatology in parents (Morris & Michalopoulos, 2003).

There are some patterns across these studies, though, suggesting that when mothers are able to choose the number of hours they work, financial incentives may improve children's behavior partly by enhancing their psychological functioning and parenting behavior (Chase-Lansdale & Pittman, 2002). Many of the mothers in MFIP Incentives Only took up the option to work part time rather than full time (D. Bloom & Michalopoulos, 2001). MFIP Incentives Only reduced mothers' depressive symptomatology and harsh parenting (though only the former effect was statistically significant), patterns not found in Full MFIP (which required at least 30 hours of employment per week). Furthermore, MFIP Incentives Only had more uniformly positive impacts on children than did the Full MFIP program (recall that Full MFIP had negative impacts on children's positive behavior, whereas MFIP Incentives Only did not). MFIP's incentives were primarily responsible for the program's beneficial effects on children (Gennetian & Morris, 2002, 2003).

Similarly, New Hope reduced hours of employment among parents in the program group, and this seemed to benefit mothers' psychological functioning, though not child well-being. New Hope required participants to work at least 30 hours per week, but this meant that program participants who were already working full time at random assignment could reduce their work hours. Indeed, this is precisely what many participants did. New Hope reduced hours worked by those employed full time at random assignment, mostly by reducing overtime and employment at second jobs (Bos et al., 1999). Two years after random assignment, New Hope had significantly increased self-reported parental warmth and parent-reported monitoring of the focal child's activities, but only among parents who were employed full time at random assignment. For the most part, the impact of New Hope on child functioning did not depend on parents' employment status at random assignment. Nonetheless, the pattern of findings from these two studies seem to warrant more examination of the conditions under which parenting behavior operates as a mediator of positive effects of earning supplement programs on child functioning.

Moderators of Effects. There is some suggestion that children in higher-risk families may benefit more

from some programs than children in lower-risk families, and conversely, that children in lower-risk families may experience more negative effects than children in higher-risk families. Morris et al.'s (2001) synthesis indicated that the positive effects of earnings supplements on parental employment and family income were stronger for long-term welfare recipients than short-term welfare recipients. Moreover, programs with earnings supplements had more pronounced effects on children of long-term welfare recipients, compared to children of parents with a shorter welfare history, boosting the functioning of the former children to a level near that of the control group children in families that had received welfare for less than 2 years. Essentially, programs with earnings supplements increased children's well-being and reduced problematic functioning to the level of the highest-functioning children in these low-income samples.

Conversely, analyses completed subsequent to the synthesis and focusing on two specific programs (FTP and MFIP) indicate that these programs had more negative effects on children from families with more economic and human capital (e.g., shorter duration of welfare receipt risk prior to program entry, higher educational attainment of parent) than children from more socioeconomically deprived families (e.g., lower school performance, increased likelihood of being suspended from school; Gennetian & Miller, 2002; Morris et al., 2001). In MFIP, for example, children of long-term welfare recipients experienced benefits of the program, whereas those in families that had recently applied to welfare were negatively affected by their parents' participation in the program (compared to the control children; Gennetian & Miller, 2002). Morris et al. speculate that this moderating effect may indicate that the child care that low-income parents were able to purchase failed to compensate for the loss of parental attention experienced by children from families with more economic and human capital.

Morris et al. (2001) found no clear pattern of gender differences across programs with earnings supplements. Some of the earnings supplement programs had positive effects (i.e., increased positive behavior, decreased behavior problems) primarily on boys (e.g., New Hope), whereas others had positive effects primarily for girls (e.g., MFIP). However, there is some suggestion from analyses completed subsequent to the synthesis that African American and Latino children may have benefited more than White children from welfare policies

that enhanced parents' human capital—a suggestion that echoes findings from prominent evaluations of Head Start and Early Head Start (ACF, 2002; ACF, 2005a; Lee et al., 1988). Analyzing data from four programs across two sites in the National Evaluation of Welfare to Work Strategies, Yoshikawa et al. (2003) found that programs emphasizing adult basic education prior to employment (human capital development approach) substantially increased math achievement among 8- to 10-year-old African American and Latino children, but had negative effects on their White counterparts. A similar though less robust pattern was found for reading achievement and in programs emphasizing immediate employment (labor force attachment approach). African American mothers' stronger value (compared to White mothers') for going to work over staying at home and Latino mothers' greater involvement in and valuation of educational activities (compared to White mothers') accounted for ethnic differences in the impact on children's math achievement, suggesting that families from different ethnic groups may experience welfare policies differently and in ways associated with initial differences in values and preferences.

It is also notable that New Hope significantly increased earnings among African American and Hispanic participants but had a negative (but not significant) impact on the earnings of White participants. These ethnic differences in earnings impact were unrelated to full-time employment status at random assignment, and additional analyses failed to produce a clear explanation for the differences. They did not translate into ethnic differences in the effects of New Hope on child functioning, but this may be due to small sample sizes. The assessment of earnings impact was based on a much larger sample (which included adults with and without children) than the one available for assessing child effects. The New Hope child sample included only 93 White children (12.5% of total), compared to 409 African American (55%) and 217 Hispanic (29%) children (Huston et al., 2001).

Adolescent Children

Whereas Morris et al.'s (2001) synthesis concerned effects of welfare and employment policies on preschool and elementary school-age children, Gennetian et al. (2002, 2004) conducted a companion synthesis focusing on adolescents. Using meta-analytic techniques, they integrated survey data collected from parents

about their adolescent children in eight studies of 16 different welfare and employment programs, all of which used a random assignment design. Adolescents were roughly 10 to 16 years old at random assignment and 12 to 18 years old when the follow-up survey data on which the synthesis is based were collected. The length of the follow-up period varied, ranging from 24 months to 60 months after random assignment. Gennetian et al.'s synthesis is based on the five experimental studies examined in Morris et al.'s synthesis (the former focusing only on 12- to 18-year-olds and the latter focusing on 10- to 12-year-olds), plus three additional experimental studies (Los Angeles Jobs First Greater Avenues for Independence, Welfare Restructuring Project, Jobs First Evaluation). Like those included in Morris et al.'s analysis, the programs in Gennetian et al.'s synthesis represented various combinations of earning supplements, mandatory employment activities, and time limits on welfare receipt. Of the 16 programs tested in the eight experimental studies, 12 required parents to work or to participate in work-related activities in order to receive welfare; 8 offered earnings supplements to parents who worked (6 allowed parents to continue receiving welfare benefits along with the earning supplements); 2 put time limits on the length of time that families could receive welfare.

Pattern of Effects. The pattern of findings that emerged from Gennetian et al.'s (2004) synthesis is in sharp contrast to that found in Morris et al.'s (2001) synthesis. Specifically, parents in the programs generally reported *worse* school performance, a *higher* rate of grade retention, and *more* use of special education services among their adolescent children than did control group parents. Effects were especially pronounced for adolescents with younger siblings. Of the nine programs examined in the seven studies that measured adolescents' school performance, six lowered performance; for grade repetition, nine of the 15 impacts were unfavorable; and for receipt of special services for an emotional, physical, or mental condition, the impacts were unfavorable in 8 of 12 comparisons. The largest negative impact was on maternal reports of school performance (.10 of a standard deviation). Overall, the sizes of the average effects were small, and many of the programs did not produce statistically significant effects. No consistent effects were found for the three policies. That is, negative effects could not be traced to any one welfare

or employment policy. For example, negative effects were found for both programs that required parents to work or to participate in work activities and programs in which parents' work participation was voluntary. On average, the programs had no effect on school dropout rates, suspension rates, or the proportion of adolescents who completed school or had children.

Mediating Effects. Gennetian et al. (2002, 2004) undertook a series of analyses to examine what might account for the negative effects on school outcomes across the different employment-based welfare and antipoverty programs. Their findings are only suggestive because several studies lacked data needed to assess mediating processes. Gennetian et al. (2002) found some evidence that negative impacts were the result of changes in adolescents' home and out-of-home environments, such as increased pressure to work long hours outside the home, greater domestic responsibilities (e.g., sibling care), and less supervision by adults. For example, SSP, the only project that provided information about adolescent employment, increased the likelihood that adolescents were employed more than 20 hours per week. This increase in adolescent employment may have been responsible for the elevated rates of delinquent behavior found in the SSP program group, in keeping with prior research linking adolescent employment to delinquent behavior (Steinberg & Dornbusch, 1991).

Gennetian et al. (2002) also found that programs that increased maternal employment and that had negative effects on adolescents' school functioning were the same programs that increased adolescents' home responsibilities. When single mothers move into employment, adolescent children may assume greater domestic responsibilities, and this may, in some circumstances, hinder academic achievement and school progress among adolescents already struggling with schoolwork. Gennetian et al. reasoned that if additional home responsibilities are a pathway by which the programs adversely affected adolescents' academic achievement and school progress, negative effects should be especially pronounced among adolescents with younger siblings, on the assumption that expanded domestic responsibilities probably included sibling care. Indeed, they found this to be the case. Whereas control group adolescents who had younger siblings at random assignment functioned similarly to control group adolescents who had no younger siblings at study entry, the detrimental effects

of the programs were larger and more consistently negative across outcomes for adolescents who had younger siblings at study entry than those who did not.

The case of Tina illustrates how a mother's entry to employment and her work schedule can adversely affect a child's academic performance by requiring that the child take on responsibilities (i.e., child care) that conflict with school. It is based on ethnographic data collected under the auspices of the Urban Change project to provide insight into how adolescent children were being affected by their mother's adjustment to mandatory work requirements, incentives, and time limits introduced by welfare reform in 1996 (Gennetian et al., 2002).

