The nature of children's numerical, arithmetical, and mathematical understanding and the mechanisms that underlie the development of this knowledge are at the center of an array of scientific, political, and educational debates. Scientific issues range from infants' understanding of quantity and arithmetic (Cohen & Marks, 2002; Starkey, 1992; Wynn, 1992a) to the processes that enable middle-school and high-school students to solve multistep arithmetical and algebraic word problems (Tronsky & Royer, 2002). The proposed mechanisms that underlie quantitative and mathematical knowledge range from inherent systems that have been designed through evolution to represent and process quantitative information (Geary, 1995; Spelke, 2000; Wynn, 1995) to general learning mechanisms that can operate on and generate arithmetical and mathematical knowledge but are not inherently quantitative (Newcombe, 2002). The wide range of competencies covered under the umbrella of children's mathematical

understanding and the intense scientific debate about the nature of this knowledge and how it changes with experience and development make this a vibrant research area. The empirical research and theoretical debate also have implications for educational policy issues (Hirsch, 1996).

The chapter begins with a brief history of the more than 100 years of research and educational debate related to children's mathematics. The focus, however, is on contemporary research on the number, counting, and arithmetical competencies that emerge during infancy and the preschool years; elementary-school children's conceptual knowledge of arithmetic and how they solve formal arithmetic problems (e.g., $6 + 9$); and how adolescents understand and solve complex word problems. Where possible, I provide discussion of the mechanisms that support knowledge representation, problem solving, and corresponding developmental change. In the final section of the chapter, I discuss the potential mechanisms that may contribute to developmental and experience-based change in mathematical domains across a continuum, ranging from inherent, evolved abilities to abilities that are culturally specific. The discussion is meant to provide a broad outline for future scientific research on children's mathematical understanding and for thinking about how mathematics might be taught in school.

Preparation of this chapter was supported, in part, by grants R01 HD38283 from the National Institute of Child Health and Human Development (NICHD), and R37 HD045914 co-funded by NICHD and the Office of Special Education and Rehabilitation Services.

HISTORY

The study of arithmetical and mathematical competencies and their development has occupied psychologists and educators for more than 100 years. The approaches include experimental studies of learning, child-centered approaches to early education (constructivism), psychometric studies of individual differences in test performance, and more recently the neonativist perspective.

Early Learning Theory

Experimental psychologists have been studying children's understanding and learning of number, arithmetic, and mathematics since the early decades of the 20th century (e.g., Brownell, 1928; O'Shea, 1901; Starch, 1911; Thorndike, 1922). The topics these researchers explored were similar to those being studied today, including the speed and accuracy with which children apprehend the quantity of sets of objects (Brownell, 1928); the strategies children use to solve arithmetic problems (Brownell, 1928); the relative difficulty of different problems (Washburne & Vogel, 1928); and the factors that influence the learning of algebra (Taylor, 1918) and geometry (Metzler, 1912). A common theme was the study of the effects of practice on the acquisition of specific mathematical competencies (Hahn & Thorndike, 1914), the factors that influence the effectiveness of practice (Thorndike, 1922), and the extent to which these competencies transferred to other domains (Starch, 1911). Practice distributed across time results in substantive improvement in the specific domain that is practiced and sometimes results in transfer to related domains. Winch (1910) found practice-related improvements in basic arithmetic were, under some conditions (e.g., student ability), associated with improved accuracy in solving arithmetical reasoning problems (multistep word problems) that involved basic arithmetic. It was also found that transfer did not typically occur across unrelated domains (Thorndike & Woodworth, 1901).

Psychometric Studies

Psychometric studies focus on individual differences in performance on paper-and-pencil ability tests and are useful for determining whether different types of cognitive abilities exist (Thurstone, 1938), and for making inferences about the source of individual differences

(Spearman, 1927). Numerical, arithmetical, and mathematical tests have been included in these studies for more than 100 years (Cattell, 1890; Spearman, 1904), and they continue to be used to this day (Carroll, 1993). One of the most useful techniques is factor analysis, which allows correlations among ability tests to be grouped into clusters that reflect common sources of individual differences. The use of factor analysis has consistently revealed two mathematical domains, numerical facility and mathematical reasoning (e.g., Chein, 1939; Coombs, 1941; Dye & Very, 1968; French, 1951; Thurstone & Thurstone, 1941). Other relatively distinct quantitative skills, such as estimation, were also identified in some but not all psychometric studies (Canisia, 1962). Across studies, the Numerical Facility factor is defined by arithmetic computation tests (e.g., tests that require the solving of complex multiplication problems), and by tests that involve a conceptual understanding of number relationships and arithmetical concepts (Thurstone, 1938; Thurstone & Thurstone, 1941). Basically, the Numerical Facility factor appears to encompass most of the basic arithmetic skills described in the "Arithmetic in School" section. Tests that define the Mathematical Reasoning factor typically require the ability to find and evaluate quantitative relationships, and to draw conclusions based on quantitative information (French, 1951; Goodman, 1943; Thurstone, 1938).

Developmentally, Osborne and Lindsey (1967) found a distinct Numerical Facility factor for a sample of kindergarten children. The factor was defined by tests that encompassed counting, simple arithmetic, working memory for numbers, and general knowledge about quantitative relationships. Meyers and Dingman (1960) also argued that relatively distinct numerical skills are identifiable by 5 to 7 years of age. The most important developmental change in numerical facility is that it becomes more distinctly arithmetical with schooling. Mathematical reasoning ability is related to numerical facility in the elementary and middle-school years, and gradually emerges as a distinct ability factor with continued schooling (Dye & Very, 1968; Thurstone & Thurstone, 1941; Very, 1967). The pattern suggests mathematical reasoning emerges from the skills represented by the Numerical Facility factor, general reasoning abilities, and schooling.

Constructivism

The constructivist approach to children's learning and understanding of mathematics also has a long history

(McLellan & Dewey, 1895), and continues to be influential (Ginsburg, Klein, & Starkey, 1998). There is variation in the details of this approach from one theorist to the next, but the common theme is that children's learning should be self-directed and emerge from their interactions with the physical world. McLellan and Dewey argued that children's learning of number and later of arithmetic should emerge through their manipulation of objects (e.g., grouping sets of objects). They argued their approach was better suited for children than teacher-directed instruction, and better than the emphasis on practice espoused by learning theorists (Thorndike, 1922). The most influential constructivist theory is that of Jean Piaget. Although his focus was on understanding general cognitive mechanisms (Piaget, 1950)—those applied to all domains such as number, mass, and volume—Piaget and his colleagues conducted influential studies of how children understand number (Piaget, 1965) and geometry (Piaget, Inhelder, & Szeminska, 1960).

For example, to assess the child's conception of number, two rows of seven marbles are presented and the child is asked which row has more. If the marbles in the two rows are aligned in a one-to-one fashion, then 4- to 5-year-old children almost always state that there are the same number of marbles in each row. If one of the rows is spread out such that the one-to-one correspondence is not obvious, children of this age almost always state that the longer row has more marbles. This type of justification led Piaget to argue that the child's understanding of quantitative equivalence was based on how the rows looked, rather than on a conceptual understanding of number. An understanding of number would require the child to state that, after the transformation, the number in each row was the same, even though they now looked different from one another. Children do not typically provide this type of justification until they are 7 or 8 years old, leading Piaget to argue that younger children do not possess a conceptual understanding of number. Mehler and Bever (1967) challenged this conclusion by modifying the way children's understanding was assessed and demonstrated that, under some circumstances, 2.5-year-olds use quantitative, rather than perceptual, information to make judgments about more than or less than (R. Gelman, 1972). With the use of increasingly sensitive assessment techniques, it now appears that preschool children and infants have a more sophisticated understanding of quantity than predicted by Piaget's theory (see "Early Quantitative Abilities" section).

Information Processing

With the emergence of computer technologies and conceptual advances in information systems in the 1960s, reaction time (RT) reemerged as a method to study cognitive processes. Groen and Parkman (1972) and later Ashcraft and his colleagues (Ashcraft, 1982; Ashcraft & Battaglia, 1978) introduced these methods to the study of arithmetical processes (for a review, see Ashcraft, 1995). As an example, simple arithmetic problems, such as $3 + 2 = 4$ or $9 + 5 = 14$, are presented on a computer monitor, and the child indicates by button push whether the presented answer is correct. The resulting RTs are then analyzed by means of regression equations, whereby statistical models representing the approaches potentially used to solve the problems, such as counting or memory retrieval, are fitted to RT patterns. If children count both addends in the problem, starting from one, then RTs will increase linearly with the sum of the problem, and the value of the raw regression weight will provide an estimate of the speed with which children count implicitly. These methods suggest adults typically retrieve the answer directly from long-term memory and young children typically count.

Siegler and his colleagues merged RT techniques with direct observation of children's problem solving (Carpenter & Moser, 1984) to produce a method that enables researchers to determine how children solve each and every problem; make inferences about the temporal dynamics of strategy execution; and make inferences about the mechanisms of strategy discovery and developmental change (Siegler, 1987; Siegler & Crowley, 1991; Siegler & Shrager, 1984). The results revealed that children use a mix of strategies to solve many types of quantitative problem (Siegler, 1996). Improvement in quantitative abilities across age and experience is conceptualized as overlapping waves. The waves represent the strategy mix, with the crest representing the most commonly used problem-solving approach. Change occurs as once dominant strategies, such as finger counting, decrease in frequency, and more efficient strategies, such as memory retrieval, increase in frequency.

The use of observational, RT, and other methods has expanded to the study of quantitative abilities in infancy (Antell & Keating, 1983; Wynn, 1992a) and, in fact, across the life span (Geary, Frensch, & Wiley, 1993). These methods have also been applied to the study of how children and adolescents solve arithmetical and

algebraic word problems (Mayer, 1985; Riley, Greeno, & Heller, 1983), and to more applied issues such as mathematics anxiety (Ashcraft, 2002) and learning disabilities (Geary, 2004b).

Neonativist Perspective

Scientific discussion of evolved mental traits arose in the latter half of the nineteenth century, following the discovery of the principles of natural selection (Darwin & Wallace, 1858). In 1871, Darwin (p. 55) noted, “[M]an has an instinctive tendency to speak, as we see in the babble of our young children; whilst no child has an instinctive tendency to . . . write.” The distinction between evolved and learned cognitive competencies was overshadowed for much of the twentieth century by psychometric, constructivist, and information-processing approaches to cognition. Neonativist approaches emerged in the waning decades of the twentieth century with the discovery that infants have an implicit, although not fully developed, understanding of some features of the physical, biological, and social worlds (e.g., Freedman, 1974; R. Gelman, 1990; R. Gelman & Williams, 1998; S. Gelman, 2003; Keil, 1992; Rozin, 1976; Spelke, Breinlinger, Macomber, & Jacobson, 1992). The neonativist emphasis on modularized competencies (e.g., language) distinguishes the approach from the general cognitive structures emphasized by Piaget.

A neonativist perspective on children’s knowledge of quantity was stimulated by R. Gelman’s and Gallistel’s (1978) *The Child’s Understanding of Number*. The gist is that children’s knowledge of counting is captured by a set of implicit principles that guide their early counting behavior and that provide the skeletal frame for learning about counting and quantity. Later, Wynn (1992a) discovered that infants have an implicit understanding of the effects of adding or subtracting one item from a small set of items, and others proposed that children’s inherent understanding of quantity could be understood in terms of a system of number-counting-arithmetic knowledge (Geary, 1994, 1995; R. Gelman, 1990; Spelke, 2000). The system was thought to be limited to an implicit ability to organize objects into sets of four or less; an ability to manipulate these sets by means of counting; and an implicit understanding of the effects of adding or subtracting from these sets. This inherent or biologically primary system was contrasted with culturally specific or biologically secondary arithmetical and

mathematical knowledge (e.g., the Base-10 system) that was learned as a result of formal or informal instruction. Although the utility of the neonativist approach is debated (Newcombe, 2002), it continues to guide theoretical and empirical research on mathematical knowledge, its development, and cross-cultural expression (Butterworth, 1999; Dehaene, Spelke, Pinel, Stanescu, & Tsivkin, 1999; Gordon, 2004; Pica, Lemer, Izard, & Dehaene, 2004).

RESEARCH

My review of empirical and theoretical research is organized in terms of early quantitative abilities (number, counting and arithmetic before formal schooling); arithmetic learned in school; and mechanisms of change.

Early Quantitative Abilities

My review of the quantitative abilities that emerge before formal schooling is focused on infants’ understanding of number and arithmetic; preschoolers’ understanding of number and counting; and preschoolers’ emerging arithmetic skills and conceptual knowledge of the properties of arithmetic.

Number and Arithmetic in Infancy

The study of infants’ numerical prowess has focused on three specific competencies. The first concerns the infant’s understanding of numerosity, that is, the ability to discriminate arrays of objects based on the quantity of presented items. The second and third respective competencies concern an awareness of ordinality, for example, that three items are more than two items, and the infants’ awareness of the effects of adding and subtracting small amounts from a set. I provide an overview of research on each of these competencies and then discuss underlying mechanisms.

Numerosity. Starkey and R. Cooper (1980) conducted one of the first contemporary investigations of the numerical competencies of infants. The procedure involved the presentation of an array of 2 to 6 dots. When an array of say three dots is first presented, the information is novel and thus the infant will orient toward the array, that is, look at it. With repeated presentations, the time spent looking at the array declines, or habituates. If the infant again orients to the array when the number of presented dots changes (dishabituation),

then it is assumed that the infant discriminated the two quantities. However, if the infant's viewing time does not change, then it is assumed the infant cannot discriminate the two quantities. With the use of this procedure, Starkey and R. Cooper found that infants between the ages of 4 and 7.5 months discriminated two items from three items but not four items from six items. Working independently, Strauss and Curtis (1984) found that 10- to 12-month-old infants discriminated two items from three items, and some of them discriminated three items from four items.

The infants' sensitivity to the numerosity of arrays of one to three, and sometimes four, items has been replicated many times and under various conditions, such as homogeneous versus heterogeneous collections of objects (Antell & Keating, 1983; Starkey, 1992; Starkey, Spelke, & Gelman, 1983, 1990; van Loosbroek & Smitsman, 1990). Among the most notable of these findings is that infants show a sensitivity to differences in the numerosity of small sets in the 1st week of life (Antell & Keating, 1983), with displays in motion (van Loosbroek & Smitsman, 1990), and intermodally (Starkey et al., 1990). In the first intermodal study, Starkey et al., presented 7-month-old infants with two photographs, one consisting of two items and the other consisting of three items, and simultaneously presented either two or three drumbeats. Infants looked longer at the photograph with the number of items that matched the number of drumbeats, suggesting that the infants somehow extracted quantity from the visual information (the photographs) and matched this with the quantity extracted from the auditory information (the drumbeats). This result suggested infants have a cognitive system that abstractly codes for numerosities up to three or four items that is neither visually nor auditorily based.

In contrast with the matching of visual and auditory quantity found by Starkey et al. (1990), infants in later studies looked at visual displays that contained a number of objects that mismatched the number of sounds or showed no preference either way (Mix, Levine, & Huttenlocher, 1997; Moore, Benenson, Reznick, Peterson, & Kagan, 1987). The former results might be interpreted as evidence for an ability to discriminate a small number of objects from a sequence of sounds, but the mixed pattern of results leaves the issue unresolved. Other investigators have questioned whether infants' numerosity discriminations are based on an implicit understanding of quantity or other factors that are correlated with quantity in the experimental procedures

(Clearfield & Mix, 1999; Newcombe, 2002; Simon, 1997). As an example, as the number of items increases, so does total surface area, overall duration of tones, and so forth. Clearfield and Mix confirmed that infants can discriminate small sets of squares that differ in quantity, but the discriminations are more strongly influenced by the length of the perimeter of the squares than by number of squares (see also Feigenson, Carey, & Spelke, 2002).

To control for some of these perceptual-spatial and other confounds, Wynn and Sharon (Sharon & Wynn, 1998; Wynn, 1996) presented 6-month-old infants with a puppet that engaged in a series of two or three actions (see also Wynn, Bloom, & Chiang, 2002). In a two-action sequence, an infant might first see the puppet jump, stop briefly, and then jump again. Evidence for infants' ability to enumerate small numbers of items was provided by their ability to discriminate between two- and three-action sequences. In a series of related studies, Spelke and her colleagues found that 6-month-old infants can discriminate visually and auditorily presented sets of larger quantities from smaller quantities, but only if the number of items in the larger set is double that in the smaller set (e.g., 16 versus 8; Brannon, Abbott, & Lutz, 2004; Lipton & Spelke, 2003; Xu & Spelke, 2000). The results were interpreted as supporting the hypothesis that people, including infants, have an intuitive sense of approximate magnitudes (Dehaene, 1997; Gallistel & Gelman, 1992), but the mechanisms underlying infants' performance in Spelke's studies may differ from those underlying infants' discrimination of sets of two items, sounds, or actions, from sets of three items, sounds, or actions, as described in the "Representational Mechanisms" section.

Ordinality. Even though infants are able to detect and represent small quantities, this does not mean they are necessarily sensitive to which set has *more* or *less* items. Initial research suggested that infants' sensitivity to these ordinal relationships, that is somehow knowing that 3 is more than 2 and 2 is more than 1, was evident by 18 months (R. Cooper, 1984; Sophian & Adams, 1987; Strauss & Curtis, 1984), although more recent studies suggest a sensitivity to ordinality may emerge by 10 months (Brannon, 2002; Feigenson, Carey, & Hauser, 2002). In an early study, Strauss and Curtis taught infants, by means of operant conditioning, to touch the side of a panel that contained the smaller or larger number of two arrays of dots. For the smaller-reward condition, the

smaller array might contain three dots and the larger array four dots; infants would then be rewarded for touching the panel associated with the smaller array. The infants might next be presented with arrays of two and three dots. If infants were simply responding to the rewarded value, they should touch the panel associated with three. In contrast, if infants respond based on the ordinal relationship (responding to the smaller array in this example), then they would touch the panel associated with two. In this study, 16-month-olds responded to the two, suggesting a sensitivity to less than (Strauss & Curtis, 1984). Ten- to 12-month-olds seemed to notice that the numerosities in the arrays had changed, but they did not discriminate less than and more than; it was simply different than (R. Cooper, 1984).

Feigenson, Carey, and Hauser (2002) adopted a procedure used to study rhesus monkeys' (*Macaca mulatta*) sensitivity to ordinality (Hauser, Carey, & Hauser, 2000). In their first experiment, crackers of various size and number were placed, one at a time, in two opaque containers and the infant was allowed to crawl to the container of their preference. Groups of 10- and 12-month-old infants consistently chose the container with the larger number of crackers when the comparison involved 1 versus 2 and 2 versus 3. When four or more crackers were placed in one of the containers, performance dropped to chance levels. Another experiment pitted number against total amount (i.e., surface area) of cracker. In this experiment, 3 out of 4 infants chose the container with the greater amount of cracker (1 large cracker) as opposed to the container with the greater number of crackers (2 smaller crackers). Brannon (2002) demonstrated that 11-month-old, but not 9-month-old, infants could discriminate ordinally arranged sets that increased (e.g., 2, 4, 8 items) or decreased (e.g., 8, 4, 2 items) in quantity. A variety of experimental controls suggested that the discriminations were based on the change in number of items in the sets, and not change in surface area or perimeter.