Tina is a 35-year-old African American mother of six who has transitioned from welfare to work. Because of Tina's work schedule, the three oldest of her children who were still living at home had to take care of her two youngest children. This added responsibility cut into her older children's free time and appeared to hurt the school performance of Tamara, her eldest daughter. Tamara was responsible for waiting with the younger children for the van that took them to their daycare center. Because the van typically came late, Tamara was usually 20 to 30 minutes late for school. As her mother put it: "She's late every day for her school, every day. And what the school says to me is . . . they gotta do what they, what's their policy. She's gotta stay after school, do her detention . . . or she'll lose her credit out of her, out of that morning class 'cause she didn't get there on time. So she feels sad and I feel bad because I gotta be at work at 7. She can't be at school by 7—she can't. We all can't be at the same place at the same time." Tina suffered tremendous guilt for imposing on her older children a responsibility that she felt was properly her own. (Gennetian et al., 2002, p. 14)

Age of Child as a Moderator of Effects across and within Studies

Whereas Morris et al. (2001) found a pattern of positive effects on preschool and elementary school-age children across programs with earnings supplements, Gennetian et al.'s (2002) analyses indicated that not only did these programs fail to improve adolescents' functioning, but, like programs with mandatory employment services and time limits, they tended to have negative effects on adolescents' school achievement and school progress. This age-related difference in the pattern of effects found in the two syntheses projects parallels age effects found in two studies (SSP and FTP) whose samples included preschoolers, children in middle childhood, and adolescents.

SSP offered a generous earnings supplement for up to 3 years to single parents who left welfare for full-time work (at least 30 hours per week), and its effects varied as a function of age of the child. For very young children (ages 3 to 5 years at 36 months after random assignment), SSP had no effect on children's outcomes. For children in middle childhood (ages 6 to 11 at 36 months after random assignment), SSP increased children's cognitive functioning (as indicated in test performance and parents' reports) and health outcomes, but had no effects on their socioemotional functioning. However, among adolescents ages 12 to 18 at 36 months after random assignment, SSP increased use of tobacco, alcohol, and drugs as well as minor delinquent behavior (e.g., staying out late or all night) and reduced average school performance (as reported by mothers). It had no effect on major delinquent behavior (e.g., stealing, carrying weapons, involvement with police), achievement test performance, or self-reported school achievement among adolescents (Morris & Michalopoulos, 2003). In the second study, the negative effects of FTP on children whose parents were least likely to be long-term dependent were most pronounced among adolescent children (i.e., arrests, convictions, involvement with police), that is, those who were ages 11 to 13 at baseline and 15 to 17 at the 4-year follow-up.

Factors that explain why some adolescents fared less well than others under these new welfare and employment policies may also account for why adolescents, on average, fared less well than preschool and elementary school-age children. These programs tended to change adolescents' ecologies in ways that were largely incompatible with their developmental needs, whereas the reverse seemed true for preschoolers and elementary school-age children. As discussed previously, among adolescents, these policies tended to increase intensive adolescent employment, decrease adult supervision, and increase domestic responsibilities—all factors that have the potential to impose time pressures that interfere with adolescents' engagement in school and homework. In contrast, for preschool and school-age children, many of these programs led to increases in the amount of time they spent in formal child care and organized afterschool activities, both of which have been linked to enhanced cognitive, academic, and social functioning (Lamb, 1997; Pierce et al., 1999; Posner & Vandell, 1999).

Differential Patterns of Involvement

Substantial variation exists in the extent to which individuals take up or use benefits offered by work-based

antipoverty and welfare reform demonstrations, driven partly by individuals' personal circumstances, resources, and preferences. Understanding factors that predict involvement in these programs is essential to efforts that aim to modify programs to better fit the needs of the service population. Using ethnographic methods, Gibson and Weisner (2002) found that four categories of personal and family circumstances were associated with take up of the services offered by the New Hope program: (a) lack of information or misinformation about the program, (b) multiple personal problems and disruptive events that prohibited systematic or sustained involvement in the program, (c) circumstances in which the gains of participating were perceived to be greater than the costs, and (d) use of services only if they contributed to a daily routine that parents were already working to achieve.

Yoshikawa, Altman, and Hsueh (2001) addressed the issue of take-up using a quantitative approach. Although the program on which their findings are based was not included in the synthesis projects discussed earlier, the findings are briefly summarized because they help fill a critical gap in our understanding of this issue and because they have important implications for the implementation of welfare reforms. These researchers identified subgroups of participants in the New Chance welfare reform demonstration on the basis of different patterns of employment, child care use, job training, and education and assessed whether subgroup membership predicted young children's cognitive and mental health functioning. New Chance was a 16-site voluntary program for 16- to 22-year-old current and former teen mothers on AFDC who had dropped out of high school. The program consisted of 6 months of GED classes and other educational activities, parenting and life skills classes, provision of free center-based child care, individual case management, and job training, work internships, or college for an additional year. Children, ages 0 to 3 at the onset of the program, were assessed at 42 months following random assignment.

Center care co-occurred with a variety of education and job training activities and with attendance at personal development classes to a greater degree than other forms of child care (e.g., grandparent care, nonrelative care). That is, the provision (at most of the New Chance sites) of on-site child care appeared to facilitate involvement in program activities that were most likely to lead to employment and long-term exits from welfare. Fifty

percent of the sample were characterized by low involvement in all program activities and made little use of relative care, nonrelative care, or center-based care. At the 42-month follow-up, these individuals were more likely than expected to be on welfare and less likely than expected to be employed. Ethnicity predicted membership in the low involvement group, with those in the low involvement group more likely to be White than Black or Latino—a finding that runs counter to societal stereotypes. Surprisingly, child demographic factors, maternal depression, and socioeconomic characteristics such as prior employment and educational attainment did not predict level of involvement.

Accounting for the effects of selection, children whose parents were in the low involvement group scored lower on a measure of cognitive school readiness than did children whose parents were in other cluster profiles. Yoshikawa et al. (2001) speculated that low levels of center-based child care experienced by the former children may have denied them opportunities to advance their cognitive functioning. In addition, parents' low levels of involvement in program activities that enhance self-sufficiency and personal development may have denied children the indirect positive influences that such activities might have. Children of mothers in a cluster profile characterized by human capital development (higher-than-average levels of involvement in education, job training, personal development classes, and center-based child care use) had higher levels of cognitive school readiness than children in cluster profiles characterized by either high levels of center-based child care use and job training or high levels of center-based child care use and education. The cumulative effects of education and job training likely increased parents' human capital, which, in turn, may have increased children's educational resources. These advantages appear to have amplified the positive and direct effects of center-based child care on children's cognitive functioning.

Summary

Findings from any single program with an income supplement require tenuous statements about the effects of income because benefits and services within a program were offered as a package, making it impossible to identify the separate effects of different components of the program. However, consideration of findings across multiple programs offering income supplements

with a mixture of other program services increases confidence in the causal effects of income supplements, as this was the common feature across these varied programs. Morris et al.'s (2001) synthesis indicates that mandatory employment services increased employment but left income unchanged, and generally had little effect on the well-being of preschool and elementary school-age children. In contrast, increases in employment accompanied by income gains benefited children in this age group. These findings together suggest that income—not employment per se—drove the positive effects on children, a conclusion supported by a comparison of the results for Full MFIP and MFIP Incentives Only (D. Bloom & Michalopoulos, 2001). Income may have improved child well-being by providing a range of cognitive and social resources (e.g., books and other learning materials; participation in organized activities during nonschool hours; stable, higher-quality child care). Parent's psychological functioning, proximal child rearing practices, and children's home environment were not key pathways of influence. There is some suggestion that African American and Latino children may benefit more than White children from programs designed to enhance parents' human capital (emphasizing adult basic education prior to employment), and that the benefits of programs with earnings supplements are greater for children in higher-risk families than those in lower-risk families.

Apparently, in the case of adolescents, the benefits of increased income were insufficient to offset the negative effects of increased unsupervised time, greater domestic responsibilities, and increased adolescent employment occasioned by mother's entry into work and employment training activities. The negative effects of these programs on adolescent outcomes signal the need to seriously reconsider the costs versus benefits of requiring single-parent welfare recipients, especially those with adolescent children, to be involved in work and work-related activities 40 hours per week instead of the current 30 hours per week (Thompson, 2003). We return to this issue briefly in a later section of the chapter.

Among mothers with infant and preschool children, provision of on-site child care appears to enhance mothers' involvement in program activities that are likely to lead to employment and exits from welfare. High levels of maternal involvement in multiple domains of human capital development (e.g., education, job training, personal development classes), combined with high use of

center-based child care, appear to boost children's cognitive school readiness.

Estimating the Causal Influence of Income

The differential effect on child well-being of employment-based antipoverty programs with and without earnings supplements brings into focus the question of whether income plays a causal role in child well-being.

There are ongoing debates about whether low income is the critical variable affecting developmental outcomes among poor children, as opposed to attributes such as low ability and low education levels of parents, genetic predispositions, poor mental health, welfare receipt, single-mother family structure, and large family size (Corcoran, 2001; Duncan & Brooks-Gunn, 1997; Huston, McLoyd, & Garcia Coll, 1997; Mayer, 1997; Rowe & Rodgers, 1997). Notwithstanding the potential for genetic-environment confounding in studies conducted within biologically related families, collectively, investigations using a variety of methods provide strong evidence that income poverty and related experiences influence children's cognitive, academic, and socioemotional functioning through environmental processes that go well beyond genetically transmitted attributes (Huston et al., 1997). Included in this corpus of studies are (a) longitudinal studies with statistical controls for genetically based shared variance (e.g., analyses of effects of poverty on children's IQ that control for maternal IQ, maternal education, or both; e.g., Duncan & Brooks-Gunn, 1997); (b) studies that control for enduring family characteristics (and hence, any stable genetically based family attributes) by using children as their own controls or by comparing siblings (e.g., Currie & Thomas, 1995); (c) studies of the effects of naturally occurring income changes (e.g., Garrett et al., 1994); and (d) experimental manipulations of income (Salkind & Haskins, 1982).

Recent findings published by Costello and her colleagues (2003) further bolster the claim that income plays a causal role in child well-being. These investigators were confronted with a natural experiment when, midway through an 8-year longitudinal study of 1,420 rural children ages 9 to 13 years at intake, the opening of a gambling casino on a reservation of the Eastern Band of Cherokee Indians substantially increased income levels in an entire community. Under the terms of the agreement with casino operators, every man, woman, and child on the reservation receives a percentage of the

profits, paid every 6 months. Children's earnings are paid into a trust fund until the age of 18 years. The payment has increased each year, reaching approximately \$6,000 in 2001. The income supplement moved 14% of study families out of poverty; 53% remained poor, and 32% were never poor (incomes of non-Indian families were not affected). Before the casino opened, children whose family was to move out of poverty had the same number of behavioral psychiatric symptoms (Conduct Disorder, Oppositional Defiant Disorder) as those who were to remain poor, and both groups had significantly more symptoms than did children whose families were never poor, consistent with other research. However, after the casino opened, behavioral symptoms of ex-poor children fell to the levels of never-poor children, and significantly below the levels of persistently poor children. The measure of behavioral symptoms was based on child and parent responses to the Child and Adolescent Psychiatric Assessment, which was used to generate diagnoses following the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (American Psychiatric Association, 1994). Analysis indicated that the beneficial effect of moving out of poverty was mediated by an increase in parental supervision resulting from fewer time demands on the index parent and, overall, fewer time constraints in the family.

Nonexperimental Studies of Mothers' Transitions off Welfare and Increased Work Involvement in Relation to Child Well-Being

Random assignment design allows more definitive causal inferences about the effects of different policy options on family life and child well-being than is possible from nonexperimental work. Nonetheless, as with the experimental studies of model preschool education programs (Haskins, 1989), there are questions about the external validity of experimental studies of welfare and employment policies. Most of the experiments were begun prior to the 1996 welfare reform legislation, most of the programs did not have time limits, and the earning supplements and child care subsidies of these programs were more generous than many current state welfare provisions (Chase-Lansdale et al., 2003). In the sections that follow, we turn to nonexperimental studies examining the association between mother's welfare and employment transitions and child well-being. Relevant studies have been conducted both prior to and after the passage of PRWORA. Taken together, these studies may

provide a closer approximation of what effects can be expected to result from welfare reform, but they are limited in their inability to definitively address issues of causality resulting from potential unmeasured characteristics of the mother that may be correlated with welfare and employment transitions and changes in children's well-being. Our review of these studies is followed by a discussion of some of the factors that are likely to influence how children respond to mothers' transitions off welfare and into employment.

Effects on Child Functioning of Receiving and Transitioning off Aid to Families with Dependent Children

Some data suggest that longer duration of welfare receipt is associated with better school performance among African American adolescent girls and higher levels of educational attainment among African American youth (Coley & Chase-Lansdale, 2000; Peters & Mullis, 1997), but the bulk of research generally shows little or no association between receipt of AFDC and child well-being after adjusting for poverty and low income (e.g., Kalil & Eccles, 1998; Zaslow, McGroder, Cave, & Mariner, 1999; Zill, Moore, Smith, Stief, & Coiro, 1995). In the Philadelphia Family Management Study, adolescents' endorsement of mainstream values toward social behavior, level of academic performance, and participation in delinquent behaviors, risky behaviors, or substance use were all unrelated to whether or not their family had received income from AFDC in the previous 12 months, although adolescents in families with a longer history of welfare receipt (number of years on welfare since the adolescent's birth) had slightly lower levels of academic performance (Kalil & Eccles, 1998). In other research, longer duration of welfare receipt predicted lower school readiness but was unrelated to positive social behaviors, internalizing behavior problems, physical health, school delinquency problems, and adolescent work orientation (Coley & Chase-Lansdale, 2000; Zaslow et al., 1999). The lack of sound data on lifetime poverty status and monthly spells of welfare receipt typical of these studies compromises estimates of welfare effects, given the substantial fluidity in welfare and poverty status among low-income families (Bane & Ellwood, 1986; Kalil & Eccles, 1998).

Hofferth and her colleagues (Hofferth, Smith, McLoyd, & Finkelstein, 2000) hypothesized that the transition from welfare to "self-sufficiency"—pre-PRWORA—would be associated with elevated levels of

externalizing and internalizing behavior problems in children because their mother would be experiencing the strain and anxiety of supporting the family without AFDC. They further predicted that this increase in behavior problems would be short term and would reverse itself over the longer term. Data from the Panel Study of Income Dynamics Child Development Supplement, a nationally representative sample of children under age 13, were consistent with these predictions. Children of single mothers who had been off welfare for 1 year or less were both more aggressive and more withdrawn than children whose mother had never received AFDC, controlling for background characteristics of the child (e.g., age, gender, race) and the mother (e.g., education, income-needs ratio). Maternal depression, family conflict, and living with a household member with drinking problems mediated some of this association. Children whose mother was currently on welfare and children whose mother had been off AFDC for 1 to 3 years did not differ in level of behavior problems from children whose mother had received no welfare in the past 3 years. Children's cognitive functioning was not consistently related to the transition off welfare.

In one of the few longitudinal studies of welfare transitions focusing on very young children, J. R. Smith and her colleagues (J. R. Smith, Brooks-Gunn, Kohen, & McCarton, 2001) found a negative association between children's cognitive test scores at age 3 and different welfare transition patterns (compared to children who never received AFDC) during the child's first 3 years of life, but most of this association was explained by preexisting maternal and family characteristics and family income, rather than by AFDC status per se. One of the most robust findings was the interactive effects of poverty status and transition off welfare. Children's cognitive test scores were negatively related to leaving AFDC by age 3 (compared to children who never received AFDC), but this effect was much stronger for families who left AFDC but remained in poverty, compared with those who left poverty when they left AFDC. These associations held even after controlling for a host of preexisting child and family characteristics, home learning environments, and parenting behaviors.

Effects on Child Functioning of Mothers' Transitions after the 1996 Welfare Reform Legislation

Research on the effects of PRWORA on child well-being needs to be viewed within the context of post-PRWORA

macroeconomic trends and aggregate-level analyses of the consequences of PRWORA for the material well-being of low-income families. Gauging the impact of welfare reform on families and children is not simply a matter of documenting the relationship of transitions into and out of TANF and employment to child and family well-being, but also assessing how policy differences under TANF versus AFDC are related to resources available to the poor overall, regardless of their welfare and employment transitions. We discuss these issues prior to summarizing what is known about the effects of welfare reform on child well-being.

Macroeconomic Trends. Since the passage of PRWORA in August 1996 and the replacement of AFDC with TANF, welfare caseloads have been cut in half, falling from 4.4 million families to 2.2 million in September 2000 (Greenberg et al., 2002). Child poverty rates also fell during this period, from 22% in 1994 to 16.2% in 2000, the lowest percentage in 20 years (Proctor & Dalaker, 2003). Implementation of TANF coincided with a strong economy that allowed low-income single mothers to enter jobs that had been added to the economy mostly in retail trade and services. It also co-occurred with policy changes that benefited workers in low-wage jobs, including an increase in the minimum wage, expansion of the Earned Income Tax Credit, and increases in child care spending and public health care coverage (Chapman & Bernstein, 2003; Greenberg et al., 2002).

As the U.S. economy took a downturn in 2001, a number of the positive post-PRWORA trends have leveled off or reversed. A sharp decrease occurred in the number of jobs in the sectors that had previously employed low-income single mothers, precipitating higher unemployment rates in this group. In 2002, the average unemployment rate of low-income single mothers was 12.3%, an increase from 9.8% in 2000 (Chapman & Bernstein, 2003). Consistent with this change is evidence from the National Survey of America's Families that the proportion of recent welfare leavers who were working and not receiving TANF was lower in 2002 than it was in 1999—42.2% versus 49.9% (Loprest, 2003a)—and that food stamp receipt among welfare leavers increased from 28% in 1999 to 35% in 2002 (Loprest, 2003b). The number of children living with an unemployed parent dropped from 4.3 million to almost 3 million between 1995 and 2000, but by 2001, this number again stood at 4 million (S. K. Martin & Lindsey,

2003). Moreover, child poverty rates have increased since 2000, and the percentage of children living in deep poverty (those below one-half of the poverty threshold) is rising toward pre-1996 levels (S. K. Martin & Lindsey, 2003; Proctor & Dalaker, 2003).