Arithmetic. Wynn (1992a) provided the first evidence that infants may implicitly understand simple arithmetic. In one experiment, 5-month-olds were shown a Mickey Mouse doll in a display area. A screen was then raised and blocked the infant's view of the doll. Next, the infant watched the experimenter place a second doll behind the screen. The screen was lowered and showed either one or two dolls. Infants tend to look longer at unexpected events (but see Cohen & Marks,

2002). Thus, if infants are aware that adding a doll to the original doll will result in more dolls, then, when the screen is lowered, they should look longer at one doll than at two doll displays. This is exactly the pattern that was found. Another procedure involved subtracting one doll from a set of two dolls and, again, infants looked longer at the unexpected (two dolls) than expected (one doll) outcome. The combination of results was interpreted as evidence that infants have an implicit understanding of imprecise addition and subtraction; they understand addition increases quantity and subtraction decreases quantity. Another experiment suggested infants may also have an implicit understanding of "precise" addition; specifically, that one item + one item = exactly two items.

Wynn's (1992a) empirical results and the claim they provide evidence for arithmetical competencies in infancy have been the focus of intense scientific study and theoretical debate (Carey, 2002; Cohen, 2002; Cohen & Marks, 2002; Kobayashi, Hiraki, Mugitani, & Hasegawa, 2004; Koechlin, Dehaene, & Mehler, 1997; McCrink & Wynn, 2004; Simon, Hespos, & Rochat, 1995; Uller, Carey, Huntley-Fenner, & Klatt 1999; Wakeley, Rivera, & Langer, 2000; Wynn, 1995, 2000, 2002; Wynn & Chiang, 1998). The findings for imprecise addition and (or) subtraction have been replicated several times (Cohen & Marks, 2002; Simon et al., 1995; Wynn & Chiang, 1998). In an innovative cross-modality assessment, Kobayashi et al., demonstrated that 5-month-olds can add one object and one tone or one object and two tones. In contrast, Koechlin et al., replicated Wynn's finding for imprecise subtraction but not addition, and Wakeley et al. failed to replicate the findings for imprecise or precise addition or subtraction. Wakeley et al. suggested that if infants do have implicit knowledge of arithmetic, then it is expressed only under some conditions. Other scientists have suggested that the phenomenon, that is, infants' looking patterns described in Wynn's original study, is robust but due to factors other than arithmetic competency (Cohen & Marks, 2002; Simon et al., 1995).

Representational Mechanisms. The proposed perceptual and cognitive mechanisms that underlie infants' performance on the tasks previously described range from a system that encodes and can operate on abstract representations of numerosity (Starkey et al., 1990; Wynn, 1995) to mechanisms that result in performance that appears to be based on an implicit understanding of numerosity but in fact tap systems that are

designed for other purposes. Included among these alternatives are mechanisms that function for object identification and individuation (Simon et al., 1995), and mechanisms that are sensitive to the contour and length of the presented objects (Clearfield & Mix, 1999; Feigenson, Carey, & Spelke, 2002). Cohen and Marks (2002) argued that an attentional preference for an optimal mix of familiarity and complexity explained Wynn's (1992a) findings. To illustrate, in Wynn's original $1 + 1 = 2$ manipulation, the expected result is two dolls and the unexpected result is one doll. However, the unexpected result is also the original condition—one doll—viewed by the infants, and thus their looking preference might have been based on familiarity, not an expectation of two dolls. Kobayashi et al.'s (2004) cross-modality study controlled for familiarity and still provided evidence that infants can add small quantities, an object and one or two tones.

Figure 18.1 provides an illustration of the mechanisms that have been proposed as potentially underlying infants' performance on quantitative tasks. On the basis of Meck's and Church's (1983) studies of the numerosity and time-estimation skills in animals, Gallistel and Gelman (1992) proposed the existence of an innate pre-verbal counting mechanism in humans. There are two ways in which preverbal counting might operate. The

first is represented by the numerosity accumulator. The gist is that infants have a mechanism that accumulates representations of up to three or four objects, sounds, or events and then compares the accumulated representation (e.g., one, or two) to abstract and inherent knowledge of the numerosity of one, two, three, and perhaps four items. The second is an analog mechanism that can represent various types of magnitudes (e.g., surface area), including numerosities of any size, but with increases in magnitude size the precision of the estimate decreases. Object file and object representation mechanisms (e.g., Kahneman, Treisman, & Gibbs, 1992) function to individuate and represent whole objects rather than numerosity. The object file generates a marker for each object in the display, whereas the object representation mechanism adds object-specific information (e.g., area, contours) to each object marker. The number of object markers that can be simultaneously held in short-term memory is three or four (Trick, 1992). Thus, these object individuation mechanisms incidentally provide numerical information.

Starkey et al. (1990), Wynn (1992a, 1995), and Gallistel and Gelman (1992), among others (e.g., Spelke, 2000), have interpreted the numerosity, ordinality, and arithmetic performance of infants as being consistent with the existence of a numerosity accumulator and an analog magnitude mechanism that has evolved specifically to represent quantity. Simon et al. (1995) and Newcombe (2002), among others (e.g., Uller et al., 1999), have argued that the same pattern of results can be explained by the object file or object representation mechanisms. A set of one item can be discriminated from a set of two items because object files representing the two sets look different, not because of an inherent understanding of the "oneness" and "twoness" of the sets. It is also possible the object file systems evolved for individuating whole objects, and that numerosity mechanisms evolved later but are dependent on information generated by the object file mechanisms; specifically, the object file information might be fed into the numerosity accumulator. The best evidence to date for an independent numerosity accumulator comes from Kobayashi et al.'s (2004) cross-modality results, given that the tones were not likely to have been represented by object file mechanisms.

At this point, a definitive conclusion cannot be drawn regarding these alternative mechanisms. Whatever mechanisms may be operating, it is clear that infants can make discriminations based on the numerosity of sets of

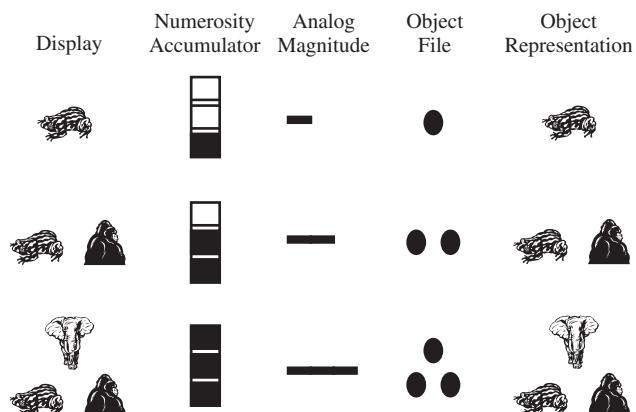

Figure 18.1 Potential mechanisms underlying infants' and young children's implicit understanding of the number. The numerosity accumulator exactly represents the number of one to three or four objects. The analog magnitude mechanism represents quantity, including number and area, but inexactly. The object file mechanism differentiates from one to three or four objects represented in visual short-term memory, and only incidentally provides information on number. The object representation mechanism is the same as the object file but in addition represents features of each object (e.g., color, shape).

three to four items (Starkey et al., 1990) and can later make simple ordinality judgments (Straus & Curtis, 1984), although their understanding of simple arithmetic is less certain. Spelke's recent studies suggest that infants can also make discriminations among larger sets of items, but only when the sets differ by a magnitude of 2 to 1 (e.g., 16 versus 8; Lipton & Spelke, 2003; Xu & Spelke, 2000). These findings support the existence of an inherent mechanism that represents analog magnitudes, but it is not known if the evolved function of the system is to represent numerosity *per se* or other forms of magnitude, such as area or distance. A recent neuroimaging study suggests that the brain regions that represent numerical magnitude also represent spatial magnitude (related size of objects) and thus these regions may not be specifically numerical in function (Pinel, Piazza, Le Bihan, & Dehaene, 2004).

Number and Counting during Preschool

Counting and number-related activities are common in industrialized and traditional societies (Crump, 1990), although the extent and form of formal number-counting systems (e.g., number words) varies considerably from one culture to the next (Gordon, 2004). Saxe studied the representational and counting systems of the Oksapmin, a horticultural society in Papua New Guinea (Saxe, 1981, 1982). Here, counting and numerical representations are mapped onto 27 body parts. "To count as Oksapmins do, one begins with the thumb on one hand and enumerates 27 places around the upper periphery of the body, ending on the little finger of the opposite hand" (Saxe, 1982, pp. 159–160). This system is used not only for counting, but also for representing ordinal position and for making basic measurements. In many cultures, there are common activities, such as parent-child play, during the preschool years and childhood that facilitate children's understanding of counting and number, and their learning the specific representational systems (e.g., number words) of the culture (Saxe, Guberman, & Gearhart, 1987; Zaslavsky, 1973).

Although these patterns suggest that children's interest in understanding the rudiments of counting and number may be inherent (Geary, 1995; R. Gelman & Gallistel, 1978), achieving a mature understanding of these concepts and their use in culturally appropriate ways spans into early childhood (Fuson, 1988; Piaget, 1965). In the following sections, I provide an overview of how children's understanding of number and counting skills change during the preschool years.

These changes include the acquisition of number concepts, number words, counting procedures, and an understanding of the use of numbers and counting for representing cardinality, ordinality, and for making measurements.

Number Concepts. To use number knowledge explicitly (e.g., to count) and to extend number concepts beyond small quantities, children must map their culture's number words and other representational systems (e.g., Arabic numerals) onto the numerosity and analog magnitude systems (Spelke, 2000). The process begins sometime between 2 and 3 years when children begin to use number words during the act of counting (R. Gelman & Gallistel, 1978), although young children do not always use the standard order of word tags (one, two, three). The child might state "three, five" to count two items, and "three, five, six" to count three items. Despite these apparent errors, this pattern has two important aspects; each number word is used only once during each count, and the sequence is stable across counted sets. For children who show this type of pattern, the implication is they implicitly understand that different number words represent different quantities and that the sequence with which the words are stated is important (R. Gelman & Gallistel, 1978). Many children as young as 2.5 years also understand that number words are different from other descriptive words. When children are asked to count a row of three red toy soldiers, they often use number words to count the set. The children understand that red describes an attribute of the counted items, but the number assigned to each soldier does not describe an attribute of the soldier but somehow refers to the collection of soldiers (Markman, 1979).

R. Gelman and Gallistel (1978; Gallistel & Gelman, 1992) argued regularities in the use of counting and number words emerge because children implicitly and automatically map counting onto representations of quantity, although the mechanisms that support this mapping are not fully understood (Sarnecka & Gelman, 2004). In any case, most 2-year-olds have not yet mapped specific quantities onto specific number words (Wynn, 1992b). Many 2.5-year-olds can discriminate four-item sets from three-item sets, and often know that the Arabic numeral 4 represents more than the numeral 3 (Bullock & Gelman, 1977), but might not be able to correctly label the sets as containing "four" and "three" items, respectively. Wynn argued that it re-

quires as long as a year of counting experience, from 2 to 3 years of age, for children to begin to associate specific number words with their mental representations of specific quantities and then to use this knowledge in counting tasks. It is likely that many 3-year-olds are beginning to associate specific number words with specific quantities, but this knowledge appears to extend only to the quantities that can be represented by the numerosity accumulator or object file systems.

The learning of specific quantities beyond four and mapping number words onto the representations of these quantities is a difficult task, because the analog magnitude system that must be adapted for this purpose functions to represent general amounts, not specific quantities (Gallistel & Gelman, 1992). Children's conception of the quantities represented by larger numbers is thus dependent to an important degree on their learning of the standard counting sequence (1, 2, 3, . . .) and properties of this sequence (e.g., successive number words represent an increase of exactly one). The conception of number also appears to be related to an ability to generate a mental number line (Dehaene, 1997), which involves mapping the Arabic numeral sequence onto the analog magnitude system. However, the ability to use the mental number line to represent specific quantities only emerges with formal schooling (Siegler & Opfer, 2003), as described in the "Arithmetic in School" section.

Number Words. Learning the culture's number words is an essential step in children's mathematical development. As noted, knowledge of the sequence of number words enables children to develop more precise representations of numbers greater than three or four, and contributes to knowledge of cardinality and ordinality described in the next section (Fuson, 1988; R. Gelman & Gallistel, 1978; Wynn, 1990). Most 3- to 4-year-olds know the correct sequence of number words from one to ten (Fuson, 1988; Siegler & Robinson, 1982). For children speaking most European-derived languages, including English, learning number words greater than ten is difficult (Fuson & Kwon, 1991; Miller & Stigler, 1987). This is because the number words for values up to the hundreds are often irregular; they do not map onto the underlying base-10 structure of the number system. For example, *twelve* is another number word in a continuous string of number words. Its special status—repetition of basic unit values—within the base-10 system is not evident from the

word itself. These irregularities slow the learning of number words and the understanding of the corresponding quantity the word represents, and result in word tagging errors, such as writing 51 when hearing 15 (Ginsburg, 1977).

Many of these confusions are avoided in East Asian languages, because of a direct one-to-one relation between number words greater than ten and the underlying base-10 values represented by the words (Fuson & Kwon, 1991; I. Miura, Kim, Chang, & Okamoto, 1988; I. Miura, Okamoto, Kim, Steere, & Fayol, 1993). The Chinese word for twelve is translated as "ten two." Using ten two to represent 12 has two advantages. First, children do not need to memorize additional word tags, such as eleven and twelve. Second, the fact that twelve is composed of a single tens value and two units values is obvious. As might be expected, the irregular structure of European-derived number words is not associated with cross-national differences in children's learning of number words less than 10, their ability to solve simple arithmetical word problems that involve manipulating quantities less than 10, or their understanding of the counting principles to be described (Miller, Smith, Zhu, & Zhang, 1995). However, differences in the structure of number words between 10 and 100 appear to contribute to later cross-national differences in ease of learning the base-10 structure of the number system and to use associated arithmetical procedures and problem-solving strategies (Geary, Bow-Thomas, Liu, & Siegler, 1996; Fuson & Kwon, 1992a).

Counting Procedures and Errors. The conceptual principles that guide counting behavior emerge during the preschool years, but it is debated as to whether these principles have an inherent basis (R. Gelman & Gallistel, 1978), or emerge through observation of the counting behavior of others and regularities in this behavior (Briars & Siegler, 1984; Fuson, 1988). And, of course, counting principles may emerge from a combination of inherent constraints and counting experience (Geary, 1995; R. Gelman, 1990). R. Gelman and Gallistel proposed children's counting behavior is guided by five inherent and implicit principles that mature during the preschool years. During those years, children's counting behavior and their description of counting suggest knowledge of these implicit rules can become more explicit and the application of these principles during the act of counting becomes more stable and accurate.

The principles are one-one correspondence (one and only one word tag, e.g., “one,” “two,” is assigned to each counted object); stable order (the order of the word tags must be invariant across counted sets); cardinality (the value of the final word tag represents the quantity of items in the counted set); abstraction (objects of any kind can be collected together and counted); and order-irrelevance (items within a given set can be tagged in any sequence). The principles of one-one correspondence, stable order, and cardinality define the initial “how to count” rules, which, in turn, provide the skeletal structure for children’s emerging knowledge of counting (R. Gelman & Meck, 1983).

Children make inductions about the basic characteristics of counting by observing standard counting behavior and associated outcomes (Briars & Siegler, 1984; Fuson, 1988). These inductions may elaborate and add to R. Gelman and Gallistel’s (1978) counting rules. One result is a belief that certain unessential features of counting are essential. These unessential features include standard direction (counting must start at one of the end points of a set of objects), and adjacency. The latter is the incorrect belief that items must be counted consecutively and from one contiguous item to the next; “jumping around” during the act of counting results in an incorrect count. By 5 years of age, many children know most of the essential features of counting described by R. Gelman and Gallistel but also believe that adjacency and start at an end are essential features of counting. The latter beliefs indicate that young children’s understanding of counting is influenced by observation of standard counting procedures and is not fully mature.

An implicit conceptual understanding of counting does not mean that children will not make counting errors; they do. Fuson (1988) has extensively documented the many different types of error committed by children while they count. A common error involves the child pointing to each item once, but speaking two or more word tags with each point. Sometimes children correctly assign one word tag to each counted object, but speak additional word tags, without pointing, in between counted objects. Sometimes children point and tag items with each syllable of a number word, and at other times they might tag and point to each item two or more times. Despite all the different types of errors that can be made during the act of counting, kindergarten children are typically proficient counters, especially for smaller set sizes.

Cardinality and Ordinality. Although an implicit understanding of cardinality and ordinality appears to emerge before children learn the sequence of number words (Bermejo, 1996; Brainerd, 1979; Brannon & Van de Walle, 2001; R. Cooper, 1984; Huntley-Fenner & Cannon, 2000; Ta’ir, Brezner, & Ariel, 1997; Wynn, 1990, 1992b), the mapping of these concepts onto the counting sequence is an essential step in the development of arithmetical competencies. Children must learn that the number word assigned to the last counted object can be used to represent the total number of counted objects—*cardinality*—and that successive number words represent successively larger quantities—*ordinality*.

One way to assess children’s understanding of cardinality is to ask them to count their fingers and then ask “how many fingers do you have?” Children who do not understand the significance of the last word tag, *five* in this example, will recount their fingers, rather than re-stating “five” (Fuson, 1991). Although some 3- and many 4- and 5-year-olds perform well on such cardinality tasks suggesting a developing sense of the concept, most preschoolers’ understanding of cardinality is not yet mature. Their performance is inconsistent and often influenced by factors other than cardinality. For small set sizes (e.g., less than 10), most children have a good grasp of cardinal value by 5 years (Bermejo, 1996; Freeman, Antonucci, & Lewis, 2000), but generalization to larger sets and a consistent focus on cardinality information over other information (e.g., perceptual cues) may not emerge for several more years (Piaget, 1965).

As with infants, the demonstration of preschool children’s knowledge of ordinal relationships requires special techniques. Bullock and Gelman (1977) assessed the ordinal knowledge of 2- to 5-year-old children, by using a “magic” game. In the first of two phases, the children were shown two plates of toys, one contained a single toy animal and the other contained two toy animals. The children were either told that the two-toy plate was the winner (more condition) or that the one-toy plate was the winner (less condition). The child was then shown a series of one- and two-toy plates, and asked to pick the winner. In Phase II, “the experimenter surreptitiously added one animal to the two-toy plate and three animals to the one-toy plate” (p. 429). The critical question was whether the children would choose the winner based on the relation, that is, more or less, that was reinforced in the first phase. The majority of 3- and 4-year-olds responded based on the relational information, but less than 50% of the 2-year-olds did. When

the memory demands of the task were reduced, more than 90% of the 2 year olds responded based on the relational information. More recent studies suggest that some 2-year-olds can make ordinal judgments comparing sets as high as five objects versus six objects, independent of perceptual factors (e.g., total surface area of the objects) or verbal counting (Brannon & Van de Walle, 2001; Huntley-Fenner & Cannon, 2000).