Changes in Family Material Resources. Studies of aggregate-level changes in the economic resources of low-income families wrought by welfare reform present a mixed picture. Researchers who base their assessment solely on cash income conclude that poverty has declined as a result of welfare reform, whereas those who base their assessment on total family income, including noncash benefits, conclude that a significant segment of families are worse off as a result of welfare reform. Accumulating data suggest that, indeed, those at the bottom of the income distribution have experienced a substantial decline in income since the implementation of TANF, principally because of a sharp drop in receipt of various welfare-related benefits (Greenberg et al., 2002; Zedlewski, 2002). Studies consistently report that about 40% of families leaving welfare are not working and that their transition off welfare was the result of sanctions or noncompliance with program requirements. Adults in these families tend to have very low levels of education, little or no work history, and multiple barriers to employment. These families represent a large percentage of those who experienced a drop in income following welfare reform (Greenberg et al., 2002).

The other 60% of families that leave welfare are working, but in jobs that are typically low paying with no employer-provided benefits. Moreover, a surprisingly large percentage (over 50% in some studies) of these families lack food stamp benefits, Medicaid coverage, and child care subsidies even when eligible—the result being that they face multiple material hardships, including unmet health needs, food insufficiency, and inadequate housing (Greenberg et al., 2002; S. K. Martin & Lindsey, 2003; Zedlewski, 2002). Low participation rates in programs intended to support working poor families have been attributed to ineffective administrative systems in state and local welfare offices, caseworkers' lack of understanding of complex eligibility rules, administrative complexities, and stigma associated with these programs (Zedlewski, 2002). Such findings underscore the important point that gauging the impact of welfare reform on families and children is not simply a matter of documenting the relationship of transitions into and out of TANF and employment to child and fam-

ily well-being, but also assessing how policy differences under TANF versus AFDC are related to resources available to the poor overall, regardless of their welfare and employment transitions.

One of the reasons for the high percentage of poor families who are currently eligible for but not receiving Medicaid coverage is that welfare reform uncoupled eligibility requirements for TANF and Medicaid (Burton et al., 2002). Before TANF, individuals receiving AFDC were automatically eligible for Medicaid. Now, individuals must qualify for TANF and Medicaid separately. This policy change, one of several intended to increase returns from low-wage work and to push welfare recipients to higher levels of employment-based self-support (Morris et al., 2001), made families at higher incomes eligible for Medicaid without regard to TANF or TANF time limits. Paradoxically, studies show a decline in families receiving Medicaid once off TANF rolls, although it is not clear how much of this is due to families being no longer eligible or being unaware of continuing eligibility. Families that are not eligible for enrollment in TANF, or who leave TANF, may not be aware or informed that they may still qualify for Medicaid. In 1997, shortly after passage of PRWORA, Congress passed the States Children's Health Insurance Program, allowing billions to enable states to insure children from working families with incomes too high to qualify for Medicaid but too low to afford private health insurance (Burton et al., 2002).

In Burton et al.'s (2002) ethnography, a complex story about family health insurance unfolded. Families clustered in three health insurance categories: (1) fully insured, (2) partially insured (some family members were covered by health insurance and some were not), and (3) uninsured. In 40% of the families, all household members (primary caregivers and children) were covered by Medicaid, private insurance, or some combination of the two. The variable insurance coverage across and within families was attributed to numerous factors, among them, (a) primary caregivers' confusion about their eligibility for TANF and Medicaid benefits (some did not know whether they or their children were insured even though they were receiving TANF); (b) primary caregivers (e.g., grandparent) who did not have legal custody of the children they cared for and, as such, could not acquire insurance for them; and (c) institutional and informational barriers that primary caregivers encountered in acquiring Medicaid for themselves and their children once they were sanc-

tioned or transitioned off TANF. As one mother said, "Once my caseworker told me I was cut off I figured that was it. I thought that means that I can't get food stamps or medical assistance. Is that right?" (p. 28). Another significant barrier was job schedule and transportation difficulties faced by working poor parents in getting to the appropriate offices to apply for Medicaid or other types of health insurance for their children.

Lowe and Weisner's (2004) ethnographic data from individuals randomly assigned to the New Hope control group provide compelling examples of administrative complexities tied to child care subsidies and the toll they take on families. To use and maintain access to child care subsidies from the state Wisconsin Shares program, for example, families had to complete paper work, meet with agency personnel to find out about child care availability, and travel back and forth between home, work, and the state offices to submit proof of employment or levels of income each month or pay period. Often, these procedures had to be repeated when family economic and child care needs shifted. Evelia's encounter with administrative missteps, briefly noted in the case presented at the beginning of this section, entailed inconvenience, but for some individuals, the barriers to access and the resulting material and psychological costs were especially high. Consider the case of Keisha (Burton et al., 2002, p. 29):

During the five hours per day Keisha spends on the bus getting back and forth to work, and her 8-hour shift, she can never get to the appropriate office before it closes to apply for Medicaid for herself and her three children. She won't take time off from work to go into the office during regular business hours for fear of losing her job. She prays every day that she and her children don't get too sick.

Danziger, Corcoran, Danziger, and Heflin's (2000) study of post-PRWORA welfare-to-work transitions in a community-based sample of women underscores the mixture of advantages and challenges that accompany the transition from welfare to work. Employment among women who were current or previous recipients of cash assistance reduced, but certainly did not eliminate, economic vulnerability and material hardships. Women currently or previously on welfare who accumulated the most labor market experience over a 20- to 23-month period post-PRWORA had higher levels of financial and subjective well-being. They garnered higher monthly earnings and income net of work-related transportation and child care expenses and experienced fewer material

hardships (e.g., food insufficiency, no phone, utilities cut-off, eviction). In addition, they were less likely to report engaging in other activities to make ends meet, such as pawning possessions, receiving food, clothing, or shelter from a charity, and engaging in illegal behavior. However, regardless of level of work involvement, a substantial proportion of women reported major economic difficulties and high levels of subjective financial strain. For example, among the women who worked every month during the nearly 2-year period, about one-third received cash welfare, two-thirds received food stamps, and one-fifth reported two or more experiences of material hardship.

Child Outcomes. We have very limited knowledge about how children's well-being is related to mothers' transitions off welfare and into employment since the implementation of the 1996 welfare reform law. Data are too sparse and too few welfare recipients have experienced some of the most draconian provisions of the law (e.g., time limits) to draw conclusions yet. That said, extant research suggests that at least in the short run, transitions off welfare into employment bear no negative relation to child well-being and, in some instances, is associated with improved child functioning (Chase-Lansdale et al., 2003; Dunifon, Kalil, & Danziger, 2003). The best known of these research efforts is the Three-City Study of Welfare, Children and Families, a longitudinal study of a sample of 2,404 families from low-income neighborhoods in Boston, Chicago, and San Antonio, with a focus on preschoolers (ages 2 to 4) and children in early adolescence (ages 10 to 14; Chase-Lansdale et al., 2003). Families participated in home interviews in 1999 and again in 2001, on average 16 months after the first interview. Extensive measures of child well-being were collected, including direct measures of children's quantitative and reading skills, adolescent self-reports of psychological distress and delinquent behavior, and maternal reports of children's emotional and behavior problems.

The researchers found that transitions into and out of welfare and employment—whether for 1 or more hours or for 40 hours per week—were not associated with negative outcomes among preschoolers. For adolescents, the predominant pattern was also one of few associations. However, when associations were found, they tended to indicate positive, though small, effects of transitions into employment. In particular, adolescents whose mother transitioned into employment, irrespective of

the number of hours of employment, reported better mental health (i.e., lower levels of anxiety and psychological distress). The findings pointed to both increases in income and mother's time with the child as mediating influences. Information from a time diary of the day before the interview was used to estimate hours that mothers spent apart from their children while working and hours that mothers spent apart from their children while not working. For preschoolers, increased family income as a result of mother's entry into employment appeared to be offset by significant decreases in the amount of time they spent with their mother, leading to no net effect of welfare and employment transitions. A trade-off between money and time was not apparent in the case of adolescents. Family income increased when mothers of adolescents entered employment, but these mothers appeared to have compensated for time away from their adolescent children by cutting down on time apart when they were not on the job.

On the whole, Chase-Lansdale et al.'s (2003) findings for preschoolers, but not for adolescents, appear consistent with the random assignment studies reviewed earlier in the chapter showing a pattern of no effects on preschoolers and elementary school-age children of programs with mandatory employment services and time limits, and a pattern of positive effects of earnings supplement programs. Chase-Lansdale et al. have offered a number of explanations for why their findings for adolescents are at odds with those from experimental studies. The Three-City sample includes both mothers on welfare facing work requirements as well as unemployed mothers not on welfare who voluntarily joined the labor force, whereas in the experimental studies, the treatment groups were subject to mandatory work requirements. There is also the possibility that direct assessments of children's reading and math skills (collected in the Three-City Study) may be more valid and reliable than teacher and parent reports of school progress. In addition, adolescents in the Three-City Study, on average, were younger (ages 11.5 to 15.5) than those in the experimental studies (ages 12 to 18) at the time of measurement. Negative effects may emerge in the former study as these teens move into late adolescence (Chase-Lansdale et al., 2003).

In terms of its relevance for the debate about welfare reform policy from the child's perspective, this study and its findings need to be viewed in light of several additional considerations. First, some have questioned

how much this study speaks directly to the effects of welfare reform policy on child well-being because the study does not differentiate between women who made welfare and employment transitions because of welfare reform and those who made transitions for other reasons (e.g., greater employment opportunities resulting from a strong economy; Kaestner, 2003). In raising this issue, Kaestner pointed to research indicating that since the implementation of the welfare reform law, only about one-third of the women who transitioned from welfare to work did so in response to public policy changes, arguing that when the causes of such transitions are different, the effect of the transitions may also be quite different. Second, the investigators of the Three-City Study have cautioned against viewing these findings as the final word on the effects of welfare reform on children because (a) findings to date are based on data collected prior to the weakening of the economy in 2001, (b) relatively few welfare families had reached their time limits at the time the data were collected, and (c) findings to date reflect short-term associations between child well-being and mothers' work and welfare transitions that might change in the long term (Cherlin, 2004).

The same cautions hold for Dunifon et al.'s (2003) longitudinal study of how transitions from welfare to work during the period from early 1997 to late 1999 are related to parenting behavior and children's behavior problems (based on maternal report) in a sample of 575 single mothers (all were welfare recipients at Wave 1) and their children ages 2 to 10 (at Wave 1). Relying on life history calendars that measured maternal employment status in each month and administrative records of TANF cash benefits in each month over the study period, at each of three waves, they classified women as being in one of five mutually exclusive categories based on their work/welfare status during at least 7 of the past 12 months: wage-reliant, welfare-reliant, combiners (women who both worked and received welfare payments simultaneously), no work/no welfare, and transitioners (women not in any of the four other categories; these women were transitioning between multiple categories over the study period). Only one of the work/welfare categories was related to child behavior problems. Moving from welfare-reliance to combining welfare and work (combiners) was associated with a decrease in internalizing and externalizing behavior problems. They found no evidence that changes in parenting behavior (e.g., harsh parenting, positive parenting),

household income, or perceived financial strain mediated this relation.

Potential Moderating Influences. As suggested earlier, how economically poor children fare in the context of welfare reform and how they respond when their mothers enter employment is likely to depend on a host of maternal, family-level, and extrafamilial factors, including mothers' human and social capital, values concerning employment, commitment to full-time parenting, proclivity toward depression, and coping skills, as well as child care and school quality, the home environment, the depth and persistence of poverty (especially for young children) that results from time limits as well as other elements of welfare reform, and local economic conditions (Chase-Lansdale et al., 2003; Coley & Chase-Lansdale, 2000; Duncan & Brooks-Gunn, 2000; D. J. Fein & Lee, 2003; Kalil, Schweingruber, & Seefeldt, 2001). Extant research provides a very sound basis for expecting that the nature and quality of the mother's job, maternal work intensity, and child care experiences, in particular, will exert strong moderating influences. Taken together, these factors make it doubtful that robust average effects of mothers' transitions of welfare will emerge (Chase-Lansdale et al., 2003).

Job Quality and the Working Poor. As previously noted, about 60% of parents who leave welfare are working, but in jobs that are typically low paying with no employer-provided health insurance or pension benefits (i.e., the classic definition of a "bad" job; Greenberg et al., 2002; Kalleberg, Reskin, & Hudson, 2000). Many employees, but especially those with low levels of education, are becoming increasingly less likely to find job security, regular wages and hours, and the benefits that have been associated with regular full-time employment (Kalleberg et al., 2000). The increase in short-term jobs with irregular hours affects the regularity and dependability of paid work available to these individuals (Lambert, Waxman, & Haley-Lock, 2002). Many of these jobs require changes in numbers of hours and shifts worked (Ehrenreich, 2001; Newman, 2001). Rotating shifts and daily or weekly assignment of different hours leave parents unable to plan ahead for their transportation, child care, and other needs (Henly & Lyons, 2000).

Many of the jobs with the highest growth rate in recent years have disproportionately high rates of nonstandard schedules (night, evening, and variable shifts), are in female-dominated occupations, and include some of

the most common jobs held by women with low levels of education (e.g., cashier, janitor, maid, waiter, nursing aide, orderly; Silvestri, 1995). Increasing numbers of working poor mothers will hold these jobs to satisfy the work effort mandated by welfare reform. Never-married mothers are more likely than married or divorced mothers to work nonstandard schedules because they have lower levels of education and lack alternative employment opportunities. Remarkably, their employment schedules, unlike those of married mothers, are unrelated to caregiving demands (e.g., having a child under the age of 5, number of children under age 14; Beers, 2000; Presser & Cox, 1997).

There is a significant body of research, much of it conducted prior to the passage of PRWORA, that provides clues about how job characteristics might influence children's home environments and adaptation to their mother's transitions from welfare to work. Research with low-income families with some history of welfare receipt indicates that girls whose mother worked had fewer behavioral problems and higher mathematics achievement scores, but only if the mother earned relatively high wages. Outcomes for girls whose mother earned very low wages were similar to those for girls with a nonworking mother (Moore & Driscoll, 1997). Higher hourly earnings also have been linked to fewer behavioral problems in children of mothers who are disproportionately from low SES backgrounds (Rogers, Parcel, & Menaghan, 1991). Especially low wages may impose severe restrictions on parents' ability to provide children adequate nutrition, health care, and material stimulation (Duncan et al., 1994). They also may diminish the quality of parent-child interaction and reduce parental monitoring of children's health by increasing psychological distress in parents (McLoyd, 1990).

Other work indicates that the quality of children's home environment worsens when single mothers enter low-wage jobs with low complexity (i.e., routine, repetitive, heavily supervised activities with little opportunity for autonomy and initiative), but not when they enter jobs with higher wages and complexity. Low-complexity jobs tend to present minimal cognitive demands to those who hold them. This job characteristic is thought to indirectly and negatively affect the learning, academic, and language stimulation children receive in their home environment (e.g., books, toys that teach academic and language skills, quality of verbal explanation to child)

by constricting parents' cognitive functioning and, in turn, lessening the value they hold for cognitive achievement in their children (Parcel & Menaghan, 1997).

In addition to posing unique child care demands for single mothers, nonstandard work schedules (night, evening, and variable shifts), as compared to standard daytime work schedules, may undermine worker health, quality of family life, and child well-being. Although extant data on these issues do not focus on the working poor, they have considerable relevance for this population because individuals with low levels of education are disproportionately represented in jobs with nonstandard work schedules. Nonstandard work schedules have been linked to poor-quality and insufficient sleep, problems with appetite, digestion, and elimination, increased risk of cardiovascular disease, and risky health behaviors (e.g., smoking, high levels of alcohol consumption, use of hypnotics; for example, Barak et al., 1995, 1996; Simon, 1990). Because workers on afternoon and rotating shifts have less regular eating times, they may substitute snacks for main meals, a practice that over time can result in weight gain, weight loss, and/or nutritional deficiency. These health problems and health-related behaviors are thought to result because nonstandard shifts upset diurnal and circadian rhythms that control sleep and wakefulness, body temperature, the cardiopulmonary system, cortisol and growth hormone secretion, metabolic activity, and digestive and eliminative processes (Simon, 1990). Shift workers also are more susceptible to mental health problems, a link thought to be the result of greater social isolation, less access to community services, and more difficulty participating regularly in recreational and social groups in their neighborhood and community, and more sleep disturbances, compared to those who work standard hours (e.g., Muhammad & Vishwanath, 1997).

Given their links to physical and mental health problems, it is not surprising that nonstandard work schedules have been linked also to family problems (e.g., divorce, marital conflict; Presser, 2000; White & Keith, 1990) and compromised child well-being. Nonstandard work schedules are associated with lower school achievement and less positive psychological functioning among children (Barton, Aldridge, & Smith, 1998; Heymann, 2000). Data from the National Longitudinal Study of Youth indicates that the more hours a parent worked evenings or nights, the lower his or her child's math and reading achievement scores and the more likely the child was to have repeated a grade and to have

been suspended from school, even after taking into account family income, parental education, marital status, the child's gender, and the total number of hours the parent worked (Heymann, 2000). Daughters (but not sons) whose father works non-day shifts report more dysphoria, lower self-esteem, and less perceived academic competence, compared to daughters whose father works day shifts (Barton et al., 1998). A standard daytime work schedule affords more parent-child contact than a nonstandard work schedule because it is generally more synchronous with children's daily school schedule. Consequently, parents who work these hours may find it easier to monitor the child's behavior, to set and enforce limits/rules, and to engage in shared activities with the child (Heymann, 2000). Given these differences, it seems likely that nonstandard work schedules undermine children's well-being partly by reducing parent-child interaction, parental involvement in the child's schooling, and parental supervision of children's time use and activities.

Work Intensity. Number of hours of maternal employment is also linked to child well-being, though this work has not focused exclusively on low-income families. Net of maternal background factors and other work characteristics (e.g., hourly wage), children whose mother works part time (20 to 34 hours/week) have greater verbal skills than children whose mother works full-time, who, in turn, have better verbal skills than those whose mother routinely works overtime. Parental work that routinely exceeds 40 hours/week may hinder, rather than facilitate, children's cognitive, social, and physical well-being by diminishing parent mental health, parental availability and involvement, and children's social capital. The combination of overtime hours and having a job low in complexity has been found to exacerbate children's behavior problems (Parcel & Menaghan, 1994).