These results suggest children as young as 2 years may have an understanding of ordinal relationships that extend to larger set sizes than found in the infancy studies. The mechanisms underlying this knowledge are not yet known, but Huntley-Fenner and Cannon (2000) argued that the analog magnitude mechanism shown in Figure 18.1 is the source of preschool children's ordinality judgments. This is a reasonable conclusion, given that knowledge of ordinal relations for larger numbers is based on knowledge of the counting-word sequence and that this sequence is likely mapped onto the analog system (Gallistel & Gelman, 1992).

Arithmetic during Preschool

As I overview in the first section, research on preschooler's emerging arithmetic skills has focused on their implicit understanding of the effects of addition and subtraction on number; their implicit understanding of some properties of arithmetic (e.g., that addition and subtraction are inverse operations); and their integration of counting and arithmetic knowledge to develop procedures for solving formal arithmetic problems (e.g., $3 + 2 = ?$). As I note in the second section, there is vigorous debate regarding the relation between these emerging skills and the representational mechanisms that were described in Figure 18.1.

Arithmetical Competencies. Some of the earliest evidence of preschoolers' implicit knowledge of arithmetic was provided by Starkey (1992; see also Sophian & Adams, 1987; Starkey & Gelman, 1982). Here, a searchbox task was designed to determine if 1.5- to 4-year-olds understand how addition and subtraction affects numerosity without using verbal counting. The searchbox "consisted of a lidded box with an opening in its top, a false floor, and a hidden trap-door in its back. This opening in the top of the box was covered by pieces of elastic fabric such that a person's hand could be inserted through pieces of the fabric and into the chamber of the searchbox without visually revealing the chamber's contents" (Starkey, 1992, p. 102). In the first of

two experiments, children placed between one and five table-tennis balls, one at a time, into the searchbox. Immediately after the child placed the last ball, she was told to take out all the balls. An assistant had removed the balls and then replaced them one at a time, as the child searched for the balls. If a child placed three balls in the searchbox and then stopped searching once three balls were removed, then it could be argued that this child was able to represent and remember the number of balls deposited, and used this representation to guide the search. The results showed that 2-year-olds can mentally represent and remember numerosities of one, two, and sometimes three; 2.5-year-olds can represent and remember numerosities up to and including three; and 3- to 3.5-year-olds can sometimes represent numerosities as high as four.

The second experiment addressed whether the children could add or subtract from these quantities without verbally counting. The same general procedure was followed, except that once all the original balls were placed in the searchbox, the experimenter placed an additional 1 to 3 balls in the box, or removed from 1 to 3 balls. If children understand the effect of addition, then they should search for more balls than they originally placed in the searchbox, or for subtraction they should stop searching before this point. Nearly all 2- to 4-year-olds responded in this manner, as did many, but not all, of the 1.5-year-olds. Examination of the accuracy data indicated that many of the 1.5-year-olds were accurate for addition and subtraction with sums or minuends (the first number in a subtraction problem) less than or equal to two (e.g., $1 + 1$ or $2 - 1$), but were not accurate for problems with larger numbers. Most 2-year-olds were accurate with values up to and including three (e.g., $2 + 1$), and there was no indication (e.g., vocalizing number words) they used verbal counting to solve the problems. None of the children were accurate with sums or minuends of four or five.

Using a different form of nonverbal calculation task, Huttonlocher, Jordan, and Levine (1994) found that 2- to 2.5-year-olds understand that addition increases quantity and subtraction decreases it, but only a small percentage of them could solve simple 1 object + 1 object or 2 objects - 1 object problems. The ability to calculate exact answers improved for 2.5- to 3-year-olds such that more than 50% of them could mentally perform simple additions ($1 + 1$) and subtractions ($2 - 1$) of objects. Some 4-year-olds correctly solved nonverbal problems that involved 4 objects + 1 object, or 4 objects - 3 objects.

Klein and Bisanz (2000) used the same procedure to assess 4-year-olds but also administered three-step problems (e.g., 2 objects + 1 object – 1 object) and assessed potential predictors of problem difficulty as measured by error rate. The three-step problems assessed children's understanding of the inverse relation between addition and subtraction; $5 \text{ objects} - 1 \text{ object} + 1 \text{ object} = 5 \text{ objects}$, because 1 object – 1 object results in no change in quantity. The indices of problem difficulty included the value of numbers in the problem, the answer, and the largest of these numbers, which was termed representational set size. So, for $5 \text{ objects} + 1 \text{ object} - 1 \text{ object}$, the representational set size is five, whereas for $3 + 1$, the size is four. Representational set size provided an index of the working memory demands of the problem and thus provided an estimate of the capacity of the underlying mechanism for representing object sets (e.g., object file or numerosity accumulator).

The results revealed that error rates increased with increases in representational set size. Holding an object file or numerosity-accumulator file of four or five items in working memory and adding or subtracting from this representation was more difficult than holding an object file or numerosity-accumulator file of two or three in working memory. Thus, errors are due to a lack of ability to apply arithmetical knowledge to larger sets or (and) to working memory failures. The strategies children used to solve the inversion problems suggested that some of these children had a nascent and implicit understanding of the associative property of addition [$(a + b) - c = a + (b - c)$], and the inverse relation between addition and subtraction. Knowledge of the former was inferred "when children overtly subtracted the c term from the a term and then added the b term, thus transforming $(a + b) - c$ to $(a - c) + b$ " (Klein & Bisanz, 2000, p. 110).

Vilette (2002) administered a variant of Wynn's (1992a) task to 2.5-, 3.5-, and 4.5-year-olds; the problems involved $2 + 1$, $3 - 1$, and an inversion problem, $2 + 1 - 1$. For these latter problems, the children first saw two dolls on a puppet theater stage. Next, a screen rotated up and the experimenter placed another doll, in full view of the child, behind the screen, and then placed his hand back behind the screen and removed a doll. The screen was then lowered and revealed two (expected) or three (unexpected) dolls. The children were instructed to respond "normal" (correct) to the expected result and "not normal" to the unexpected result. As a group, 2.5-year-olds solved 64% of the $1 + 1$ problems, but failed

nearly all the $3 - 1$ and inversion problems. The 4.5-year-olds solved all the problems with greater than 90% accuracy, in keeping with Klein's and Bisanz's (2000) findings that some 4-year-olds have an implicit understanding of the inverse relation between addition and subtraction. The negative findings for younger children need to be interpreted with caution, because poor performance could be due to the working memory demands of the task or to lack of arithmetical knowledge.

In any event, by 4 to 5 years, children have coordinated their counting skills, number concepts, and number words with their implicit arithmetical knowledge. The result is an ability to use number words to solve simple addition and subtraction problems (Baroody & Ginsburg, 1986; Groen & Resnick, 1977; Saxe, 1985; Siegler & Jenkins, 1989). The specific strategies used by children for solving these problems may vary somewhat from one culture to the next, but typically involve the use of concrete objects to aid the counting process. When young children in the United States are presented with verbal problems, such as "how much is $3 + 4$," they will typically represent each addend with a corresponding number of objects, and then count all the objects starting with one; counting out three blocks and then four blocks, and then counting all the blocks. If objects are not available, then fingers are often used as a substitute (Siegler & Shrager, 1984). Korean and Japanese children apparently use a similar strategy (Hatano, 1982; Song & Ginsburg, 1987). Somewhat older Oksapmin use an analogous strategy based on their body-part counting system (Saxe, 1982).

Mechanisms. There is debate whether the mechanisms underlying preschoolers' arithmetic competencies are inherently numerical (Butterworth, 1999; Dehaene, 1997; Gallistel & Gelman, 1992; Geary, 1995) or emerge from nonnumerical mechanisms (Houdé, 1997; Huttenlocher et al., 1994; Jordan, Huttenlocher, & Levine, 1992; Vilette, 2002). Inherent mechanisms would involve some combination of the numerosity accumulator and analog magnitude system (Spelke, 2000), with the assumption that the latter automatically results in at least imprecise representations of the quantities being processed (Dehaene, 1997; Gallistel & Gelman, 1992). Integrated with these systems for representing numerosity would be an inherent understanding of at least basic principles of addition (increases quantity) and subtraction (decreases quantity), and a later integration with counting competencies to provide a procedural system

for solving arithmetic problems. These inherent biases are thought to provide the core knowledge that initially guides children's attention to numerical (e.g., seeing a group of objects as sets) and arithmetical (e.g., combining sets of objects) aspects of their experiences. These biases interact with these experiences to flesh out their conceptual knowledge and procedural competencies (Geary, 1995; R. Gelman, 1990). The fleshing out would involve extension of this knowledge and procedures to larger and larger quantities as well as making inductions about regularities in arithmetical processes and outcomes (e.g., inverse relation between addition and subtraction). In contrast, Huttenlocher et al. argued that preschoolers' arithmetical competencies emerge from a combination of a domain-general ability to mentally represent symbols—objects in the object file (as was shown in Figure 18.1)—and general intelligence, whereby children learn to manipulate representations of these symbols based on the rules of arithmetic they induce by engaging in arithmetical activities.

Arithmetic in School

As children move into formal schooling, the breadth and complexity of the mathematics they are expected to learn increases substantially. The task of understanding children's development in these areas has become daunting, and our understanding of this development is thus only in the beginning stages. In the first section, I make a distinction between potentially inherent and culturally-universal quantitative competencies and culturally-specific and school-dependent competencies, which I return to in "Mechanisms of Change." In the remaining sections, I provide an overview of children's conceptual knowledge of arithmetic in the elementary school years; how children solve formal arithmetic problems (e.g., 16 – 7); and the processes involved in solving word problems.

Primary and Secondary Competencies

Most of the competencies reviewed in the "Early Quantitative Abilities" section emerge with little if any instruction, and some may be in place in the first days or weeks of life. As far as we know, most of these competencies are found across human cultures, and many are evident in other species of primate (Beran & Beran, 2004; Boysen & Berntson, 1989; Brannon & Terrace, 1998; Gordon, 2004; Hauser et al., 2000) and in at least

a few nonmammalian species (Lyon, 2003; Pepperberg, 1987). The combination of early emergence, cross-cultural ubiquity, and similar competencies in other species is consistent with the position that some of these competencies are inherent (Geary, 1995, R. Gelman, 1990; R. Gelman & Gallistel, 1978), no matter whether the evolved function is specifically quantitative. In contrast, much of the research on older children's development is focused on school-taught mathematics. It is thus useful to distinguish between inherent and school-taught competencies, because it is likely that some of the mechanisms involved in their acquisition differ, as discussed in the "Mechanisms of Change" section. Geary (1994, 1995; see also Rozin, 1976) referred to inherent forms of cognition, such as language and early quantitative competencies, as *biologically primary abilities*, and skills that build on these abilities but are principally cultural inventions, such base-10 arithmetic, as *biologically secondary abilities*.

Conceptual Knowledge

Properties of Arithmetic. The commutativity and associativity properties of addition and multiplication have been understood by mathematicians since the time of the ancient Greeks. The commutativity property concerns the addition or multiplication of two numbers and states that the order in which the numbers are added or multiplied does not affect the sum or product ($a + b = b + a$; $a \times b = b \times a$). The associativity property concerns the addition or multiplication of three numbers and again states that the order in which the numbers are added or multiplied does not affect the sum or product [$(a + b) + c = a + (b + c)$; $(a \times b) \times c = a \times (b \times c)$]. Both commutativity and associativity involve the decomposition (e.g., of the sum) and recombination (e.g., addition) of number sets; specifically, an understanding that numbers are sets composed of smaller-valued numbers that can be manipulated in principled ways. Research on children's understanding of these properties has focused largely on addition and commutativity (Baroody, Ginsburg, & Waxman, 1983; Resnick, 1992), although some research has also been conducted on children's understanding of associativity (Canobi, Reeve, & Pattison, 1998, 2002).

One approach has been to study when and how children acquire an understanding of commutativity and associativity as related to school-taught arithmetic (Baroody et al., 1983). The other approach has focused on the more basic and potentially biologically primary

numerical and relational knowledge that allows children to later understand commutativity in formal arithmetical contexts (R. Gelman & Gallistel, 1978; Resnick, 1992; Sophian, Harley, & Martin, 1995). The latter approach meshes with the ability of infants and preschool children to mentally represent and manipulate sets of small quantities of objects.

Resnick (1992) proposed that aspects of these competencies provide the foundational knowledge for children's emerging understanding of commutativity as an arithmetical principle. The first conceptual step toward building an explicit understanding of commutativity is prenumerical and emerges as children physically combine sets of objects. One example would involve the physical merging of sets of toy cars and sets of toy trucks, and the understanding (whether inherent or induced) that the same group of cars and trucks is obtained whether the cars are added to the trucks or the trucks are added to the cars. The next step in Resnick's model involves mapping specific quantities onto this knowledge, as in understanding that $5 \text{ cars} + 3 \text{ trucks} = 3 \text{ trucks} + 5 \text{ cars}$. At this step, children only understand commutativity with the addition of sets of physical objects. The third step involves replacing physical sets with numerals, as in knowing that $5 + 3 = 3 + 5$, and the final step is formal knowledge of commutativity as an arithmetical principle, that is, understanding $a + b = b + a$. Empirical studies of children's emerging knowledge of commutativity are consistent with some but not all aspects of Resnick's model (Baroody, Wilkins, & Tiliakainen, 2003).

An implicit understanding that sets of physical objects can be decomposed and recombined emerges at about 4 years of age (Canobi et al., 2002; Klein & Bisanz, 2000; Sophian & McCordy, 1994; Sophian et al., 1995). Most children of this age understand, for instance, that the group of toy vehicles includes smaller subsets of cars and trucks. Between 4 and 5 years, an implicit understanding of commutativity as related to Resnick's (1992) second step is evident for many children (Canobi et al., 2002; Sophian et al., 1995). As an example, Canobi et al. presented children with two different colored containers that held a known number of pieces of candy. The two containers were then given in varying orders to two toy bears and the children were asked to determine if the bears had the same number of candy pieces. The task was to determine if, for example, a container of 3 candies + a container of 4 candies was equal to a container of 4 candies + a container of 3 can-

dies, and was therefore a commutativity problem. In a variant of this task, a third set of candies was added to one of the two containers. For one trial, four green candies were poured into a container of three red candies, a manipulation that is analogous to $(4 + 3)$. When presented with the second container of candy, the task represented a physical associativity problem; (a container of 3 candies + 4 candies) + a container of 4 candies. In keeping with Resnick's (1992) model, most of the 4-year-olds implicitly understood commutativity with these physical sets (see also Sophian et al., 1995), but many of them did not grasp the concept of associativity (Canobi et al., 2002).

Inconsistent with Resnick's (1992) model was the finding that performance on the commutativity task was not well integrated with their knowledge of addition. In other words, many of the children solved the task correctly because both bears received a *collection* of red candies and a *collection* of green candies and they understood that the order in which the bears received the containers of candy did not matter. Many of the children did not, however, approach the task as the addition of specific quantities.

Baroody et al. (1983) assessed children's understanding of commutativity as expressed during the actual solving of addition problems in a formal context (e.g., $3 + 4 = 4 + 3$)—Resnick's third step—in first, second, and third graders. The children were presented with a series of formal addition problems, in the context of a game. Across some of the trials, the same addends were presented but with their positions reversed. For example, the children were asked to solve $13 + 6$ on one trial and $6 + 13$ on the next trial. If the children understood that addition was commutative, then they might count "thirteen, fourteen, . . . nineteen" to solve $13 + 6$, but then state, without counting, "19" for $6 + 13$, and argue "it has the same numbers, it's always the same answer" (p. 160). In this study, 72% of the first graders, and 83% of the second and third graders consistently showed this type of pattern. Using this and a related task, Baroody and Gannon (1984) demonstrated that about 40% of kindergartners recognized commutative relations across formal addition problems. For these kindergarten children and the first graders in the Baroody et al. study, commutative relations were implicitly understood before formal instruction on the topic. Many of the older children explicitly understood that, for example, $3 + 2 = 2 + 3$, but it is not clear when and under what conditions (e.g., whether

formal instruction is needed) children come to explicitly understand commutativity as a formal arithmetical principle; that $a + b = b + a$.

With respect to associativity, several studies by Canobi and her colleagues (Canobi et al., 1998, 2002) suggest that some kindergarten children recognize associative relations when presented with sets of physical objects, as described, and many first and second graders implicitly understand associative relations when they are presented as addition problems. These studies are also clear in demonstrating that an implicit understanding of associativity does not emerge until after children implicitly understand commutativity, suggesting that implicit knowledge of the latter is the foundation for implicitly understanding the former.

In summary, the conceptual foundation for commutativity emerges from or is reflected in children's manipulation of physical collections of objects and either an inherent or induced understanding that the order in which sets of objects are combined to form a larger collection is irrelevant (R. Gelman & Gallistel, 1978; Resnick, 1992). When presented with sets of physical collections that conform to commutativity, 4- to 5-year-olds recognize the equivalence; that is, they implicitly understand commutativity but they do not explicitly understand commutativity as a formal principle nor do all of the children implicitly understand that commutativity is related to addition at all. Some kindergarteners and most first graders recognize commutative relations in an addition context, but it is not clear when children explicitly understand commutativity as a formal arithmetical principle. Recognition of associative relations with physical sets emerges in some children in kindergarten but only for children who implicitly understand commutativity; an implicit understanding of associativity in an addition context is found for many first and second graders, but it is not known when and under what conditions children come to explicitly understand associativity as a formal arithmetical principle. Even less is known about children's implicit and explicit knowledge of commutativity and associativity as related to multiplication.

Base-10 Knowledge. The Hindu-Arabic base-10 system is foundational to modern arithmetic, and thus knowledge of this system is a crucial component of children's developing mathematical competencies. As an example, children's understanding of the conceptual meaning of spoken and written multidigit numerals,

among other features of arithmetic, is dependent on knowledge of the base-10 system (Blöte, Klein, & Beishuizen, 2000; Fuson & Kwon, 1992a). The word *twenty-three* does not simply refer to a collection of 23 objects, it also represents two sets of ten and a set of three unit values. Similarly, the position of the individual numerals (e.g., 1, 2, 3 ...) in multidigit numerals has a specific mathematical meaning, such that the "2" in "23" represents two sets of 10. Without an appreciation of these features of the base-10 system, children's conceptual understanding of modern arithmetic is compromised.

The base-10 system is almost certainly a biologically secondary competency, the learning of which is not predicted to come easily to children (Geary, 1995, 2002). The more inherent mechanisms that might support learning of the base-10 system are discussed in the "Mechanisms of Change" section. For now, consider that studies conducted in the United States have repeatedly demonstrated that many elementary-school children do not fully understand the base-10 structure of multidigit written numerals (e.g., understanding the positional meaning of the numeral) or number words (Fuson, 1990; Geary, 1994), and thus are unable to effectively use this system when attempting to solve complex arithmetic problems (Fuson & Kwon, 1992a). The situation is similar, though perhaps less extreme, in many European nations (I. Miura et al., 1993). Many of these children have at least an implicit understanding that number-word sequences can be repeated (e.g., counting from 1 to 10 in different contexts) and can of course learn the base-10 system and how to use it in their problem solving. Nonetheless, it appears that many children require instructional techniques that explicitly focus on the specifics of the repeating decade structure of the base-10 system and that clarify often confusing features of the associated notational system (Fuson & Briars, 1990; Varelas & Becker, 1997). An example of the latter is the fact that sometimes 2 represents two units; other times it represents two tens; and still other times it represents two hundreds (Varelas & Becker, 1997).