Extrapolating from extant findings, it is reasonable to hypothesize that children in working poor families, on average, are likely to fare better if their parents work part time, do not routinely work overtime, and hold jobs that afford higher wages, more occupational complexity, and a standard daytime work schedule. The Bush administration's proposal for reauthorization of welfare reform calls for single-parent welfare recipients to be involved in work and work-related activities 40 hours per week instead of the current 30 hours per week (Thompson, 2003). This proposal, if enacted, may well undermine mothers' ability to meet their children's health and developmental needs. Meeting these needs

often requires that parents are available to take children to well-child or illness-related medical appointments during regular business hours, to care for sick children, to manage chronic disease exacerbations such as asthma (both chronic diseases and exacerbations are more prevalent among poor children than nonpoor children; Fernandez, Foss, Mouton, & South-Paul, 1998; Halfon & Newacheck, 1993), and to have children evaluated for cognitive and behavior problems—caregiving that is especially difficult when a single parent is working full time in a job with little flexibility (Heymann & Earle, 1999). High work intensity in combination with certain nonstandard work schedules is of particular concern as a threat to adolescent well-being because of its potential to markedly undermine parents' ability to monitor and supervise the child's behavior (Gennetian et al., 2002).

Child Care. A full discussion of child care issues in relation to welfare reform is beyond the scope of this chapter. These issues have been considered at length by others (Fuller, Kagan, Caspary, & Gauthier, 2002; Lowe & Weisner, 2004; Lowe, Weisner, Geis, & Huston, 2005). However, several points bear brief mention here. Fuller et al.'s review of studies suggests that age of child, trust and flexibility, costs, and accessibility are prominent considerations in parents' decisions about child care. When mothers' participation in welfare-to-work programs begins, they typically rely on informal child care arrangements, but as they move off welfare and into stable jobs, they are more likely to choose center day care or a family child care home (Fuller et al., 2002). Consistent with the child care preferences of Evelia, whose case was presented earlier, low-income mothers tend to trust kin and friends as caregivers more than center-based caregivers, partly because they share child-rearing values and practices and because caregiver kin and friends tend to be more flexible (Fuller et al., 2002). However, many low-income parents prefer center care when it is available and affordable (Quint, Polit, Bos, & Cave, 1994).

The impact of mothers' employment transitions on children is likely to be influenced by the quality of care children receive in their mother's absence. The impact of child care on children's social and cognitive development depends partly on its quality, which is typically defined by structural features (e.g., low ratios of children to adults, trained caregivers) and process features (e.g., responsiveness of caregiving; Lamb, 1997). Research indicates that when quality is equivalent, formal center-based care is associated with more advanced

cognitive and language development than is home-based child care, and this seems partly due to the educational materials and activities that centers typically provide (Lamb, 1997; NICHD Early Child Care Research Network, 2000). On average, poor children have less access to and are less likely to be enrolled in high-quality child care programs than their more advantaged peers (Fuller et al., 2002). However, when they are enrolled in high-quality center care, they accrue more benefits from such care than their advantaged counterparts (Loeb, Fuller, Kagan, & Carrol, 2004).

Loeb et al. (2004) recently documented the longitudinal effects of type (center care versus family child care home versus individual kith and kin), quality, and stability of child care among low-income children of working poor mothers. Consistent with the experiences of Evelia's daughter recounted earlier, Loeb et al. found strong positive effects of center-based care. Among children who were between 12 and 42 months when their mother entered welfare-to-work programs, those in center-based child care programs had higher levels of performance on several indicators of cognitive functioning than children who remained with individual kith and kin providers (controlling for income and numerous maternal and child background factors). Quality of care (based on half-day observations of centers and home-based care settings) as well as stability of care were associated with higher school readiness and cognitive functioning, but even taking these factors into account, center care predicted more positive cognitive outcomes. Effects of type of child care on children's social competence were less consistent. Children in family child care homes exhibited more behavioral problems than those in other types of care settings, but the only significant effect was for aggression. Children in family child care homes were more aggressive than children cared for by kith and kin.

PROGRAMS FOR POOR CHILDREN AND FAMILIES: POLICY AND PRACTICE CONSIDERATIONS

In this final section of the chapter, we consider the ideological bases and limitations of early childhood education as an antipoverty strategy in light of social-structural and macroeconomic forces, and offer suggestions to guide the practices of those working with poor children and families.

Early Childhood Education in Context

The extent of childhood poverty and the strategies used to reduce its prevalence and its effects are not preordained, but rather reflect society-level choices and, hence, values. Understanding the ideology that undergirds these choices is important partly because forging different or a richer palette of choices is conditional on changes in ideology. Appreciation of the sociostructural, macroeconomic, and historical contexts within which early childhood education is situated is an antidote to unreasonable expectations about the benefits that these interventions can bestow on poor children. We turn to these issues next.

Ideological Context

Americans are far more supportive of government action to ensure educational opportunity than other types of social welfare (e.g., universal minimal income and health insurance), and this disparity in preference is much more pronounced among Americans than among citizens in other Western industrialized countries (Haller et al., 1990). It is not surprising, then, that early childhood education, either alone or in combination with other services, has long been the predominant government-sponsored strategy used in the United States to fight poverty and its negative effects. As a large-scale, publicly funded strategy, it dates back more than 150 years, to the establishment of free and universal public education for White American children and the assurance by its proponent, Horace Mann, that this reform would virtually eradicate poverty. It is a natural outgrowth of America's tendency to focus on children as instruments of reform (de Lone, 1979).

Head Start's broad-based support derives from several sources, including strong support from Head Start parents and staff, public campaigns by advocacy groups such as the Children's Defense Fund, positive media attention, and empirical evidence of early childhood education's effects on children's school readiness and academic achievement (Zigler & Styfco, 1994a). Not to be underestimated as a source of its popularity, though, is Head Start's compatibility with Americans' preference for indirect rather than direct approaches (e.g., universal minimal income) to poverty reduction (Haskins, 1989; Zigler, 1985). It is politically palatable because of its avowed promotion of equality of opportunity rather than equality of condition.

That is, early childhood interventions touted as anti-poverty programs essentially hold out the promise of ending poverty in the next generation, while preserving social harmony and buttressing the Protestant work ethic and beliefs about equal opportunity and unlimited economic and social mobility (de Lone, 1979). Because the ideal of equality of opportunity stands in sharp contrast to the reality of gross economic inequality in the United States, "the mission of childhood in this country has been defined to a considerable extent by the promise of equal opportunity" (p. 34). This promise exerts a powerful grip on the American psyche, for what poor parent dares not hold fast to the dream of rearing offspring who "make it," who do better economically than their parents? Reality, however, is more sobering. The escape hatch is not a large one and, indeed, may be growing smaller if research on intergenerational income mobility (Solon, 1992) and the changing prevalence of chronic poverty (Rodgers & Rodgers, 1993) is any indication. Using intergenerational data from the Panel Study of Income Dynamics, Solon found father-son and mother-son correlations of about .40 or higher in long-run earnings, hourly wages, and family income. Based on this estimate, a son whose father is in the bottom 5% of earners has only a 1 in 20 chance of making it into the top 20% of families, a 1 in 4 chance of rising above the median income of American families, and a 2 in 5 chance of staying poor or near poor. The parent-son correlations for earnings and family income reported by Solon are higher than those typically reported in past studies (most report correlations of .20 or less, and most present data on fathers but not mothers). Correlations for ethnic minorities are likely to be even higher due to racial and ethnic barriers. Solon argues compellingly that previous studies systematically underestimated the correlation between father and son income status (and hence overestimated intergenerational income mobility) as a result of flawed and limited data (e.g., single-year measures of earnings) and unrepresentative, homogeneous samples.

The United States espouses a liberal ideology that minimizes class distinctions and proclaims equal opportunity, yet it has intergenerational mobility rates roughly comparable to those in European countries where class distinctions are exaggerated (de Lone, 1979). This contradiction exists because Americans are less likely to interpret intergenerational mobility as tied to family background and more likely to view it as evidence of the openness of their society than are individu-

als in, for example, Great Britain, West Germany, Austria, or Italy (T. Smith, 1990). Liberal ideology has tempered class consciousness in the United States, but so have ethnicity, religion, and especially race as sources of identity. America's heightened racial and ethnic consciousness is inextricably tied to the lingering effects of its systematic subordination of castelike ethnic and racial minorities, including its enslavement and legal segregation of African Americans, conquest and forced displacement of American Indians and Hispanics, and the economic exploitation of Asian immigrants (Ogbu, 1978).

Sociostructural and Macroeconomic Contexts

Many of the causes of poverty and the difficult life conditions confronting poor families in the United States are largely impervious to child- and family-level interventions (e.g., historic and contemporary racism in the labor market, lending institutions, housing; poor-quality schools; low wages paid by traditionally "female" jobs; unavailability of affordable, high-quality child care). Smeeding and his colleagues (Smeeding, Rainwater, & Burtless, 2001), for example, found that America's exceptionally high rate of child poverty, compared to the rates in other Western industrialized countries, is partly due to a comparatively high incidence of low-paid employment. A substantial proportion of variance in cross-national poverty rates was accounted for by cross-national variation in the prevalence of low-paid employment, defined as the proportion of a nation's full-time workers who earn less than 65% of national median earnings on full-time jobs. In the 1990s, of 14 industrialized countries, the United States had the highest proportion of such workers. The prominence of these sociostructural factors as contributors to poverty do not augur well for the success of antipoverty policies whose core strategy involves educating or ministering to the acute needs of poor youngsters in the absence of job creation and the presence of massive numbers of jobs that do not pay their parents a living wage. As Halpern (1988, 1990a) contends, it is a case of using secondary strategies to deal with primary problems.

Rather than effect structural changes to remedy poverty and its social ills, U.S. policymakers have overly relied on a variety of social services and programs that call for ameliorating poverty and its attendant problems largely by changing individuals, not structures. The evolving ecological approach in early childhood intervention with its emphasis on altering so-

cial contexts in ways that enhance family life and children's development surely represents an advance over more unidimensional, person-centered approaches, but it has not and indeed cannot alone produce significant structural or institutional change in American society. The social and economic conditions that produce developmental risks are as prevalent as ever today, despite an ever increasing proliferation of ecologically sensitive home-based and center-based programs and expansion of our national early childhood education program for poor children and families. This overreliance on services and programs, many of which were designed to be a last resort rather than the principal resource base for developing children (Garbarino, 1992), reflects either genuine opacity about the limits of what such programs and services can realistically accomplish, or "an unwillingness to acknowledge that many of our most serious problems are a result of chosen social and economic arrangements and a reluctance to use the political process to alter arrangements even when it is acknowledged that they are harmful" (Halpern, 1991, p. 344). Moreover, because the reforms and programs invariably fall markedly short of their promise, insufficient acknowledgment of what they can accomplish bodes well for the cyclical and predictable resurrection of genetic hypotheses proclaiming the intrinsic inferiority of those individuals whom reformers sought to help (de Lone, 1979; see also Herrnstein & Murray, 1994).

As a genre, early childhood education is no more likely to significantly reduce poverty in the United States than did universal public education, for it does not directly increase material resources or fundamentally alter most of the environmental conditions that produce problematic developmental outcomes and intergenerational poverty. At best, it only blunts the powerful force of poverty and renders modest improvements in children's environmental circumstances and developmental outcomes. As is clearly documented in research studies reviewed in this chapter, although Head Start and other preschool education programs significantly increase poor children's school readiness, they leave wide gaps between poor children's school competence and that of more economically advantaged children and have only weak, if any, impacts on participants' postschool labor market participation (Royce et al., 1983). Moreover, the positive effects on preschoolers of these interventions, especially large-scale, educational programs, are not sustained because of the tangle of environmental risk factors and their

multiplicative adverse effects that is the lot of too many poor children in the United States (Rutter, 1979).

This problem is well illuminated in a study by Lee and Loeb (1995) that sought to clarify why the cognitive gains produced by children's participation in Head Start and model programs fade or disappear completely within 2 to 3 years after the intervention. This study, based on a sample of more than 15,000 eighth graders enrolled in 975 middle schools (based on a sample drawn from the National Education Longitudinal Study of 1988), points to poor-quality schooling subsequent to preschool intervention as a potential culprit. Compared to students who attended other preschools, former Head Start enrollees were in middle schools distinguished by considerably less academic rigor as reported by students, parents, and principals, lower overall quality, lower average student performance on mathematics, science, reading, and social studies achievement tests, and lower SES (i.e., average SES of children attending the school). The middle schools of former Head Start enrollees also were perceived to be less safe than those attended by non-Head Start counterparts. These differences were evident after controlling for family income-to-need ratio, parents' education, and children's race and ethnicity. Similar, but less pronounced, differences were also found in school quality favoring students who did not attend preschool, as compared to students who formerly attended Head Start. Additional insight could be brought to bear on this issue by tracking changes in children's academic performance from the preschool years through elementary and secondary school in relation to the quality of schooling.

The challenge of producing positive effects potent enough to be of some long-term or even immediate significance in parents' and children's lives, in spite of a multiplicity of ongoing and unremitting environmental stressors, is no less daunting for service programs that are billed, not as instruments of poverty reduction, but as strategies that prevent or ameliorate poverty's negative effects on family life and children's development. As we have seen, randomized trials of home visitation programs, even those that are more comprehensive in nature, have had little overall success in preventing child maltreatment, preterm delivery, and low birthweight. They have proven more effective in promoting positive child-rearing practices and producing gains in children's cognitive functioning, though it is not known whether these effects translate into better long-term outcomes for children (Olds & Kitzman, 1990, 1993).

Recognizing the negative consequences of overoptimism, some of the most ardent supporters of these programs have conceded and even emphasized the limitations of what early childhood intervention programs and two-generation programs can accomplish (Washington, 1985; Zigler & Styfco, 1994a). Zigler and Styfco, for example, lamented that "neither Head Start nor any preschool program can inoculate children against the ravages of poverty. Early intervention simply cannot overpower the effects of poor living conditions, inadequate nutrition and health care, negative role models, and substandard schools" (p. 129). To argue that early childhood education programs or various other forms of social and educational services are insufficient to reduce poverty to a significant degree is not to suggest that they be eliminated. Rather, in the spirit of Zigler and Styfco's admonition, it is a call to acknowledge that child- and family-level interventions and service programs can "counter some of the injuries of inequality, but . . . cannot destroy inequality itself" (de Lone, 1979, p. 68) and, in so doing, relieve these programs of a responsibility they cannot discharge: producing greater equality. Moreover, program effects on employment status and wages are likely to be highly dependent on circumstances, such as the local economy, that are beyond the control of these programs (Swartz et al., 1995). Ultimately, significant progress toward reducing the high incidence of childhood poverty in the United States is likely to require the creation of government-supported work programs that mix work and benefits (e.g., the New Hope Program; Bos et al., 1999) and the provision of more generous earnings supplements under the Earned Income Tax Credit (Smeeding et al., 2001; W. J. Wilson, 1996), strategies that are more in keeping with American values than the social insurance policies operating in many European countries (Smeeding & Torrey, 1988).

Historical Context

Recent trends in childhood poverty raise questions about whether early childhood intervention and service delivery based on models developed during the 1960s and 1970s are even less effective today than in previous times. Since the mid-1970s, poverty has become more geographically concentrated and its environmental stressors more pervasive and life-threatening (e.g., homelessness, street violence, illegal drugs; Shinn & Gillespie, 1994; W. J. Wilson, 1996). It also appears to have become more chronic and less transitory, though the data

on this are less conclusive (Duncan & Rodgers, 1991; Rodgers & Rodgers, 1993). Conversely, jobs, public and private services (e.g., parks, community centers, child care), and informal social supports have become less accessible to the poor (W. J. Wilson, 1996; Zigler, 1994).

These changes in the persistence, context, and environmental correlates of poverty signal more acute needs among the poor. Although Head Start apparently has always served the poorest of the poor (Schnur et al., 1992), the deprivation experienced by that group may well increase over the years as more experience the draconian elements of welfare reform (i.e., time limits). If the disadvantages resulting from poverty have increased, the injurious effects of poverty may have intensified as well, necessitating modifications in extant programs. This inference is supported by evidence that persistent poverty is more deleterious to children's development and home environments than is transitory poverty, and research indicating that neighborhood poverty has adverse effects on children's functioning independent of family-level poverty (Brooks-Gunn et al., 1995; Duncan et al., 1994). Consequently, programs based on models of intervention, prevention, and service delivery developed prior to the mid-1970s may be less effective in buffering the effects of today's poverty (Zigler, 1994). Achieving remediation effects equivalent to those produced by interventions implemented in earlier times may require interventions that are more intensive, comprehensive, and integrative. To some extent, the flexibility accorded Head Start programs, whereby they are permitted to adapt components to local needs and resources, mitigates the latter concern. However, this flexibility does not result in incremental funding if the needs of those to be served increase.

At the very least, the family support services component of Head Start should be intensified and such a component added to early childhood education programs lacking it. Better integration of services also is needed (Illback, 1994; Ramey, 1999). These recommendations are justified on the basis of the changing nature of poverty and strong evidence of the adverse and cumulative effects on children's cognitive functioning and home learning environment of risk factors such as low social support and stressful life events (Brooks-Gunn et al., 1995; Sameroff et al., 1987). The relationship of these risk factors within the family ecology to children's cognitive functioning is consistently stronger in poor families than affluent families, suggesting that need for these support services may be especially acute and their

provision particularly beneficial to children whose parents are poor (Bee et al., 1982).

The potential for devolution, or shifting Head Start from federal to state control—raises yet another historical consideration. If proponents of devolution prevail—and there are strong reasons for concern about the wisdom of such a change in policy—it will be critical to determine how devolution impacts Head Start implementation, quality, access, and efficacy (Ripple, Gilliam, Chanana, & Zigler, 1999; Zigler & Styfco, 2004b).

Working with Poor Children and Families

The effectiveness of programs intended to enhance poor children's intellectual and educational achievement is not only a function of whether the services provided by the programs are sufficiently intensive, comprehensive, content-appropriate, and flexible to meet families' needs. It would be a serious error to ignore the potency of the affective dimension of programs. It is this dimension on which we concentrate here.

Schorr (1989) found that staffs of successful programs were not only technically skilled, but were committed to and respectful of the families they served, making it possible for them to establish caring and trusting relationships with service recipients. According families wide latitude to decide what services to utilize and how they wanted to participate and taking account of the families' particular goals for their children were among the ways respect and trust were established and maintained.

The established link between attribution biases and psychological well-being suggests that blaming the poor for their plight will exacerbate their psychological problems, heighten mistrust and apprehension, and undercut the professional's role as facilitator and helper (Belle, 1984; Crockenberg, 1987). Hence, programmatic efforts to ameliorate or prevent negative outcomes in parental functioning, parental psychological well-being, and children's functioning should be unambivalently supportive rather than punitive in nature. Although the family support movement and ecological approaches to intervention essentially endorse this position, effectively actualizing this principle requires recognition of the formidable cognitive challenges it poses to prevailing sentiments.