East Asian students, in contrast, tend to have a better grasp of the base-10 system. I. Miura and her colleagues (I. Miura et al., 1988, 1993) provided evidence supporting their prediction that the earlier described transparent nature of East Asian number words (e.g., "two ten three" instead of "twenty three") facilitates East Asian children's understanding of the structure of the base-10

system and makes it easier to teach in school (but see Towse & Saxton, 1997). Using a design that enabled the separation of the influence of age and schooling on quantitative and arithmetical competencies, Naito and H. Miura (2001) demonstrated that Japanese children's understanding of the base-10 structure of numerals and their ability to use this knowledge to solve arithmetic problems was largely related to schooling. Because all the children had an advantage of transparent number words, the results suggest teacher-guided instruction on base-10 concepts also facilitates their acquisition (Fuson & Briars, 1990; Varelas & Becker, 1997).

Fractions. Fractions are ratios (or part-whole relations) of two or more values and an essential component of arithmetic. They can be represented as proper fractions (e.g., $\frac{1}{2}$, $\frac{1}{3}$, $\frac{7}{8}$), mixed numbers (e.g., $2\frac{1}{3}$, $6\frac{2}{3}$), or in decimal form (e.g., 0.5), although they are often represented pictorially during early instruction. As with the base-10 system, research in this area has focused on children's conceptual understanding of fractions, their procedural skills, as in multiplying fractions (Clements & Del Campo, 1990; Hecht, 1998; Hecht, Close, & Santisi, 2003), and the mechanisms that influence the acquisition of these competencies (I. Miura, Okamoto, Vlahovic-Stetic, Kim, & Han, 1999; Rittle-Johnson, Siegler, & Alibali, 2001). When used in a formal mathematical context (e.g., as a decimal), fractions are biologically secondary, although children's experiences with and understanding of part/whole relations among sets of physical objects, such as receiving $\frac{1}{2}$ of a cookie or having to share one of their two toys, may contribute to a nascent understanding of simple ratios (Mix, Levine, & Huttenlocher, 1999).

In a study of implicit knowledge of simple part-whole relations, Mix et al. (1999) administered a nonverbal task that assessed children's ability to mentally represent and manipulate $\frac{1}{4}$ segments of a whole circle, and demonstrated that many 4-year-olds recognize fractional manipulations. For example, if $\frac{3}{4}$ of a circle was placed under a mat and $\frac{1}{4}$ of the circle was removed, the children recognized that $\frac{1}{2}$ of a circle remained under the mat. However, it was not until 6 years when children began to understand manipulations that were analogous to mixed numbers; for instance, placing $1\frac{1}{4}$ circles under the mat and removing $\frac{1}{2}$ a circle. The results suggest that about the time children begin to show an understanding of part-whole relations in other contexts, as described earlier (Resnick, 1992; Sophian et al., 1995),

they demonstrate a rudimentary understanding of fractional relations. Further, Mix et al., argued these results contradicted predictions based on the numerosity and analog magnitude mechanisms shown in Figure 18.1. This is because R. Gelman (1991) and Wynn (1995) argued these mechanisms only represent whole quantities, and their operation should in fact interfere with children's ability to represent fractions. In this view, fractional representations such as $\frac{1}{4}$ of a circle can only be understood in terms of discrete numbers, such as 1 and 4, and it is possible that the children in the Mix et al. study represented the $\frac{1}{4}$ sections of the circles as single units and not as parts of a whole. At this point, the mechanisms underlying children's intuitive understanding of simple fractions, as assessed by Mix et al., remain to be resolved.

Nonetheless, children have considerable difficulty in learning the formal, biologically secondary conceptual and procedural aspects of fractions. During the initial learning of the formal features, such as the meaning of the numerator/denominator notational system, most children treat fractions in terms of their knowledge of counting and arithmetic (Gallistel & Gelman, 1992). A common error when asked to solve, for example, $\frac{1}{2} + \frac{1}{4}$ is to add the numerators and denominators, yielding an answer of $\frac{2}{6}$ instead of $\frac{3}{4}$. As another example, elementary-school children will often will conclude that since $3 > 2$, $\frac{1}{3} > \frac{1}{2}$. The names for fractions may also influence children's early conceptual understanding. In East Asian languages, the part-whole relation of fractions is reflected in the corresponding names; "one-fourth" is "of four parts, one" in Korean. I. Miura et al. (1999) showed these differences in word structure result in East Asian children grasping the part-whole relations represented by simple fractions (e.g., $\frac{1}{2}$, $\frac{1}{4}$) before formal instruction (in first and second grade) and before children whose native language does not have transparent word names for fractions (Croatian and English in this study). Paik and Mix (2003) demonstrated that first- and second-grade children in the United States perform as well as or better than the same-grade Korean children in the Miura et al. study, when fractions such as $\frac{1}{4}$ were worded as "one of four parts."

Studies of older elementary-school children and middle-school children have focused on the acquisition of computational skills (e.g., to solve $\frac{3}{4} \times \frac{1}{2}$), conceptual understanding (e.g., that $\frac{21}{18} > 1$), and the ability to solve word problems involving fractional quantities (Byrnes & Wasik, 1991; Rittle-Johnson

et al., 2001). Hecht (1998) assessed the relation between children's accuracy at recognizing formal procedural rules for fractions (e.g., when multiplying, the numerators are multiplied and the denominators are multiplied), their conceptual understanding of fractions (e.g., of part-whole relations), their basic arithmetic skills and their ability to solve computational fraction problems, word problems that include fractions, and to estimate fractional quantities. Among other findings, the results demonstrated that scores on the procedure-recognition test predicted computational skills (i.e., accuracy in adding, multiplying, and dividing proper and mixed fractions), above and beyond the influence of IQ, reading skills, and conceptual knowledge. And, conceptual knowledge predicted accuracy at solving word problems that involved fractions and especially accuracy in the estimation task, above and beyond these other influences.

In a follow-up study, Hecht et al. (2003) demonstrated the acquisition of conceptual knowledge of fractions and basic arithmetic skills were related to children's working memory capacity and their on-task time in math class. Conceptual knowledge and basic arithmetic skills, in turn, predicted accuracy at solving computational problems involving fractions; conceptual knowledge and working memory predicted accuracy at setting up word problems that included fractions; and conceptual knowledge predicted fraction estimation skills. Rittle-Johnson et al. (2001) demonstrated that children's skill at solving decimal fractions was related to both their procedural and their conceptual knowledge of fractions and that learning procedural and conceptual knowledge occurred iteratively. Good procedural skills predicted gains in conceptual knowledge and vice versa (Sophian, 1997). The mechanism linking procedural and conceptual knowledge appeared to be the children's ability to represent the decimal fraction on a mental number line.

In all, these studies suggest that preschool and early elementary-school children have a rudimentary understanding of simple fractional relationships, but the mechanism underlying this knowledge is not yet known. It might be the case that the ability to visualize simple part-whole relations (e.g., $\frac{1}{2}$ of natural objects that can be decomposed, as in eating an apple) is biologically primary. Difficulties arise when children are introduced to biologically secondary features of fractions, specifically, as formal mathematical principles and as formal procedures that can be used in problem-solving contexts.

A source of difficulty is the misapplication of counting knowledge and arithmetic with whole numbers to fractions. Children's conceptual understanding of fractions and their knowledge of associated procedures emerges slowly, sometimes not at all, during the elementary and middle school years. The mechanisms that contribute to the emergence of these biologically secondary competencies are not fully understood, but involve instruction, working memory, and the bidirectional influences of procedural knowledge on the acquisition of conceptual knowledge and conceptual knowledge on the skilled use of procedures.

Estimation. Although not a formal content domain, the ability to estimate enables individuals to assess the reasonableness of solutions to mathematical problems and thus it is an important competency within many mathematical domains. Estimation typically involves some type of procedure to generate an approximate answer to a problem when calculation of an exact answer is too difficult or is unnecessary. The study of children's ability to estimate in school-taught domains and the development of these skills has focused on computational arithmetic (Case & Okamoto, 1996; Dowker, 1997, 2003; LeFevre, Greenham, & Waheed, 1993; Lemaire & Lecacheur, 2002b) and the number line (Siegler & Booth, 2004, 2005; Siegler & Opfer, 2003). Studies in both of these areas indicate that the ability to generate reasonable estimates is difficult for children and some adults and only appears with formal schooling.

Dowker (1997, 2003) demonstrated that elementary-school children's ability to generate reasonable estimates to arithmetic problems (e.g., $34 + 45$) is linked to their computational skills. More specifically, children can estimate within a zone of partial knowledge that extends just beyond their ability to mentally calculate exact answers. Children who can solve addition problems with sums less than 11 (e.g., $3 + 5$) can estimate answers to problems with sums less than about 20 (e.g., $9 + 7$), but guess for larger-valued problems (e.g., $13 + 24$). Children who can solve multidigit problems without carries (e.g., $13 + 24$) can estimate answers to problems of the same magnitude with carries (e.g., $16 + 29$), but guess for larger-valued problems (e.g., $598 + 634$). Studies of how children and adults estimate have revealed that, as with most cognitive domains (Siegler, 1996), they use a variety of strategies (LeFevre et al., 1993; Lemaire & Lecacheur, 2002b). For younger children, a common strategy for addition is to round the units or

decades segments down to the nearest decade or hundreds value and then add, as in $30 + 50 = 80$ to estimate $32 + 53$, or $200 + 600 = 800$ to estimate $213 + 632$. Older children and adults use more sophisticated strategies than younger children, and may for instance compensate for the initial rounding to adjust their first estimate. An example would involve adding $10 + 30 = 40$ to the initial estimate of 800 for the $213 + 632$ problem.

Siegler and his colleagues (Siegler & Booth, 2004; Siegler & Opfer, 2003) have studied how children estimate magnitude on a number line, as in estimating the position of 83 on a 1 to 100 number line. As with arithmetic, young children are not skilled at making these estimates but improve considerably during the elementary school years, and come to use a variety of strategies for making reasonable estimates. The most intriguing finding is that young children's performance suggests their estimates are supported by the analog magnitude mechanism described in the "Early Quantitative Abilities" section. Figure 18.2 provides an illustration of how this mechanism would map onto the number line. The top number line illustrates the values across the first 9 integers as defined by the formal mathematical system. The distance between successive numbers and the quantity represented by this distance are precisely the same at any position in the number line (e.g., 2 3, versus 6 7, or versus 123 124). The bottom number line illustrates perceived distances predicted to result from estimates based on the analog magnitude mechanism (Dehaene, 1997; Gallistel & Gelman, 1992). As magnitude increases, the number line is "compressed" such that distances between smaller-valued integers, such as 2 to 3, are more salient and more easily discriminated than distances associated with larger-valued integers.

When kindergarten children are asked to place numbers on a 1 and 100 number line, they place 10 too far to the right and compress the placement of larger-valued

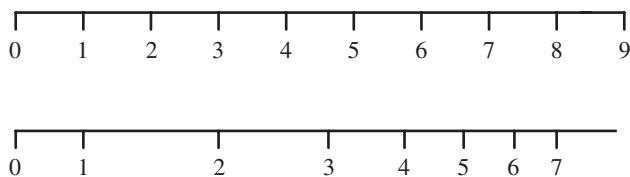

Figure 18.2 Spatial representations of number-line magnitudes. The top is the standard mathematical number line, and the bottom is the number line generated when numbers are mapped onto the analog magnitude mechanism.

numbers (Siegler & Booth, 2004), in keeping with the view that their initial understanding of Arabic numerals maps onto the analog magnitude mechanism (Spelke, 2000). By the end of elementary school, most children develop the correct mathematical representation of number placement and the meaning of this placement (Siegler & Opfer, 2003). Dehaene (1997), Gallistel and Gelman (1992), and Siegler and Booth (2005) proposed the analog magnitude mechanism onto which the mathematical number line is mapped is spatial. Indeed, Zorzi, Priftis, and Umiltà (2002) found that individuals with injury to the right-parietal cortex showed deficits in spatial orientation and number line estimation. Dehaene et al. (1999) showed adults' computational estimation may also be dependent on a similar spatial system, that is, a mental number line.

Arithmetic Operations

Research in this area is focused on children's explicit and goal-directed solving of arithmetic problems, as contrasted with an implicit understanding of the effects of addition and subtraction on the quantity of small sets. In the first section, I provide an overview of arithmetical development across cultures and in the second focus on addition to more fully illustrate developmental and schooling-based changes in how children solve arithmetic problems. In the third section, I provide a few examples of how children solve subtraction, multiplication, and division problems (for a more thorough discussion, see Geary, 1994); and in the final section I discuss the relation between conceptual knowledge and procedural skills in arithmetic.

Arithmetic across Cultures. Even before formal instruction, there are important cross-cultural similarities in children's arithmetical development. Within all cultural groups that have been studied and across all four arithmetic operations, development is not simply a matter of switching from a less mature problem-solving strategy to a more adult-like strategy. Rather, at any given time most children use a variety of strategies to solve arithmetic problems (Siegler, 1996). They might count on their fingers to solve one problem, retrieve the answer to the next problem, and count verbally to solve still other problems. Arithmetic development involves a change in the mix of strategies, as well as changes in the accuracy and speed with which each strategy can be executed. A more intriguing finding is that children do not

randomly choose one strategy, such as counting to solve one problem, and then retrieval to solve the next problem. Rather, children "often choose among strategies in ways that result in each strategy's being used most often on problems where the strategy's speed and accuracy are advantageous, relative to those of other available procedures" (Siegler, 1989, p. 497).

With instruction, a similar pattern of developmental change in strategy usage emerges for children in different cultures, although the rate with which the mix of strategies changes varies from one culture to the next (Geary et al., 1996; Ginsburg, Posner, & Russell, 1981; Saxe, 1985; Svenson & Sjöberg, 1983). Children in China shift from one favored strategy to the next at a younger age than do children in the United States, whereas the Oksapmin appear to shift at later ages (Geary et al., 1996; Saxe, 1982). These cultural differences appear to reflect differences in the amount of experience with solving arithmetic problems (Stevenson, Lee, Chen, Stigler, Hsu, & Kitamura, 1990), and to a lesser extent the earlier described language differences in number words. As an example, Ilg and Ames (1951) provided a normative study of arithmetic development for American children between the ages of 5 and 9 years. These children received their elementary-school education at a time when basic skills were emphasized much more than today. The types of skills and problem-solving strategies they described for American children at that time was very similar to arithmetic skills we see in present day same-age East Asian children (Fuson & Kwon, 1992b; Geary et al., 1996). Today, however, the arithmetic skills of East Asian children are much better developed than those of their same-age American peers (see also Geary et al., 1997).

Addition Strategies. The most thoroughly studied developmental and schooling-based improvement in arithmetical competency is change in the distribution of procedures, or strategies, children use during problem solving (e.g., Ashcraft, 1982; Carpenter & Moser, 1984; Geary, 1994; Lemaire & Siegler, 1995; Siegler & Shrager, 1984). Some 3-year-olds can explicitly solve simple addition problems and do so based on their counting skills (Fuson, 1982; Saxe et al., 1987). A common approach is to use objects or manipulatives. If the child is asked "how much is one cookie and two cookies," she will typically count out two objects, then one object, and finally all of the objects are counted starting from one.

The child states, while pointing at each object in succession, "one, two, three." The use of manipulatives serves at least two purposes. First, the sets of objects represent the numbers to be counted. The meaning of the abstract numeral, "three" in this example, is literally represented by the objects. Second, pointing to the objects during counting helps the child to keep track of the counting process (Carpenter & Moser, 1983; R. Gelman & Gallistel, 1978). The use of manipulatives is even seen in some 4- and 5-year-olds, depending on the complexity of the problem (Fuson, 1982).

By the time children enter kindergarten, a common strategy for solving simple addition problems is to count both addends. These counting procedures are sometimes executed with the aid of fingers, the finger-counting strategy, and sometimes without them, the verbal counting strategy (Siegler & Shrager, 1984). The two most commonly used counting procedures, whether children use their fingers or not, are called *min* (or counting on) and *sum* (or counting all; Fuson, 1982; Groen & Parkman, 1972). The *min* procedure involves stating the larger-valued addend and then counting a number of times equal to the value of the smaller addend, such as counting 5, 6, 7, 8 to solve $5 + 3$. With the *max* procedure, children start with the smaller addend and count the larger addend. The *sum* procedure involves counting both addends starting from 1. The development of procedural competencies is related, in part, to improvements in children's conceptual understanding of counting and is reflected in a gradual shift from frequent use of the *sum* procedure to the *min* procedure (Geary, Bow-Thomas, & Yao, 1992; Siegler, 1987).

The use of counting also results in the development of memory representations of basic facts (Siegler & Shrager, 1984). Once formed, these long-term memory representations support the use of memory-based problem-solving processes. The most common of these are direct retrieval of arithmetic facts and decomposition. With direct retrieval, children state an answer that is associated in long-term memory with the presented problem, such as stating "eight" when asked to solve $5 + 3$. Decomposition involves reconstructing the answer based on the retrieval of a partial sum. The problem $6 + 7$ might be solved by retrieving the answer to $6 + 6$ and then adding 1 to this partial sum. With the fingers strategy, children raise a number of fingers to represent the addends, which appears to trigger retrieval of the answer. The use of retrieval-based processes is moderated

by a confidence criterion that represents an internal standard against which the child gauges confidence in the correctness of the retrieved answer. Children with a rigorous criterion only state answers that they are certain are correct, whereas children with a lenient criterion state any retrieved answer, correct or not (Siegler, 1988a). The transition to memory-based processes results in the quick solution of individual problems and reductions in the working memory demands that appear to accompany the use of counting procedures (Delaney, Reder, Staszewski, & Ritter, 1998; Geary et al., 1996; Lemaire & Siegler, 1995).

The general pattern of change is from use of the least sophisticated problem-solving procedures, such as sum counting, to the most efficient retrieval-based processes. The relatively unsophisticated counting-fingers strategy, especially with use of the sum procedure, is heavily dependent on working memory resources and takes the most time to execute, whereas direct retrieval requires little of working memory and is executed quickly, and with practice accurately and automatically (Geary, Hoard, Byrd-Craven, & DeSoto, 2004). However, as noted, development is not simply a switch from use of a less sophisticated strategy to use of a more sophisticated strategy. Rather, the change is best captured by Siegler's (1996) overlapping waves metaphor of cognitive development, as noted earlier. An example is provided by Geary et al.'s (1996) assessment of the strategies used by first-, second-, and third-grade children in China and the United States to solve simple addition problems. In the fall of first grade, the Chinese and American children, as groups and as individuals, used a mix of counting and retrieval to solve these problems. The American children used finger counting and verbal counting, but the Chinese children rarely used finger counting, although they did use this strategy in kindergarten. Across grades, there is an increase in use of direct retrieval and a decrease in counting for both groups, but a much more rapid (within and across school years) change in the strategy mix for the Chinese children.

When solving more complex addition problems, children initially rely on the knowledge and skills acquired for solving simple addition problems (Siegler, 1983). Strategies for solving more complex problems include counting, decomposition or regrouping, as well as the formally taught columnar procedure (Fuson, Stigler, & Bartsch, 1988; Ginsburg, 1977). Counting strategies typically involve counting on from the larger number (Siegler & Jenkins, 1989). For instance, $23 + 4$ would be

solved by counting "twenty-three, twenty-four, twenty-five, twenty-six, twenty-seven." The decomposition or regrouping strategy involves adding the tens values and the units values separately. So the problem $23 + 45$ would involve the steps $20 + 40$, $3 + 5$, and then $60 + 8$ (Fuson & Kwon, 1992a). The most difficult process involves carrying or trading, as in the problem $46 + 58$. These problems are difficult because of the working memory demands of trading (Hamann & Ashcraft, 1985; Hitch, 1978; Widaman, Geary, Cormier, & Little, 1989), and because trading requires an understanding of place value and the base-10 system.

Subtraction, Multiplication, and Division Strategies. Many of the same strategic and development trends described for children's addition apply to children's subtraction (Carpenter & Moser, 1983, 1984). Early on, children use a mix of strategies but largely count, often using manipulatives and fingers to help them represent the problem and keep track of the counting (Saxe, 1985). With experience and improvements in working memory, children are better able to mentally keep track of the counting process, and thus gradually abandon the use of manipulatives and fingers for verbal counting. There are two common counting procedures, counting up or counting down. Counting up involves stating the value of the subtrahend (bottom number), and then counting until the value of the minuend (top number) is reached. For example, $9 - 7$ is solved by counting "eight, nine." Since two numbers were counted, the answer is two. Counting down is often used to solve more complex subtraction problems, such as $23 - 4$ (Siegler, 1989), and involves counting backward from the minuend a number of times represented by the value of the subtrahend. Children also rely on their knowledge of addition facts to solve subtraction problems, which is called addition reference ($9 - 7 = 2$, because $7 + 2 = 9$). The most sophisticated procedures involve decomposing the problems into a series of simpler problems (Fuson & Kwon, 1992a), or solving the problem using the school-taught columnar approach.

Developmental trends in children's simple multiplication mirror the trends described for children's addition and subtraction, although formal skill acquisition begins in the second or third grade, at least in the United States (Geary, 1994). The initial mix of multiplication strategies is grounded in children's knowledge of addition and counting (Campbell & Graham, 1985; Siegler, 1988b). These strategies include repeated addition and

counting by n . Repeated addition involves representing the multiplicand a number of times represented by the multiplier, and then successively adding these values; for example, adding $2 + 2 + 2$ to solve 2×3 . The counting by n strategy is based on the child's ability to count by 2s, 3s, 5s, and so on. Somewhat more sophisticated strategies involve rules, such as $n \times 0 = 0$, and decomposition (e.g., $12 \times 2 = 10 \times 2 + 2 \times 2$). Use of these procedures results in the formation of problem/answer associations such that most children are able to retrieve most multiplication facts from long-term memory by the end of the elementary school years (Miller & Paredes, 1990). Considerably less research has been conducted on children's strategies for solving complex multiplication problems, but the studies that have been conducted with adults suggest that many individuals eventually adopt the formally taught columnar procedure (Geary, Widaman, & Little, 1986).

The first of two classes of strategy used for solving division problems are based on the child's knowledge of multiplication (Ilg & Ames, 1951; Vergnaud, 1983). For example, the solving of $20/4$ (20 is the dividend, and 4 is the divisor) is based on the child's knowledge that $5 \times 4 = 20$, which is called multiplication reference (see also Campbell, 1999). For children who have not yet mastered the multiplication table, a derivative of this strategy is sometimes used. Here, the child multiplies the divisor by a succession of numbers until she finds the combination that equals the dividend. To solve $20/4$, the sequence for this strategy might be $4 \times 2 = 8$, $4 \times 3 = 12$, $4 \times 4 = 16$, $4 \times 5 = 20$. The second class of strategies is based on the child's knowledge of addition. The first involves a form of repeated addition. To solve $20/4$, the child would produce the sequence $4 + 4 + 4 + 4 + 4 = 20$, and then count the fours. The number of counted fours represents the quotient. Sometimes children try to solve division problems based directly on their knowledge of addition facts. For instance, to solve the problem $12/2$, the child might base her answer on the knowledge that $6 + 6 = 12$; thus 12 is composed of two 6s.

Conceptual Knowledge. The progression in the mix of problem-solving strategies described in the preceding sections is related to frequency of exposure to the problems, instruction, and to children's understanding of related concepts (Blöte et al., 2000; Geary et al., 1996; Klein & Bisanz, 2000; Siegler & Stern, 1998). For example, children's use of min counting, as contrasted with sum counting, as well as their use of decomposition

to solve simple and complex addition problems is related to their understanding of commutativity (Canobi et al., 1998; R. Cowan & Renton, 1996) and to their understanding of counting principles (Geary et al., 2004). Children's understanding of the base-10 system facilitates their understanding of place value and is related to the ease with which they learn to trade from one column to the next when solving complex addition and subtraction problems (e.g., $234 + 589$; $82 - 49$) and to the frequency with which they commit trading errors (Fuson & Kwon, 1992a). For trading in the problem $34 + 29$, children must understand that the 1 traded from the units- to the tens-column represents 10 and not 1. Failure to understand this contributes to common trading errors, as in $34 + 29 = 513$ where $4 + 9$ is written as 13 without the trade (Fuson & Briars, 1990).

Arithmetical Problem Solving

The study of children's and adolescents' mathematical problem solving typically focuses on competence in solving arithmetical or algebraic word problems, and the cognitive processes (Hegarty & Kozhevnikov, 1999; Mayer, 1985) and instructional factors (Fuchs et al., 2003a; Sweller, Mawer, & Ward, 1983) that drive the development of this competence. The ability to solve all but the most simple arithmetical and algebraic word problems does not come easily to children or many adults, and represents an important biologically secondary mathematical competence. A full review is beyond the scope of this chapter (see Geary, 1994; Mayer, 1985; Tronsky & Royer, 2002), but I illustrate some of the core issues as related to the solving of arithmetical word problems.

Problem Schema. Word problems can be placed in categories based on the relations among objects, persons, or events described in the problem and the types of procedures needed to solve the problem (G. Cooper & Sweller, 1987; Mayer, 1985). The relations and procedures that define each category compose the schema for the problem type. As shown in Table 18.1, most simple word problems that involve addition or subtraction can be classified into four general categories: change, combine, compare, and equalize (Carpenter & Moser, 1983; De Corte & Verschaffel, 1987; Riley et al., 1983). Change problems imply some type of action be performed by the child, and are solved using the same procedures children use to solve standard arithmetic problems (e.g., $3 + 5$; Jordan & Montani, 1997). Most

TABLE 18.1 Classification of Arithmetic Word Problems

	Change
1.	Andy had two marbles. Nick gave him three more marbles. How many marbles does Andy have now?
2.	Andy had five marbles. Then he gave three marbles to Nick. How many marbles does Andy have now?
3.	Andy had two marbles. Nick gave him some more marbles. Now Andy has five marbles. How many marbles did Nick give him?
4.	Nick had some marbles. Then he gave two marbles to Andy. Now Nick has three marbles. How many marbles did Nick have in the beginning?
	Combine
1.	Andy has two marbles. Nick has three marbles. How many marbles do they have altogether?
2.	Andy has five marbles. Three are red marbles and the rest are blue marbles. How many blue marbles does Andy have?
	Compare
1.	Nick has three marbles. Andy has two marbles. How many fewer marbles does Andy have than Nick?
2.	Nick has five marbles. Andy has two marbles. How many more marbles does Nick have than Andy?
3.	Andy has two marbles. Nick has one more marble than Andy. How many marbles does Nick have?
4.	Andy has two marbles. He has one marble less than Nick. How many marbles does Nick have?
	Equalize
1.	Nick has five marbles. Andy has two marbles. How many marbles does Andy have to buy to have as many marbles as Nick?
2.	Nick has five marbles. Andy has two marbles. How many marbles does Nick have to give away to have as many marbles as Andy?
3.	Nick has five marbles. If he gives away three marbles, then he will have as many marbles as Andy. How many marbles does Andy have?
4.	Andy has two marbles. If he buys one more marble, then he will have the same number of marbles as Nick. How many marbles does Nick have?
5.	Andy has two marbles. If Nick gives away one of his marbles, then he will have the same number of marbles as Andy. How many marbles does Nick have?

kindergarten and first-grade children can easily solve the first type of change problem shown in the table. Children typically represent the meaning of the first term, "Andy had two marbles," through the use of two blocks or uplifted fingers. The meaning of the next term, "Nick gave him three more marbles," is represented by three blocks or uplifted fingers. Some children then answer the "how many" question by literally moving the two sets of blocks together and then counting them or counting the total number of uplifted fingers (Riley & Greeno, 1988).

The change and combine problems are conceptually different, even though the basic arithmetic is the same

(Briars & Larkin, 1984; Carpenter & Moser, 1983; Riley et al., 1983). Combine problems involve a static relationship, rather than the implied action found with change problems. The first examples under the change and combine categories presented in Table 18.1 illustrate the point. Both problems require the child to add 2 + 3. In the change problem, the quantities in Andy's and Nick's sets differ after the action (addition) has been performed. In the combine example, however, the status—the quantity of owned marbles—of Andy's set and Nick's set is not altered by the addition. Compare problems involve the same types of static relationships found in combine problems. The quantity of the sets does not change. Rather, the arithmetic operation results in determining the exact quantity of one of the sets by reference to the other set, as illustrated with the third and fourth compare examples in Table 18.1. The first and second compare examples involve a more straightforward greater than/less than comparison. Examination of the equalize problems presented in Table 18.1 reveals that they are conceptually similar to change problems. The action, or arithmetic, performed results in a change in the quantity of one of the sets. The change is constrained such that the result is equal sets once the action has been completed, whereas there is no such constraint with change problems.

Across categories, the complexity of word problems increases with increases in the number of steps or procedures needed to solve the problem; the complexity of these procedures (e.g., differentiation in calculus versus simple addition); and the complexity of the relations among persons, objects, or events (e.g., timing of two events) conveyed in the problem. These more complex problems can still be categorized in terms of schemas, that is, the specific nature of the relations among these persons, objects, or events and the types of procedures needed to solve the problem (Mayer, 1981; Sweller et al., 1983).

Problem-Solving Processes. The processes involved in solving word problems include translating each sentence into numerical or mathematical information, integrating the relations among this information, and executing the necessary procedure or procedures (Briars & Larkin, 1984; Kintsch & Greeno, 1985; Mayer, 1985; Riley et al., 1983; Riley & Greeno, 1988). For complex, multistep problems and especially unfamiliar problems, an additional step is solution planning—making explicit metacognitive decisions about problem type and potential procedural steps for solving the problem

(Fuchs, Fuchs, Prentice, Burch, Hamlett, Owen, & Schroeter, 2003; Mayer, 1985; Schoenfeld, 1987). The latter is important, because the number of potential ways a problem can be solved (e.g., sequence in which procedures are executed) increases with increases in problem complexity. The translation process is straightforward for most of the problems shown in Table 18.1, but integrating this information across sentences can be more difficult. Consider the second compare problem. Here, the key word “more” will often prompt children to add the quantities. These types of error can often be avoided if, for example, the relations between the quantities held by Nick and Andy are concretely represented on a visuospatial number line. Once represented in this way, the child can easily count from 2 to 5 on the number line and correctly determine that Nick has three more than Andy.

Improvement in the ability to execute these problem-solving processes and thus the ability to solve complex word problems is related to intraindividual and extraindividual factors. The latter include the quantity (e.g., amount of practice) and form of instruction (Fuchs, Fuchs, Prentice, Burch, Hamlett, Owen, & Schroeter, 2003; Sweller et al., 1983), and more general curricular factors, such as the grade in which multistep problems are introduced and the quality of textbooks (Fuson et al., 1988). One of the more difficult competencies to teach is the ability to transfer knowledge from familiar to novel problems. Teaching of this competence often requires explicit instruction on how to make links (e.g., based on problem type) between familiar and novel problems (Fuchs et al., 2003). For children and adults, intraindividual factors include working memory capacity (Geary & Widaman, 1992; Tronsky & Royer, 2002), basic computational skills (Sweller et al., 1983), knowledge of problem type and schema (G. Cooper & Sweller, 1987), the ability to form visuospatial representations of relations among problem features (Hegarty & Kozhevnikov, 1999; Lewis & Mayer, 1987), as well as self-efficacy and the resultant tendency to persist with problem-solving efforts (Fuchs, Fuchs, Prentice, Burch, Hamlett, Owen, & Schroeter, 2003).

Mechanisms of Change

The processes that result in variability, competition, and selection drive change at all levels, ranging from gene frequency in populations to the pattern of corporate successes and failures. The combination of variability,

competition, and selection is thus a useful organizing framework for studying the mechanisms underlying the development of children’s mathematical competence and for understanding cognitive development in general (Siegler, 1996). Developmental or experience-related improvements in cognitive competence in turn are indexed by efficiency in achieving goals, such as solving an arithmetic problem or generating plans for the weekend, with efficiency typically measured in terms of the speed and accuracy with which the goal or subgoals are achieved. From this perspective, developmental or experience-related improvement in goal achievement will be related, in part, to (a) variability in the procedures or concepts that can be employed to achieve the goal; (b) underlying brain and cognitive mechanisms that generate this variability; and (c) contextual as well as brain and cognitive feedback mechanisms that select the most efficient procedures or concepts.

In the first section, I outline some basic mechanisms related to variability, competition, and selection among different problem-solving approaches; more detailed discussion of associated brain (Edelman, 1987) and cognitive (Shrager & Siegler, 1998; Siegler, 1996) mechanisms can be found elsewhere. In the second section, I conjecture about developmental change in these mechanisms, as related to biologically primary and biologically secondary competencies (Geary, 2004a, 2005). The discussion in both sections is necessarily preliminary but should provide an outline for conceptualizing how change might occur in mathematical and other domains.

Darwinian Competition

Variability and Competition. Siegler and his colleagues have demonstrated that children use a variety of procedures and concepts to solve problems in nearly all cognitive domains, and that with development and experience they become more efficient in achieving problem-solving goals (Shrager & Siegler, 1998; Siegler, 1996; Siegler & Shipley, 1995). The issue at this point is not whether variability in problem-solving approaches is an integral feature of cognitive development, but rather the mechanisms that result in variability and competition among these approaches. In Figure 18.3, I provide a skeletal framework for conceptualizing the mechanisms that might contribute to variability in, and competition among, problem-solving approaches at the level of cognitive and brain systems.

First, goal achievement requires an attentional focus on features of the external context that are either related

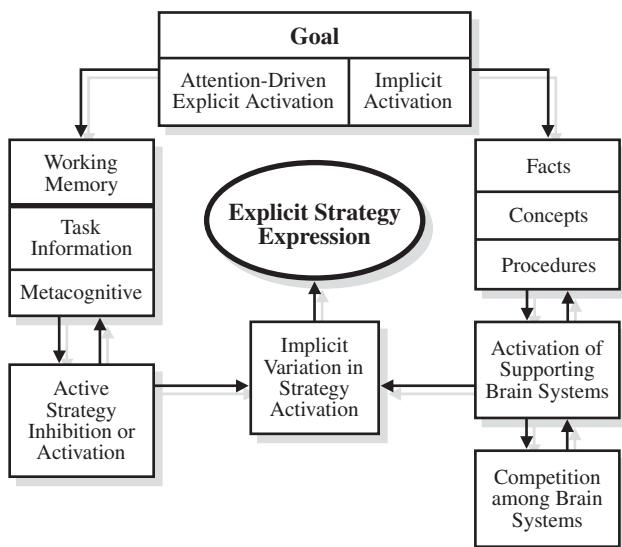

Figure 18.3 Outline of explicit and implicit mechanisms that appear to contribute to the explicit use of one problem-solving strategy or another (see text for detailed description).

to the goal (e.g., a sheet of arithmetic problems to solve) or to an internally generated mental model of an anticipated goal-related context (Geary, 2005). Goal generation and a narrowing of attention onto the features of the external or internally represented context will result in the implicit activation—above baseline levels of activation but outside conscious awareness—of goal-related facts, concepts, and procedures (Anderson, 1982). These can be learned facts, concepts, and procedures associated with previous problem solving (Shrager & Siegler, 1998; Siegler, 1996) or inherent but rudimentary concepts and procedures (R. Gelman, 1990, 1991). The implicit activation of goal-related information means that existing conceptual knowledge and memorized facts and procedures may influence where attention is allocated and thus influence problem solving. Knowledge of the base-10 system and memorized procedures for solving complex arithmetic problems should influence the temporal pattern of attentional focus, from the units-column numbers to the tens-column numbers, and so on. More generally, conceptual knowledge can be understood at multiple levels, ranging from explicit descriptors of categorical features (e.g., sets of ten) to patterns of brain activity that direct attention toward specific goal-related features of the environment (e.g., columnar numbers, eyes on a human face; Schyns, Bonnar, & Gosselin, 2002).

The implicit activation of goal-related information will often mean that multiple facts, concepts, or proce-

dures are simultaneously activated and, as indicated by the bidirectional arrows in the right-hand side of Figure 18.3, multiple underlying systems of brain regions will be simultaneously activated. Edelman (1987) proposed these activated populations of neurons compete, as integrated groups, for downstream explicit, behavioral expression. As is also shown in the right-hand side of Figure 18.3, competition at the level of brain systems—relative activation of neuronal groups and inhibition of competing groups—creates variation in the level of implicit activation of corresponding facts, concepts, and procedures associated with goal-related behavioral strategies and thus variation in the probability of the expression of one strategy or another. Edelman also proposed that normal neurodevelopmental processes create a pattern of brain organization that will necessarily result in variation and competition at the level of neuronal groups and thus variation and competition at the levels of perception, cognition, and behavioral expression. The resulting systems of neuronal groups are well understood for only a few restricted perceptual or cognitive phenomena related to classical and operant conditioning (e.g., McDonald & White, 1993; Thompson & Krupa, 1994), although they are beginning to be explored in mathematical domains (Dehaene et al., 1999; Pinel et al., 2004). The point is that competition among neuronal groups activated by goal-related contextual features creates variation at the level of activation of cognitive representations (e.g., long-term memories of goal-related facts) and thus variation in the probability that one strategy or another will be expressed.