Americans harbor a profound ambivalence toward and suspicion of poor people, partly because the value and myth of independence and self-sufficiency are so

deeply etched in American society as to be virtually sacrosanct. A sense of morality, ethics, and magnanimity moves us to help them, but our steadfast ideological commitment to individual culpability as a primary explanation of poverty compels us to punish them (Halpern, 1991; Pelton, 1989). Racism, cultural ethnocentrism, and ignorance of nonmainstream cultural traditions intensify these negative attitudes when the poor in question are ethnic minorities. The typical middle-class service provider or teacher has never experienced the stressors that children and families living in concentrated poverty routinely confront. This lack of common history and experience, combined with the negative view of the poor that prevails in American society, means that persons who work with poor children and families in intervention and prevention programs must confront and work arduously and self-consciously to minimize ambivalence about the character and worth of poor people and to bridge the class- and culture-linked chasms between them and the poor. Otherwise, their effectiveness will be undermined. Visits to clients' neighborhoods and homes, when undertaken as a genuine educational experience, can help interventionists appreciate clients' ongoing struggles to survive and raise their children in the midst of daunting environmental realities (Belle, 1984). Educators and service providers also need to grapple with ethical issues that often arise in intervention programs for poor children and parents (e.g., procedures that restrict the autonomy of participants who are highly vulnerable and in greatest need; activities that usurp the parental role and conflict with the child's family heritage and values; McAdoo, 1990).

Knowing and demonstrating sensitivity to the cultural characteristics and class-linked expressions of the families to be served cannot be overemphasized (Slaughter, 1988), although it is equally important to recognize the existence of individual differences within groups of poor and ethnic minority families. Without this competence, status cues assume exaggerated importance in unfamiliar interpersonal situations, often operating to the detriment of lower-class individuals and hindering the establishment of a trusting and mutually respectful relationship. For example, as early as kindergarten, status cues appear to contribute to negative biases about the intellectual capacity of poor children, which in turn can impede their educational and economic mobility through various classroom dynamics (Rist, 1970). In a well-designed study of first-grade teachers and students in a socially

heterogeneous, urban public school system, Alexander, Entwistle, and Thompson (1987) found that first-grade teachers' own social origins tempered their reactions to the status attributes (i.e., race and SES) of their students and that these reactions had significant implications for children's achievement. High-SES teachers (i.e., those who grew up in middle-class homes), compared to low-SES teachers (i.e., those who grew up in lower-class homes), held more negative attitudes about the maturity and social competence of poor, African American first graders and held lower performance expectations for them than for their White peers. African American students in classrooms taught by high-SES teachers began first grade with test scores very similar to their White counterparts, but by year's end they had fallen markedly behind. Race differences in grades were especially pronounced. In classrooms taught by low-SES teachers, however, pupil race was unrelated to teachers' affective orientations and judgments, and no race differences in grades or test performance were found. Alexander et al. speculate that high-SES teachers may be less committed to African American students and think less well of their abilities partly because they are less familiar with poor and minority individuals and their surroundings and culture. This can lead them to misconstrue certain cues (e.g., style of dress, deportment, language usage) as fundamental failings in the child.

It is also the case that negative stereotypes can have untoward effects on the behavior of individuals who are the objects of stereotyping. A case in point is the stereotype of African Americans as intellectually inferior to Whites. In a series of laboratory experiments, Steele and Aronson (1995) found that, controlling for verbal and quantitative scores on the Scholastic Aptitude Test, African American college students at a prestigious private university underperformed in relation to Whites when tests (items taken from the Graduate Record Examination study guides) were presented as diagnostic of intellectual ability, but matched the performance of Whites when the same tests were described as laboratory problem-solving tasks. Even asking students to indicate their race on an information sheet immediately prior to taking the test was sufficient to depress African Americans' performance compared to Whites; when students were not asked to indicate their race, there were no race differences in performance. If these effects are generalizable to the classroom, we would predict that African Americans would perform less well than Whites of equal ability on tests construed as measures of intellectual ability.

Members of stigmatized groups typically buffer their self-esteem from the prejudice of others through a variety of social and psychological mechanisms. In their extensive literature review, Crocker and Major (1989) presented compelling, convergent evidence of the use of three of these self-protective mechanisms: (a) attributing negative feedback to prejudice against members of the stigmatized group, (b) selectively comparing their outcomes with those of members of their own group, and (c) selectively devaluing those attributes on which their group typically fares poorly and valuing those attributes on which their group excels. Although these self-protective mechanisms have positive consequences for self-esteem, each of them may undermine motivation to improve one's individual performance in areas where one's group is disadvantaged. Ultimately, the performance level of stigmatized groups may lag behind that of nonstigmatized groups even when individual capabilities do not warrant these differences. In the domain of school achievement, these processes can lead to academic helplessness and low levels of motivation among poor children and children stigmatized because of their racial and ethnic minority status. Paradoxically, to the degree that they operate, these self-protective strategies advance a trajectory of underachievement set in motion by teachers' prejudiced attitudes and behavior and other stigmatizing experiences in the broader environment. A number of scholars have provided compelling evidence of these dynamics among African American and poor students (Brantlinger, 1991). Treatment of individuals belonging to stigmatized groups in a caring and respectful manner minimizes the need for them to invoke self-protective strategies.

Relatively high rates of immigration among minorities are contributing to the growth in the proportion of racial and ethnic minorities in the American population. Because of the socioeconomic and demographic characteristics of recent immigrants (Portes & Zhou, 1993), the ethnic diversity of the poverty population will increase, which, in turn, may well intensify the challenges of designing and implementing antipoverty programs for poor children and families that are culturally sensitive (e.g., have awareness and respect for socialization values and practices; Williams, 1987). Educational interventions and family support programs that serve African Americans and Latinos have provided valuable lessons about some of the essentials for accomplishing this goal (e.g., Larner et al., 1992; Slaughter, 1988; Walker et al., 1995). However, because newcomers often experience

stressors uncommon to or less pronounced among long-time residents (e.g., language barriers, dislocations and separations from support networks, dual struggle to preserve identity and to acculturate, changes in SES status; Rogler, 1994), adaptations in the program content and service delivery may be required to achieve optimal cultural sensitivity and maximum effectiveness in programs serving immigrant parents and their children.

Since the 1980s, research in the field of children and the law is one of the fastest growing areas in all of developmental psychology mainly because it calls on the expertise of researchers in such a variety of areas. Yet, despite the diversity of topics, all share the common goal of studying behaviors and processes that impact the legal status of children both in and out of the courtroom. Although the research is oriented toward applied issues, it is grounded in developmental theory and in some cases has produced innovative developmental paradigms, theories, and frameworks.

The wide set of topics included in research on children and the law reflects their importance to current societal problems. For example, there is a growing literature on the effects of family constellations and parenting on children's adjustment, such as the effects of gay or lesbian parenting (Golombok et al., 2003; Patterson, 1997), effects of divorce and custody arrangements (Amato, 2000; Bauserman, 2002; Emery, Laumann-Billings, Waldron, Sbarra, & Dillon, 2001; Gindes, 1998; Kelly & Lamb, 2003), and adoption and foster parenting (Goodman, Emery, & Haugaard, 1998; Haugaard & Hazan, 2002). Another recent avenue of study involves the child in the juvenile justice system when the

child is the perpetrator. In part, this interest is due to rising crime in this age group and to the fact that a number of jurisdictions have become more conservative in dealing with this group of children in the forensic area. Some of these studies, which mainly focus on older children, examine the extent to which they understand the legal proceedings and their legal rights (Grisso & Schwartz, 2000; Grisso et al., 2003; Salekin, 2002; Steinberg & Cauffman, 1996; Steinberg & Scott, 2003).

The greatest amount of work in the field of children and the law has focused on issues related to the maltreatment of children. In 2002, an estimated 896,000 children in the United States were determined to be victims of child abuse. Although the annual rate of victimization per 1,000 children in the U.S. population has dropped from 13.4 in 1990 to 12.3 in 2002, these figures greatly underestimate the extent of the problem because they are based on cases reported to agencies only. A general theme of the research in this area is the prevalence, correlates, consequences of, and treatments for maltreatment (Kendall-Tackett, Williams, & Finkelhor, 1993).

Issues of maltreatment have also been responsible for perhaps the most significant area of study in children and the law: factors related to children's ability to pro-

vide accurate testimony about experienced events. For several reasons, these studies have mainly focused on young children (ages 3 to 7) and have been framed to address issues concerned with sexual abuse. First, there has been a growing awareness and concern about the incidence of child sexual abuse in our society. In the United States, where national archives are kept for each type of maltreatment, the numbers are telling: For the 49 states reporting in the National Center on Child Abuse and Neglect's (NCCAN) 1998 national data system, there were 103,600 cases of *substantiated* sexual abuse (1.5 per 1,000 children), nearly 38% of which involved children age 7 and younger. In 2002, the rate dropped to 1.2 per 1,000 children (Child Maltreatment, 2004).

Second, prior to the 1980s, children were rarely admitted as witnesses in the legal arena (see Ceci & Bruck, 1995). This pattern changed as a result of society's reaction to the dramatic increases in child abuse¹ and as a result of the ineffective prosecution of child abuse cases. During the 1980s, all but a few jurisdictions in the United States dropped their corroboration requirement for children in sexual abuse cases, a crime that by its nature lacks corroboration. Many states began to allow children to testify regardless of the nature of the crime, permitting the jury to determine how much weight to give to the child's testimony. In Canada, with the adoption of Bill C-15, the court could now convict on the basis of a child's unsworn testimony. In England, children over 3 years of age were admitted as witnesses in the courtroom and could provide unsworn corroborated testimony in sexual abuse cases.