It is also clear that attentional focus can result in an explicit and conscious representation of the goal and goal-related facts, concepts, and procedures in working memory (N. Cowan, 1995; Dehaene & Naccache, 2001; Engle, 2002; Shrager & Siegler, 1998), as shown in the left-hand side of Figure 18.3. The working memory system provides at least two strategy-selection mechanisms. The first is composed of explicitly represented task or metacognitive knowledge that can guide the strategy execution and enable inferences to be drawn about goal-related concepts or procedures based on observation of problem-solving processes and outcomes. A task-relevant inference was provided by Briars' and Siegler's (1984) finding that preschool children's knowledge of counting is derived, in part, through observation of culture-specific procedures, such as counting from left to right. Metacognitive mechanisms operate across tasks and represent the ability to monitor problem solving for ways to improve efficiency. An example is chil-

dren's discovery of min counting (Siegler & Jenkins, 1989). Although many children switch from sum counting to min counting before they are explicitly aware they have done so, others correctly infer that you do not have to count both addends to solve the problem and adjust their problem solving accordingly. In other words, explicit monitoring of goal-related problem solving can result in the identification and elimination of unnecessary problem-solving steps.

The second way in which explicit attentional control can influence problem solving is through active strategy inhibition or activation. An example is provided by choice/no choice problem-solving instructions (Siegler & Lemaire, 1997). Here, participants are instructed to solve one set of problems (e.g., arithmetic problems, spelling items) using any strategy they choose (e.g., finger counting, or retrieval), and are instructed to solve a comparable set of problems using only a single strategy, such as direct retrieval. Problem solving is more accurate under choice conditions, in keeping with the prediction that strategy variability is adaptive (Siegler, 1996). Equally important, the ability to explicitly inhibit the expression of all but one problem-solving strategy is easily achieved by most elementary-school children (Geary, Hamson, & Hoard, 2000; Jordan & Montani, 1997; Lemaire & Lecacheur, 2002a). Brain-imaging studies suggest that the dorsolateral prefrontal cortex is involved in attentional control, monitoring of explicit problem-solving, and the inhibition of task-irrelevant brain regions (Kane & Engle, 2002); maturation of these brain regions may contribute to developmental change in the ability to consciously influence strategy choices (Welsh & Pennington, 1988). As shown in the bottom left-hand side of Figure 18.3, these brain regions can amplify or inhibit the implicitly activated brain regions represented at the right-hand side of the figure. The combination of bottom-up competition and top-down mechanisms that amplify or inhibit these competing systems results in the expression of one behavioral strategy or another.

Selection. Variability and competition at levels of brain and cognition result in the execution of one problem-solving strategy or another. Over time, adaptive goal-related adjustments lead to the most efficient strategies being used more often and less efficient strategies becoming extinct (see Siegler, 1996 for review). Given this pattern, the *consequence* (e.g., successful problem solving) and *process* of strategy execution must be among the selection mechanisms acting on indi-

vidual strategies. The specific means through which these selection processes operate are not well understood, but must involve changes in the pattern of memory and concept representation at both the brain (Edelman, 1987) and cognitive (Siegler, 1996) levels. Just as natural selection results in changes in gene frequencies across generations, selection processes that act on strategic variability result in a form of inheritance: changes in memory patterns, strategy knowledge, and physical changes in the underlying neuronal groups.

At a behavioral level, the most fundamental selective mechanisms are classical and operant conditioning (Timberlake, 1994), as illustrated by the learning of simple addition (Siegler & Robinson, 1982). As noted, early in skill development, children rely on finger and verbal counting. The repeated execution of these procedures has at least two effects. First, the procedures themselves are executed more quickly and with greater accuracy (Delaney et al., 1998), indicating the formation and strengthening of procedural memories. Second, the act of counting out the addends creates an associative link between the addend pair and the generated answer, that is, the formation of a declarative memory (Siegler & Shrager, 1984; see also Campbell, 1995). The neural changes that result in the formation and strengthening of these procedural and declarative memories are not known, but may require a simultaneous and synchronized firing of neurons within the associated neuronal group (e.g., Damasio, 1989). At a cognitive level, the formation of the associative memory results in greater variation in the number of processes (e.g., counting and retrieval) that can be used to achieve the goal and thus increases competition among these processes for expression.

Empirically, it is known that direct retrieval of arithmetic facts eventually obtains a selective advantage over the execution of counting procedures. Speed of retrieval (Siegler & Shrager, 1984) and the lower working memory demands of direct retrieval versus procedural execution (Geary et al., 2004) almost certainly contribute to this selective advantage. With sufficient experience, the speed of retrieval increases and the generated answer tends to be as accurate or more accurate than that generated by counting procedures. In effect, the greater efficiency of retrieval means that the goal is achieved before the execution of alternative processes can be completed. Goal achievement in turn may act—in ways not yet understood—to inhibit the expression of these alternative processes and may further enhance the competitive advantage of direct retrieval. At the level of

brain systems, Edelman (1987) predicted that these selection mechanisms will strengthen connections among neurons within the selected neuronal group supporting retrieval in this example, and result in the death of neurons or at least fewer connections among the neurons within the neuronal groups supporting strategies that are not expressed (counting in this example).

Primary and Secondary Domains

Primary. Primary competencies are composed of an inherent, though often not fully developed, system of implicit concepts, procedures, and supporting brain systems represented at the right-hand side of Figure 18.3. The result is attentional, affective, and information-processing biases that orient the child toward the features of the ecology that were of significance during human evolution (Geary & Bjorklund, 2000). Coupled with these biases are self-initiated behavioral engagements of the ecology (Bjorklund & Pellegrini, 2002; Scarr, 1992). The latter generate evolutionarily expectant experiences that provide the feedback needed to adjust the architecture of primary brain and cognitive systems to nuances in evolutionarily significant domains (Greenough, Black, & Wallace, 1987), such as allowing the individual to discriminate one face from another. These behavioral biases are expressed as common childhood activities, such as social play and exploration of the environment.

Proposed biologically primary mathematical competencies include an implicit understanding of the quantity of small sets (Starkey et al., 1990); the effects of addition and subtraction on quantity (Wynn, 1992a); counting concepts and how to execute counting procedures (R. Gelman & Gallistel, 1978); and relative quantity (Lipton & Spelke, 2003). There is little developmental change in some of these primary competencies, such as the ability to estimate the quantity of small sets (Geary, 1994; Temple & Posner, 1998), and substantive developmental improvement in other competencies, such as skill at executing counting procedures and the emergence of an explicit understanding of some counting concepts (R. Gelman & Gallistel, 1978). Developmental change in these latter competencies is predicted to emerge from an interaction between early attentional biases and related activities such as counting sets of objects (R. Gelman, 1990). These activities allow inherent biases to be integrated with culturally specific practices, such as the culture's number words or manner of representing counts (e.g., on fin-

gers or other body parts, as with the Oksapmin). By the end of the preschool years, all these competencies appear to be well integrated and allow children to perform basic measurements, count, and do simple arithmetic (Geary, 1995).

Secondary. Biologically secondary, academic development involves the modification of primary brain and cognitive systems for the creation of culturally specific competencies (Geary, 1995). Some of these competencies are more similar to primary abilities than others. Spelke (2000) proposed that learning the Arabic numeral system involves integrating primary knowledge of small numbers and counting with the analog magnitude system. In this way, the primary understanding of small sets and the understanding that successive counts increase quantity by one can be extended beyond the small number sizes of the primary system. Siegler's and Opfer's (2003) research on children's number-line estimation is consistent with this proposal. Recall, Figure 18.2 shows children's number-line estimates that conform to predictions of the analog magnitude system (bottom) and estimates that conform to the Arabic, mathematical system (top). With experience across numerical ranges (e.g., 1 to 100 or 1 to 1,000), children's representation of the number line based on the biologically primary analog-magnitude system is gradually transformed into the secondary mathematical representation (Siegler & Booth, 2004).

Other features of academic mathematics, such as the base-10 system, are more remote from the supporting primary systems (Geary, 2002). Competency in base-10 arithmetic requires a conceptual understanding of the mathematical number line, and an ability to decompose this system into sets of ten and then to organize these sets into clusters of 100 (10, 20, 30 . . .), 1,000, and so forth. Whereas an implicit understanding of number sets is likely to be primary knowledge, the creation of sets around 10 and the superordinate organization of these sets is not. This conceptual knowledge must also be mapped onto a number-word system (McCloskey, Sokol, & Goodman, 1986), and integrated with school-taught procedures for solving complex arithmetic problems (Fuson & Kwon, 1992a). The development of base-10 knowledge thus requires the extension of primary number knowledge to very large numbers, the organization of these number representations in ways that differ from primary knowledge, and the learning of procedural rules for applying this knowledge to the secondary domain of

complex, mathematical arithmetic (e.g., to solve $234 + 697$). In other words, multiple primary systems must be modified and integrated during children's learning of base-10 arithmetic.

Little is known about the mechanisms involved in modifying primary systems for learning secondary mathematics, but research on learning in other evolutionarily novel domains suggests the explicit attentional and inhibitory control mechanisms of the working memory system shown in Figure 18.3 are crucial (e.g., Ackerman & Cianciolo, 2002). It is known that some secondary mathematical learning, such as arithmetic facts or simple arithmetical relations, can occur implicitly but only with attentional focus and the repeated presentation of the same or similar arithmetical patterns (e.g., Siegler & Stern, 1998). In theory, the implicitly represented facts, concepts, and procedures (right-hand side of Figure 18.3) that result from this repetition will only emerge through modification underlying primary systems. There is no inherent understanding that $9 + 7 = 16$, but the repeated solving of this problem results in the development of a language-based (primary system) declarative fact (Dehaene & Cohen, 1991).

The explicit and conscious representation of information in working memory and through this the ability to make inferences about school-taught mathematics appears to require the synchronized activity of the dorsolateral prefrontal cortex and the activity of the brain regions that implicitly represent goal-related facts, concepts, or procedures (Dehaene & Naccache, 2001; Posner, 1994). The details of how this might occur as related to academic learning are presented elsewhere (Geary, 2005), but there are several basic points. First, repetition of mathematical problems in school should result in the formation of implicitly represented facts, concepts, or procedures in long-term memory (e.g., Siegler & Stern, 1998). This knowledge will influence problem solving and remain implicit unless the activity of the underlying brain regions becomes synchronized with activity of the dorsolateral prefrontal cortex, as will often happen when attention is focused on achieving a specific goal. When this occurs, the fact, concept, or procedural pattern will "pop" into conscious awareness, and thus be made available for drawing inferences about the information, forming metacognitive knowledge, and so forth. Second, an explicit representation of goal-related features in working memory (e.g., through direct instruction) should, in theory, result in a top-down influence on the pattern of activation and inhibi-

tion of brain regions that might support problem solving. These top-down processes may bias which implicitly represented facts, concepts, or procedures are used to approach the problem and may direct changes in the associated implicit knowledge.

In this view, change occurs through the repeated processing of a mathematical problem or pattern. The result is the repeated activation of a set of brain regions that process the pattern and through competition and selection at the level of corresponding neuronal groups (Edelman, 1987) form implicit biologically secondary facts, concepts, or procedures. Developmental change can occur with the maturation of the brain systems (e.g., dorsolateral prefrontal cortex) that support the explicit, working memory mechanisms shown in Figure 18.3. These regions appear to mature slowly through childhood and early adolescence (Giedd et al., 1999; Welsh & Pennington, 1988), and result in an improved ability to focus attention on goal-related problem solving, inhibit irrelevant information from interfering with problem solving, make explicit inferences about the goal and problem-solving processes, and form metacognitive knowledge.

CONCLUSIONS AND FUTURE DIRECTIONS

During the past 2 decades and especially in recent years, the study of children's mathematical development has emerged as a vibrant and exciting area. Although there is much to be learned, we now have considerable knowledge of infants', preschoolers' and young children's understanding of number, counting, arithmetic, and some aspects of more complex arithmetical and algebraic problem solving (Brannon & Van de Walle, 2001; Briars & Larkin, 1984; Siegler, 1996; Starkey, 1992; Wynn, 1992a). As a sign of a maturing field, the empirical findings in most of these areas are no longer contested, but the underlying cognitive mechanisms and the mechanisms of developmental change are the foci of vigorous theoretical debate (Cohen & Marks, 2002; Newcombe, 2002). Much of the debate centers on the extent to which the most basic quantitative abilities emerge from inherent and potentially evolved brain and cognitive systems that are designed to attend to and process numerical features of the environment (Gallistel & Gelman, 1992; Wynn, 1995), or whether brain and cognitive systems designed for other functions (e.g., object identification) are the source of these abilities (Mix et al., 1997).

Future research in this field will undoubtedly be focused on addressing this issue. In fact, recent behavioral (Brannon, 2002; Kobayashi et al., 2004) and brain-imaging (Pinel et al., 2004) studies have used sophisticated techniques to determine if the cognitive systems that support quantitative judgments are uniquely numerical, and whether the underlying brain regions are uniquely designed to process numerical information. The overall results are mixed, and thus a firm conclusion must await further studies. An equally important area of current debate and future study concerns the mechanisms that underlie children's cognitive development in the domain of mathematics and more generally (Siegler, 1996). We now have some understanding of the cognitive mechanisms (e.g., working memory, attention) that contribute to developmental change (Shrager & Siegler, 1998), and we are beginning to understand the operation of the supporting brain systems (Geary, 2005), but there is much to be learned about how these systems operate and change from one area of mathematics to another. A final direction is to apply knowledge derived from the scientific study of children's mathematical development to the study of how children learn mathematics in school.

A debate over the nature of social cognition was engaged very early in the history of developmental psychology. Piaget assumed that the child is naturally egocentric. Thus, even when the child uses a social tool such as language, it is put to egocentric use rather than to communicate. By contrast, Vygotsky assumed that the child is naturally social so that any nonsocial, egocentric use of language comes later in development. Despite this early debate—and the compelling arguments advanced by Vygotsky for acknowledging the very young child's capacity for social engagement—it was Piagetian theory that dominated the study of cognitive development throughout most of the 1960s and 1970s. Against that backdrop, it is not surprising that the development of social cognition was largely construed as the gradual breakdown of egocentrism—or the slow emergence of the capacity for role taking. On this view, the child's

task was to increasingly recognize and make allowances for differences between self and other. Two influential texts that emerged from that era are *The Development of Role-Taking and Communication Skills in Children* by Flavell and his colleagues (Flavell, Botkin, Fry, Wright, & Jarvis, 1968) and Kohlberg's (1969) chapter offering a cognitive-developmental approach to social cognition and to key issues in socialization.

In the following decade, a flurry of research with young infants gave pause to those wedded to the classic, Piagetian view of the young infant as egocentric. Several studies produced results that strongly suggested a capacity for sharing and mutuality from the earliest months. For example, Meltzoff demonstrated—albeit not without controversy—an early, imitative sensitivity to the facial and manual gestures of a partner (Meltzoff, 1976; Meltzoff & Moore, 1977). Trevarthen laid out a theory of early intersubjectivity (Trevarthen & Hubley, 1978). Scaife and Bruner (1975) published a pioneering

paper showing that infants can engage in joint attention with an adult partner before the age of 12 months. These various demonstrations showed that the young infant is nicely attuned to other people. At the same time, they did not in themselves lead to any radically new theorizing in the larger study of social cognitive development. Rather, they added to the growing list of findings showing that the young infant was much more competent than standard Piagetian theory might lead us to believe. They also showed quite clearly that experimental analysis of the infant's social cognition was a feasible and potentially fruitful avenue to explore.

A FRESH START

Vygotsky's developmental account had woven together two different strands. First, as a developmental psychologist, he emphasized functional changes that emerged in the course of development. In particular, he stressed the way that thought and language coalesce to form a new functional whole in the child's mind. At the same time, Vygotsky took a comparative approach to development. The available findings in primatology suggested to him that no such coalescence took place in the course of chimpanzee development. Oddly enough, despite his strong interest in evolution and a biological approach to the genesis of knowledge, Piaget rarely adopted a comparative approach to cognitive development, and—given the dominance of Piagetian theory—no such comparative approach was taken to the study of social cognition.

A landmark paper by two primatologists—David Premack and Guy Woodruff (1978)—showed that the study of social cognition can benefit greatly from a comparative flavor. They asked if the chimpanzee has a theory of mind, by which they meant does the chimpanzee go beyond the observation of overt behavior to infer the goals and plans that guide behavior. To answer that question, they showed their chimpanzee subject, Sarah, film clips of a human agent struggling unsuccessfully with a practical problem—for example, trying to reach some bananas overhead. After seeing each clip, Sarah was invited to indicate what the agent would do next by choosing from among several possible illustrated continuations to the film clip. Sarah was quite successful in selecting likely continuations. For example, she judged that the agent trying to reach the bananas would pile boxes underneath the bananas rather than push boxes aside. Premack and Woodruff concluded that

Sarah must have been able to figure out what the agent was trying to do and indicated his or her next steps appropriately in the light of that goal.

Commentaries on the results homed in on one further point. Ever since Kohler's famous experiments on the problem-solving abilities of chimpanzees, we have known that they can solve practical problems such as those with the bananas: They can search for boxes, pile them up, and climb on them in order to reach up. So, said the commentators, maybe the chimpanzee is not such a sophisticated psychologist after all. Maybe the chimpanzee is simply projecting onto the human agent what it would do in similar circumstances.

To counter this possibility, various commentators suggested an alternative experimental setup in which the observing subject is invited to make a prediction about a mistaken or misinformed protagonist. Such a setup would oblige the subject to differentiate between what he or she would do in the circumstances and what the mistaken protagonist would do. In other words, a simple strategy of projection would be wrong—it would not make appropriate allowance for the subjective stance of the protagonist. Prompted by this challenge, Wimmer and Perner (1983) reported a set of studies in which children were invited to make predictions about a doll protagonist that was mistaken about the current location of an object. For example, the protagonist put his chocolate in one cupboard and then left the scene; his brother moved the chocolate to another hiding-place in his absence. Wimmer and Perner (1983) found that 4- and 5-year-olds could accurately anticipate where the protagonist would search for the chocolate on his return (i.e., in the cupboard where he had first put it) but younger children could not (i.e., they assumed he would search at its new hiding-place).

This clever experiment triggered an avalanche of replications and challenges. Some who had been raised on the Piagetian notion of egocentrism—such as myself—were impressed and surprised that 4-year-olds could solve the problem at all. Others, by contrast, were dubious about the failure of 3-year-olds and attempted various experimental manipulations in an effort to uncover greater competence at that age. Alongside this program of research in developmental psychology, two other related research programs rapidly got underway. First, Baron-Cohen, Leslie, and Frith (1985) discovered that autistic children, even those with a relatively advanced mental age, frequently fail a variant of Wimmer and Perner's false-belief task. This led to a series of

studies aimed at assessing the extent to which the various symptoms of the autistic syndrome can be understood as an innate deficit in the normal development of a theory of mind. Second, Byrne and Whiten asked whether detailed field observations of nonhuman primates might reveal mind-reading skills similar to those found in human children (Byrne & Whiten, 1988; Whiten, 1991). For example, does a chimpanzee realize that another member of the group might hold a false belief, and might even be led to such a false belief by a deliberate act of deception? This comparative perspective—fueled by dialog with developmental psychology and by debate in primatology among experimentalists—has kept the question of the biological origin of the child's theory of mind in focus. Arguably, key aspects of the child's theory of mind might be the result of some dedicated module, peculiar to the human species. Alternatively—as Vygotsky might have speculated—they might be better seen as the elaboration of an intuitive psychology found in the higher apes but transformed by their fusion with language and conversation. I return to these contentious issues later.

The three-pronged research program that emerged in the 1980s—comprising human development, developmental psychopathology, and comparative primatology—has increasingly assimilated a variety of older concepts and research traditions in social cognition. For example, studies of the development of metacognition (Flavell, Green, & Flavell, 1995) and of emotion understanding (Harris, 1989; Harris, Olthof, & Meerum Terwogt, 1981) have been transported into the capacious tent of theory-of-mind research. At the same time, other concepts and traditions have been mostly swept aside. For better or worse, few contemporary researchers debate the extent to which the young child is egocentric. Moreover, few look—as they once did (Graham & Weiner, 1986)—to social psychology or more specifically to attribution theory for an understanding of the development of social cognition.

What does this lively and relatively ecumenical program ignore? Most theory-of-mind research assumes that the child is equipped with categories for decomposing and explaining the workings of the prototypical human mind: timeless and universal. However, beneath that level of analysis, the child surely faces questions about what particular people are like as opposed to people in general—questions about the personality, skills, and reliability of specific individuals, especially those individuals whom he or she encounters firsthand in the

context of the family or community. Some of those individual differences will occasionally boil down to differences in the very categories emphasized by theory-of-mind research: This individual is misinformed but that individual is not. However, there are other individual differences that have to do with enduring traits. For example, this individual is trustworthy but that individual is not. Attachment theory has long called attention to the fact that infants, even in the 1st year of life, are quite sensitive to individual differences among their caregivers—for example, they may be securely attached to their father but display an avoidant attachment to their mother. It would be hard to deny that such sensitivity is part of the child's early social cognition. Yet, theory-of-mind researchers mostly ignore it. In a concluding section, I explore ways in which research on theory-of-mind might advance our understanding of children's sensitivity to individual differences in trustworthiness.

INFANT SOCIAL COGNITION

Recent work on infant social cognition has been inspired both by the striking experimental results that began to appear in the 1970s and by the question of what precursors there might be to the relatively sophisticated understanding of false beliefs shown by 4- and 5-year-olds.

The Detection of Goal-Directed Agency

To the extent that human beings move autonomously, infants are in a position to distinguish them from inanimate objects. Indeed, from about 7 months of age, infants are puzzled by the spontaneous motion of inanimate objects but not that of people (Golinkoff, Harding, Carlson, & Sexton, 1984; Spelke, Phillips, & Woodward, 1995). However, human beings also engage in a particular class of movements—their movements are autonomous and directed at some goal or target. This is particularly obvious in the case of hand and arm movements. Human agents do not simply wave a hand; they reach out and grasp objects. Recent research has actively focused on such targeted movements with a view to diagnosing the extent to which infants interpret them as goal-directed.

A study by Woodward (1998) offers an illustrative example. Infants of 5 and 9 months were habituated to the sight of a human hand and arm reaching toward and

grasping one of two objects. Subsequently, infants saw an alteration in the reach: It was either directed to the same object along a different path; alternatively, it was directed to a different object along the same path. Infants treated the change of target object as more novel—as indexed by an increase in looking times. By implication, when infants watched the initial reach during habituation trials, they were more likely to encode the goal object that it was directed toward rather than the precise trajectory of the reach. As a result, they were more “surprised” by the change of target object than the change of trajectory.

At the same time, it is also clear that young infants do display some sensitivity to the trajectory of an object-directed movement: They expect it to be direct and efficient rather than unnecessarily circuitous. This fact has emerged in a series of experiments by Gergely and his colleagues (Csibra, Gergely, Biró, Koós, & Brockbank, 1999; Gergely, Nádasdy, Csibra, & Biró, 1995). Infants watched a film in which a “baby” circle went toward a larger, “mother” circle by moving up and over a barrier that separated them. After habituation, infants saw trials in which the barrier had been removed and the baby circle now either took the shorter, direct route toward mother or continued to follow the same up-and-over route—even in the absence of the barrier. Infants of 9 and 12 months looked longer at—and by implication were surprised by—the adoption of the indirect up-and-over route even though it corresponded exactly to the route taken during the previous habituation trials. Apparently, they expected the more direct route to be taken once the barrier was removed.

Summarizing across these studies on goal-directed movement, it appears that toward the end of the 1st year, infants encode the object that a movement is directed toward and generally anticipate that a movement will be direct and efficient rather than circuitous. How do infants establish such expectations? One possibility is that they learn a great deal from first-person experience. After all, by the end of the 1st year, infants will have engaged in countless deliberate, goal-directed behaviors. They will have reached for, and crawled toward, all sorts of objects. Arguably, such firsthand experience of efficient, targeted action leads infants to assume that a similar interpretation can be placed on many of the actions that they see others engaged in.

Three-month-old infants do not show the type of goal encoding that is evident among older infants. However, infants of this age are quite poor at reaching out to grasp

an object themselves. If first-person experience is a vital ingredient in the interpretation of others’ actions, this early lack of goal encoding is just what we might expect. Sommerville, Woodward, and Needham (2005) examined the potential role of first-person experience. When 3-month-old infants were fitted out with Velcro mittens that enabled them to grasp objects more successfully, they were subsequently able to encode the goal structure of reaching and grasping actions. So, should we conclude that infants are attributing goals on the basis of their own experience of goal-directed actions with the Velcro mittens? Possibly, but not necessarily. When the infants wore the mittens, they had the experience of being an agent. However, they could also watch—spectatorlike—as they executed such successful reaches. Arguably, the psychological experience of being an agent is critical, but it is also possible that sustained visual monitoring of reaching is sufficient to teach infants to encode action in terms of its goals.

These various findings demonstrate that the simple act of reaching can serve as an informative vehicle for figuring out how infants encode goal-directed action—and on what basis they do so. Nevertheless, a focus on such simple, and discrete, actions does not do full justice to the interpretive problems facing the infant. Consider the 12-month-old seated in a highchair. He watches as his mother goes to the refrigerator, opens the door, removes a carton of juice, pours juice into a cup, and hands him the cup. As Lashley pointed out more than 50 years ago (Lashley, 1951), such actions can scarcely be produced as a set of moment-by-moment responses to a serially ordered set of stimuli in the environment. Rather, they depend on some internal organization enabling the agent to control his or her own behavior. Miller, Galanter, and Pribram (1960) argued that the production of action is best construed as a problem of hierarchical organization, in which subordinate goal-oriented sequences are organized into a larger, overall sequence. Because it has been difficult for psychologists to understand the production of a planned sequence of actions, we might assume that infants have virtually no understanding of such a sequence. Yet, in contrast to Lashley and his contemporaries, there is no sign that young infants initially approach the problem with any predilection for stimulus-response explanations. Arguably, some form of hierarchical, goal-based analysis comes naturally to them.

In a pioneering effort to understand whether and how infants parse the stream of action, Baldwin, Baird, Say-

lor, and Clark (2001) showed 10- to 11-month-old infants a video of an adult engaging in an everyday action sequence. For example, in one video a woman notices a towel on the floor, reaches for the towel and picks it up, then moves toward a towel rack and places the towel on the rack. After being familiarized with this sequence, infants were given two test sequences. In the *completing* video, a still-frame pause was inserted at the point where the woman had just grasped the towel. In the *interrupting* video, by contrast, a still-frame was inserted as the woman reached down to pick up the towel. Infants spent longer looking at the interrupting video than the completing video. Baldwin et al. (2001) plausibly interpret this differential reaction as evidence that infants recognize that within a normally continuous action sequence there are subunits. Hence, a pause inserted between two identifiable subunits is less disconcerting than a pause inserted in a subunit. As the authors acknowledge, however, it is not clear how far infants' parsing into subunits is guided by a "top-down" appreciation of the subgoals that are completed in a larger hierarchy (e.g., in the case just described, an appreciation that the goal of grasping the towel has been completed) or by a "bottom-up" processing of cues that are correlates of such subdivisions. For example, if infants keep track of the direction in which an agent is moving, they might spot marked changes of direction and parse accordingly. Thus, in the case of the towel retrieval, they might parse a downward reach as one unit and an upward lift as another with little insight into the agent's intended goals.

Such theoretical issues might seem a little arcane but from an infant's point of view, they are likely to be quite practical. Consider a 12-month-old who is watching her father dip a spoon into a bowl of vegetables and then lift the spoon to her mouth. After attentively watching, the infant seeks to imitate—more or less—what he has done. On the top-down reading, she realizes that there are two goal-directed subunits: (1) lowering the spoon in order to fill it with food and (2) transporting this spoonful of food to her mouth. She tries to do the same. On the bottom-up reading, by contrast, she simply notes that the spoon is moved downward and then raised upward. She imitates her father by plunging the spoon into the bowl and lifting it up again. Whether the food is lifted to her mouth—or splattered over the table—is regarded as incidental.

Evidence for top-down processing has emerged from studies by Woodward and Somerville (2000). When 11-month-olds watched an agent produce a single ambigu-

ous single action—touching a box—they (understandably) showed no signs during a test phase of being able to decide whether the reach was aimed at the box itself or the toy inside the box. However, if they had previously seen the agent not simply touch the box lid but go on to extract the toy, they interpreted subsequent reaches to the box lid as directed at the contents of the box and not just at the box itself. By implication, watching the agent first touch the lid and then extract the toy led infants to interpret the action of touching the lid in light of the goal that it was ultimately directed at—recovery of the object. Further evidence of early top-down processing was reported by Sommerville and Woodward (2005). Infants watched an agent pull a cloth to retrieve a distant toy placed on the cloth. Subsequently, when they saw the agent simply pull a cloth they were likely to construe that action as aimed at retrieving the toy. A follow-up study with 10-month-olds revealed that this interpretation was only made by infants who could successfully retrieve objects with a cloth-pulling strategy, again suggesting—in line with the findings on 3-month-olds reported by Sommerville, Woodward, and Needham (2005)—that action production facilitates action interpretation.

Studies of imitation have also provided evidence of top-down processing. Carpenter, Call, and Tomasello (2002) invited 2-year-olds to open a box after watching an adult demonstrate the right technique—namely to pull at a wooden pin at the side of the box which enabled the front of the box to be lifted in a flaplike fashion. Most 2-year-olds failed to open the box after this demonstration. Why? Almost certainly, because when they watched the adult tug at the pin, they had no idea what she was trying to do—after all tugging at a protrusion is not standard operating procedure for getting inside a box. Support for this interpretation came from several other conditions in which children were first made aware of the adult's goal and then copied her much more successfully. For example, in one condition, the adult first tugged at the front of the box, failed to lift it, and only then pulled at the pin to release the door. Similar results, albeit with slightly older children, emerged in a study of imitation by Want and Harris (2001). If 3-year-olds saw an adult try to extract a toy from a tube by first poking a stick into the wrong end of the tube, withdrawing it, and then poking it into the correct end, they were much more likely to select the correct end when it was their turn to retrieve the toy than were children who saw the adult select the correct end straightaway. Again,

it looks as if unsuccessful attempts highlight what an agent is aiming at so that the niceties of a successful attempt can be more easily encoded and reproduced.

In summary, recent evidence shows that infants rapidly come to see actions as goal-directed, and they generally expect such acts to be carried out efficiently. Two year-olds, and arguably even younger children, also recognize that any given action can be embedded in an organized hierarchy; it is aimed at a subgoal, which in turn serves a superordinate goal. Toddlers are not equipped to understand complex, long-term plans such as building a house or a railroad. Nevertheless, it looks as if they have an intuitive grasp of the hierarchical structure of human action from an early age. It is somewhat ironic that this insight emerges so early—albeit at a tacit level. That same insight is regarded as a major turning point in cognitive science (Boden, 2006).

Emotion and Preverbal Dialogue

The understanding of emotion is, arguably, just one part of the child's more general understanding of mental states. Nevertheless, we might expect to find that sensitivity to other people's emotional states is one of the more precocious aspects of early mental state understanding. After all, except on rare occasions, people's beliefs cannot be read from their faces and even their desires are not so legible. Their emotional states, however, come with an expressive signature that might be read even by infants during the 1st year of life.

Darwin's writings on facial expression (Darwin, 1872/1998) have led to a systematic research program endorsing his claim that there is a universal, innate basis to the production of a small set of facial expressions (Ekman, 1973). However, Darwin made a nativist claim about the interpretation of facial expressions as well as their production. His argument was based on probabilistic reasoning and on analogy with other species: "Do our children acquire their knowledge of expression solely by experience through the power of association and reason? As most of the movements of expression must have been gradually acquired, afterwards becoming instinctive, there seems to be some degree of *a priori* probability that their recognition would likewise have become instinctive" (Darwin, 1872/1998, p. 353). With this hypothesis in mind, Darwin studied the emotional development of his own son and concluded that some degree of unlearned recognition was probably present. Thus, when his son's nurse deliberately pretended to

cry, his son—then aged 6 months—assumed "a melancholy expression." Given the infant's lack of experience of other people crying, Darwin reasoned that "an innate feeling must have told him that the pretended crying of his nurse expressed grief: and this, through the instinct of sympathy, excited grief in him" (Darwin, 1872/1998, p. 354).

Darwin's bold but plausible assertion of instinctive recognition has proved difficult to either verify or refute. What has emerged in the past 20 years is a small number of studies showing that young infants do respond appropriately to adults' facial expressions. For example, Termine and Izard (1988) observed a differentiated reaction by 9-month-olds to their mothers' displays of happiness versus sadness. Indeed, Haviland and Lelwica (1987) observed that babies of 10 weeks responded differently and for the most part appropriately to their mothers' displays of happiness, sadness, and anger. Yet, even by the age of 10 weeks, it could be argued that infants have had some opportunities for learning.

A related but different research theme concerns the way in which infants come to expect their caregivers to be responsive and expressive. If infants are confronted by someone who deliberately remains still and unresponsive, they become upset (for a review of this so-called still-face paradigm, see Muir & Hains, 1993). By the age of 2 to 3 months, infants show considerable sensitivity to the contingent relationship between their own expressive movements and those of an adult partner. Although they interact normally with a live image of their mother via closed-circuit television they show signs of distress if they are shown a video rather than a live image of their mother (Murray & Trevarthen, 1985; Nadel, Carchon, Kervella, Marcelli, & Réservat-Plantey, 1999). Indeed, by 3 months, infants are sensitive to the exact timing of the relationship between their own expressive movements and those of an adult partner—if a very subtle delay of 1 second is introduced into the live relay of their caretaker's image, they become less attentive (Henning & Striano, 2004; Striano, Henning, & Stahl, 2005).

There is also credible evidence that infants do not simply acquire a global expectation—that caregivers are likely to be contingently responsive. Rather, they appear to acquire a more specific expectation that is guided by the expressive style of their primary caregiver. Thus, 3- to 6-month-old infants of mothers suffering from depression are likely to adopt a less ex-

pressive style than infants with nondepressed mothers. Indeed, there is some evidence that infants of depressed mothers "overgeneralize" this flat, interactive style, adopting it even when interacting with a stranger (Field, 1984; Field, Healy, Goldstein, 1988).

Such sensitivity to the expressive style of a caretaker should not, however, be surprising. Attachment theorists have long argued that infants are sensitive to the responsiveness and availability of a caregiver. By the age of 12 months, characteristic modes of interacting with a caretaker can be identified and these characteristic modes tend to remain stable. The research on early dyadic interaction simply alerts us to the possibility that these distinctive modes can probably be discerned well before the infant is 12 months of age and well before the infant is capable of the kind of active locomotion and distal contact that is generally studied by attachment theorists in the context of the Strange Situation.

In summary, even if it is still not clear whether Darwin was right to postulate an innate, interpretive mechanism for decoding the expression of emotion, there is evidence that infants rapidly come to distinguish positive from negative emotional expressions and respond appropriately to each. They also come to expect a caregiver to be expressive and indeed to respond in a very brief time frame to their own expressive movements. Finally, infants appear to discern the emotional styles of their caregivers and to attune their own expressive behaviors to that style.

Gaze Following and Social Referencing

At around 9 months, infants start to follow and direct the attention of a caregiver. As noted earlier, the phenomenon was first identified by Scaife and Bruner (1975). They found that when an adult turned to look either to the right or to the left, there was an increasing tendency with age for the infant to turn to look in the same direction (66% at 8 to 10 months, 100% at 11 to 14 months). Since this pioneering investigation, a variety of studies have described and analyzed the basic phenomenon in some detail. By 15 months, babies are able to differentiate not only one side from another but also the adult's direction of gaze within a side (Morissette, Ricard, & Decarie, 1995). Carpenter, Nagell, and Tomasello (1998) studied infants' ability to both follow and direct attention. In the study of following, an adult called the baby by name, then looked toward an object on the left or right with an excited vocalization, and

then looked back and forth from object to baby. In a related condition, the adult added a pointing gesture to these various indicative behaviors. Gaze following increased in frequency between 9 and 13 months; point following also increased during the same age period and was generally somewhat more frequent.

In the study of directing, a stuffed animal was made to dance in midair or a puppet emerged from a partition. Adults pretended not to notice. A pointing gesture was credited if the child stretched toward the object and alternated gaze between object and adult's face. Give/show was credited if the infant gave or showed the object, gazed between the object and the adult's face, and vocalized as if to comment on the object. Both pointing and give/show increased markedly between 9 and 13 months with give/show being more frequent throughout. Taken together, these findings underscore the infant's emerging ability to engage in a triadic relationship comprising the self, another person, and an object of (potentially) mutual attention.

Infants capitalize on such triadic relationships in the context of what has come to be called social referencing. They receive emotional information from a caregiver and regulate their behavior toward a given object in the light of that information. An illustrative—and influential—study was reported by Sorce, Emde, Campos, and Klinnert (1985). They looked at the influence of the mother's emotional expression on whether babies would crawl over what they took to be a sharp drop (the so-called visual cliff). When the cliff was of intermediate height, such that babies hesitated to cross, most of them did cross if their mother smiled, whereas none of them did so if she produced a fearful facial expression.

Since identification of the basic phenomenon of social referencing, subsequent research has sought to analyze the exact mechanism involved. Two interpretations have seemed plausible. The caregiver's facial expression might serve as a mood-changing signal that shifts the baby toward either confident exploration or wariness. On this argument, the baby need not draw any conclusions about what object or situation has provoked the mother's emotion; rather, the baby simply resonates to the mother's expressive signals—and ends up acting appropriately—proceeding forward if she smiles but coming to a halt or retreating if she looks fearful. The second interpretation builds on the gaze-following competence just described. Suppose that the infant notices not only the caregiver's expression but also notes the object that she is attending to. The infant might treat the

expression as a predicate or comment that refers to the object in question. On this account, the mother's emotional signal would not produce a broad shift toward either exploration or wariness; rather, it would produce a narrow shift in the infant's emotional stance toward a particular object.

The study reported by Sorce et al. (1985) is open to either interpretation. Various follow-up studies, however, allow us to distinguish between them. These studies indicate that although mood effects cannot be completely ruled out, infants of 12 months and upward are indeed sensitive to the referential specificity of the emotional signal (Hornik, Risenhoover, & Gunnar, 1987; Mumme, Won, & Fernald, 1994; Repacholi, 1998). For example, in a study by Repacholi (1998) infants of 14 and 18 months watched as an adult, by means of her gaze direction and actions, expressed pleasure at the (hidden) contents of one box and disgust at the (hidden) contents of another. Although infants touched both boxes, they preferred to search for the pleasurable rather than the disgusting object. Moreover, infants remained loath to retrieve the disgusting object throughout the trial period of 45 seconds. Thus, infants appropriately interpreted the adult's emotional signals as commentaries on the contents of the boxes and appropriately distinguished between the signals directed at each. This pattern of findings indicates referential specificity rather than a more global mood switch. Additional support for the claim that infants can understand referential specificity has emerged using techniques other than social referencing. Phillips, Wellman, and Spelke (2002) found that 12-month-olds, but not 8-month-olds, expected that an actor was likely to grasp the object that she had looked at with positive affect and were surprised when she did not.

Finally, it is worth underlining the limits on social referencing. As Baldwin and Moses (1996) have noted in a thoughtful commentary, it is tempting to conclude that infants *seek out* information from others. For example, when the infant approaches the visual cliff, comes to a halt, and looks up at his or her mother, it is tempting to assume that the infant is seeking information and guidance from the caregiver in the face of uncertainty. However, an equally plausible, indeed more plausible, interpretation is that infants are displaying an attachment-based strategy rather than an epistemic one. More specifically, infants who feel uncertain or apprehensive may check back to their mother in anticipation of reassurance. They are not looking to their mother in anticipa-

tion of information. Thus, it is reasonable to suppose that infants seek reassurance and are then offered guidance, including referentially specific guidance; we have no need to presume that infants are tacitly posing a question of the mother regarding the situation that has provoked their uncertainty. That said, it is obviously reasonable to raise the possibility that infants at some point—either in the second year or later—do come to regard other people as sources of information—sources who can identify and name unknown objects, demonstrate how to use an unfamiliar tool, or bring a means-end sequence to fruition. I return to the question of when and how infants come to regard other people as potential informants in a later section.

Comforting and Helping

Among chimpanzees, acts of comforting and consolation are readily identifiable—especially in the aftermath of a conflict. De Waal and Aureli (1996) recorded affiliative contacts (kissing, embracing, grooming, gentle touching, and mounting) directed by bystanders toward victims of aggression. The frequency of such contacts was compared after severe aggression, mild aggression, and during randomly chosen baseline periods. In the minutes immediately following a bout of aggression, victims were much more likely to receive affiliative contact than during a baseline period, especially if the aggression had been severe rather than mild. By contrast, approaches to the aggressor were much less frequent. Were bystanders making a moral judgment and siding with victims? Conceivably, but more likely, they were simply sensitive to the higher level of distress expressed by the victims. Such selective comforting is not found throughout the primate order. For example, de Waal and Aureli (1996) found no postconflict elevation of contact among long-tailed macaques. Finally, it is worth noting that acts of consolation do not appear to be triggered by overt distress in the animal who is offering consolation. Visual records of such acts indicate that the victim may well be screaming but the consoler is not. By implication, consolers appear to grasp the distress displayed by a victim, not via some form of low-level contagion, but via some form of sympathy.

Do we find a similar set of consolation behaviors among human infants? In my view, the evidence points to a considerable continuity. To anticipate, human infants offer consolation, they do so in response to overt distress, and they do so based on sympathy rather than

low-level contagion. Consider the following episode reported by Wolf (1982):

When we came home this afternoon, I slipped and fell and came down really hard whacking my nose. I was in real pain and sat down on the rocker in J.'s room, holding and rubbing my nose. J. (14 months) was very sympathetic. He acted for me the way I do when he hurts himself. He hugged and patted me and even offered me his blanket that he uses when he's hurt or tired.

Or consider the following reported by Hoffman (1976, pp. 129–130):

Michael, 15 months, is struggling with his friend Paul over a toy. Paul starts to cry. Michael appears concerned and lets go of the toy so Paul has it. But Paul continues to cry. Michael pauses, then gives his own teddy bear to Paul; Paul continues crying. Michael pauses again, runs to the next room, gets Paul's security blanket, and gives it to him. Paul stops crying.

Finally, here is the following favorite of mine, reported by Dunn and Kendrick (1982, pp. 115–116):

Fifteen-month-old Len, was a stocky boy with a fine round tummy, and he played at this time a particular game with his parents that always made them laugh. His game was to come toward them, walking in an odd way, pulling up his T-shirt and showing his big stomach. One day his elder brother fell off the climbing frame in the garden and cried vigorously. Len watched solemnly. Then he approached his brother, pulling up his T-shirt and showing his tummy, vocalizing, and looking at his brother.

These apparent acts of consolation are difficult to explain as mere contagion. The child offers consolation but does not cry. The child makes obvious efforts to reduce the distress of the other person (e.g., via hugs, pats, comfort objects, and parlor tricks). Such efforts do not appear to be simply aimed at minimizing aversive expressions of distress—after all, the child will sometimes leave the scene (thereby escaping the distress altogether) but nevertheless comes back (e.g., with the victim's security blanket).

Zahn-Waxler, Radke-Yarrow, Wagner, and Chapman (1992) carried out a longitudinal study of such comforting behaviors in the 2nd year of life. They recorded naturally occurring instances of physical comforting (e.g., hugs, pats, or kisses), verbal comforting (e.g., "You be okay"), verbal advice (e.g., "Be careful"), helping (e.g.,

putting on a bandage or giving a bottle) and miscellaneous interventions (e.g., getting mother to retrieve a rattle for a baby, sharing food, attempting distraction, and trying to prevent further injury). Up to the age of 15 months, acts of comforting were mostly physical, but beyond 18 months, the entire repertoire was displayed across the sample. The investigators also looked at the frequency with which distress elicited concerned behavior and observed a marked increment from the beginning of the 2nd year, when only about 10% of distress episodes elicited concern, to the end of the 2nd year, when about 50% of distress episodes did so. Moreover, this increment was stable across various contexts—it was found for naturally occurring episodes of distress, for simulated episodes (e.g., where the mother deliberately feigned hurt and distress), and for distress that children had caused themselves (e.g., by taking another child's toy).

Recall that the chimpanzee data suggest that the act of comforting is not necessarily accompanied by any obvious distress on the part of the comforter. Much the same can be said of the human toddler. Zahn-Waxler et al. (1992) compared how often toddlers responded to another's distress by getting distressed themselves and by offering comfort. The frequency of both types of behavior was comparably low at the beginning of the 2nd year; toward the end, however, comforting behaviors were much more common than distress reactions. In other words, older toddlers frequently offer comfort in the absence of any overt signs of distress. This is especially true when toddlers have not been the cause of the other person's distress and are innocent bystanders.

In summary, concern for other people's distress appears to emerge in the 2nd year of life. It is displayed whether or not children have caused the distress, and when they show concern for another's distress, children are not necessarily distressed themselves. This emerging pattern of concern strongly suggests that toddlers appreciate the emotional state of the other person, and feel concern, even if they are not yet engaging in any sophisticated form of mind reading (Nichols, 2001).

Looking forward to developments in the 3rd and 4th year of life, it seems highly likely that this capacity for concern feeds into young children's moral judgment. A solid body of evidence indicates that 3- and 4-year-olds regard various moral breaches (e.g., hitting another child or taking another child's toy) as more serious than conventional breaches (e.g., putting toys away in the wrong place; Smetana, 1981). How do they come to that

conclusion? One possibility is that they are guided by adult feedback. For example, Hetherington and Parke (1999, p. 635) emphasize that mothers and other family members respond to social-conventional violations by focusing on the disorder that the act created ("Look at the mess you made!"), whereas they respond to moral transgressions by focusing on the consequences of the acts for others' rights and welfare or by making pleas for perspective-taking requests ("Think about how you would feel if you were hit"). However, to the extent that mothers effectively respond to both types of violation—conventional as well as moral—it is far from clear that they thereby alert children to their differential gravity. A more probable explanation can be traced back to the capacity for concern at another's distress that has just been described as emerging in the 2nd year of life. It is plausible to suppose that children will soon observe that certain types of misdemeanor, such as hitting another child or taking another child's toy, cause distress, whereas other types of misdemeanor are met with indifference—at least by other children. For example, other children are likely to be indifferent if someone puts toys away in the wrong place. By implication, peers are likely to be excellent tutors, or, more precisely, the distress reactions of peers are likely to be an excellent cue to the serious nature of moral breaches as compared to the less serious nature of conventional breaches.

Consistent with this argument, preschoolers who are told about an unfamiliar action (e.g., "mibbing" another child) in a story context will conclude that it is akin to a moral breach if they are also told that the action in question causes distress (Smetana, 1985). Finally, it is worth dwelling on one further striking result reported by Smetana and her colleagues (Smetana, Kelly, & Twentyman, 1984): Preschool children with abusive and neglecting parents show no obvious difficulty in distinguishing between moral and conventional rules. This result is paradoxical if one assumes that parental feedback is a key element in making the distinction—as implied by Hetherington and Parke (1999). On the other hand, the result is quite plausible if one focuses on the role of peers and specifically of peer distress. The children were all attending preschools. Hence, irrespective of their home background they had an opportunity to discover how peers respond with distress to moral breaches but remain unmoved by conventional violations.

In conclusion, there is a fascinating continuity between the sensitivity that toddlers display to distress

and hurt in other people and the relatively sophisticated moral judgments that they come to make at the age of 3 and 4 years. However, this is not to say that preschool children are constantly behaving like good Samaritans and always do what is right. We soon take a look at the dark side of early social cognition. First, however, it is useful to examine one further prosocial behavior: helping.

Offering Help and Cooperation

Although helping is obviously a benevolent form of behavior there are reasonable grounds for expecting that it might display a different ontogenetic and phylogenetic pattern when compared to comforting. As I emphasized earlier, comforting—whether among human toddlers or among chimpanzees—appears to be triggered by evident distress on the part of the comforted. The trigger for an act of helping is obviously different, more variable, and probably more complex. Recall the earlier discussion of toddlers' ability to analyze an agent's goal-directed action. Toddlers imitate an action sequence more effectively if the goal of that action sequence is made salient to them (Carpenter et al., 2002; Want & Harris, 2001). By implication, at least in certain circumstances, toddlers are well able to analyze the goal not only of a discrete movement or displacement but also of an action sequence with subgoals. When and how do toddlers start to offer assistance to someone whose action sequence goes awry or needs a helping hand?

Rheingold (1982) carried out a pioneering investigation into toddlers' inclination to help an adult engaged in various household tasks. Children aged 18, 24, and 30 months were observed in a domestic setting as an adult (the child's mother, father, or an unfamiliar adult) carried out various household chores such as laying the table or gathering up books. Even 18-month-olds offered help for more than half of the tasks. By 30 months, this figure rose to almost 90% of the tasks. Thus, toddlers were remarkably willing to offer assistance. Indeed, as Rheingold (1982) comments the children helped with alacrity: "They carried out their efforts with quick and energetic movements, excited vocal intonations, animated facial expressions, and with delight in the finished task" (p. 119).

How should this cooperative attitude be construed? On one interpretation, children may have been engaged in relatively low-level, albeit enjoyable, imitation of the adult's actions. Seeing the adult carry a book and stack

it on the table, perhaps they did likewise. An alternative, richer interpretation is that children figured out the adult's overall goal and saw themselves as contributing to that goal. Various pieces of evidence favor the latter interpretation. Children sometimes started to provide help when the adult announced their intention but had not yet begun to act. They also stated their intention to perform a task, appeared to know when the task was complete, and supplied elements that were neither suggested nor modeled by the adults.

Dunn and Munn (1986) provide complementary data on children's willingness to help and cooperate with a sibling rather than an adult. They found that on average 18-month-olds cooperate with an older sibling 6 to 7 times each hour and by the age of 24 months that figure climbs to 10 to 11 times per hour. Not surprisingly, some of the collaborative acts are carried out in the context of pretend play but the majority are not. Moreover, as observed in the context of adult-child cooperation, collaborative acts cannot be reduced to imitation: Children take on complementary activities in pursuit of a common goal.

The capacity for such complementary activity was highlighted by Brownell and Carriger (1990) in a study of peer cooperation. Children ranging from 12 to 33 months were given various novel, practical problems that depended on their adoption of complementary roles for their solution. For example, to retrieve some toy animals, one child needed to stand away from and opposite to another child who rotated a handle that transported the animals in a cup toward the first child. Cooperation at 18 months was rare and possibly accidental. By 24 months, however, cooperation was generally rapid and effective.

Summarizing across these studies, it is clear that toddlers are disposed to cooperate. They spontaneously offer help to a parent, an unfamiliar adult, a sibling, or a peer. Sometimes they provide help to someone whose plan of action is already underway or established—they temporarily adopt the other's goal as their own. Sometimes, they cooperate in a more symmetrical fashion as when they adopt complementary roles to further a game of pretend or a practical activity. In either case, it is apparent that children can adjust their goals to those of another person. It is tempting to take such cooperative activity for granted given its familiarity and spontaneity. However, it is worth underlining the possibility that it is a uniquely human trait. Indeed, Tomasello, Carpenter, Call, Behne, and Moll (2005) conclude that there are

no published experimental studies showing that chimpanzees collaborate by playing different and complementary roles in an activity. If they are right, their conclusion underlines the importance of distinguishing between prosocial acts of comforting and prosocial acts of cooperation. Whereas chimpanzees may be capable of the former, the latter looks as if it is a powerful but unique human disposition.

Hurting and Teasing

In an earlier section, we saw that young children recognize others' distress and that in the 2nd year of life they acquire a repertoire of strategies for alleviating that distress. The ability to recognize distress and some of its causal elicitors can be put to other uses. Children can deliberately seek to tease, upset, frustrate, and provoke. As one might expect, given the increased frequency of comforting in the 2nd year, there is a parallel increase in acts of teasing (Dunn & Munn, 1985). By the middle of the 2nd year, many incidents between siblings involve the removal of the sibling's comfort object or an attack on some favorite possession. By 24 months, however—again in line with the pattern for comforting—the child's repertoire becomes more elaborate. For example, one child teased her older sister by pretending to be her imaginary companion.

Sibling relationships are often characterized by an admixture of teasing and comforting (Dunn, Kendrick, & MacNamee, 1981). Moreover, it is often the older sibling who is the prime instigator of hostile interactions (Abramovitch, Corter, & Lando, 1979; Abramovitch, Corter, & Pepler, 1980; Dunn & Kendrick, 1982). Despite these overall tendencies, investigators also note huge variation across sibling pairs in the proportion of mutually hostile and mutually friendly encounters. For example, in some sibling pairs, there are virtually no mutually hostile interactions; in others, they occur about half the time.

Some children display a pattern of social interaction that seems to lie outside the range of behaviors observed in the hurly-burly of everyday family life. When children who have been subjected to physical abuse by their parents are observed in a preschool setting, they often display a bias toward hostile as opposed to cooperative interaction. More specifically, as compared to children from the same social class background but with no known history of abuse, abused children are likely to display more aggression and less helping and sharing

(Hoffman-Plotkin & Twentyman, 1984; Trickett & Kuczynski, 1986). The response of abused children to the distress of other children is especially noteworthy because the pattern of concern described earlier appears to be disrupted. When abused toddlers were confronted by another's distress in a day-care setting, they never responded with obvious concern. At most, they patted or attempted to quiet the crying child. Their more frequent response was to respond in a negative fashion, with hostile or fearful gestures or sometimes with direct physical attacks on the crying child (George & Main, 1979). A similar pattern of results emerged among abused preschoolers aged 3 to 5 years even though they had had the opportunity to interact with nonabusive caregivers and peers for 1 or 2 years in their day-care setting (Klimes-Dougan & Kistner, 1990).

These observations underline the fact that the gestures of comfort and concern described in the previous section, and identified as part of our primate heritage, are not irreversibly wired into the young child's social cognitive repertoire. Whatever sensitivity infants and toddlers display to another's distress, it is likely that active and benevolent concern for that distress is a relational mode that abused children experience with their abusive parents much less often than nonabused children.

MENTAL STATE UNDERSTANDING IN EARLY CHILDHOOD

When children move beyond infancy and begin to talk, it becomes somewhat easier to study the development of social cognition. We can analyze their spontaneous remarks and probe their understanding with a rich set of story formats. This shift in technique is especially evident in the study of children's understanding of goals and desires.

Goals, Desires, and Intentions

Recall that Premack and Woodruff (1978) found that their chimpanzee subject was able to figure out what the actor in the film clip was aiming to do. We have also seen that infants are able to diagnose the goal that a human action is directed toward. Indeed, as discussed in the section on helping, toddlers will sometimes offer help or comfort by fetching an object that someone is

trying to get or needs. Should we not assume that chimpanzees as well as human infants and toddlers realize that other people have wants? A somewhat leaner interpretation is plausible. Chimpanzees or young humans might be good at diagnosing the direction or goal that an ongoing action, or even a sequence of actions, is aimed at—its external, perceptible target—without an understanding of the mental state of desire that initiates and guides such actions or states.

Under what circumstances might we be prepared to attribute a more mentalistic concept of desire to young children? My guess is that there is no straightforward, acid test. However, what does emerge from approximately 18 months upward is the competence to talk about desires and to articulate various contrasts using the key concept of desire. Bartsch and Wellman (1995) analyzed the spontaneous utterances of a small group of children regularly observed and recorded between the ages of 18 months and 5 years. Bartsch and Wellman searched through approximately 200,000 utterances and identified about 12,000 that included mental state terms that they divided into two broad categories—thought and belief terms such as *think* and *know* and desire terms such as *want*, *wish*, and *hope*. They found that children begin to use desire terms from about 18 to 24 months. In addition, when children are between 24 and 30 months, they begin to produce various contrastive utterances. For example, they begin to contrast what they want with what they actually get or are about to get (e.g., "I want a turtle, but I can't have one"). They also contrast what one person wants with what another person wants. Bartsch and Wellman (1995) plausibly conclude that children's references to "wants" are not references to actions-tending-toward-goals. Rather, they are references to internal states that are different from, albeit linked to, the actions that they motivate and the goals that they are directed toward.

The available data from children's spontaneous utterances also underline the fact that the concept of desire plays a central, organizing role in children's emerging understanding of mental states. First, children refer to desires earlier, and more often, than they refer to cognitive states such as thinking and knowing. Second, they do so despite the fact that their parents talk about cognitive states as often as they talk about desires. Third, the early discussion of desires is not confined to English-speaking children. It appears also in studies of Mandarin- and Cantonese-speaking children (Tardif & Wellman, 2000). Finally, children with

autism—who show various problems in the understanding of belief—are relatively competent at talking about desires (Tager-Flusberg, 1993; Tan & Harris, 1991).

Experimental studies support the idea that 2- and 3-year-olds understand the way that desires are linked to actions and indeed to various simple emotions. For example, they understand that people will search for what they want and that if they obtain it, they will feel happy and that if they do not obtain it, they will persist in searching and feel sad or angry (Hadwin & Perner, 1991; Stein & Levine, 1987; Wellman & Woolley, 1990). Moreover, when invited to account for a story character's actions 3-year-olds also offer explanations couched in terms of desires (Bartsch & Wellman, 1989).

How does children's early understanding of desire connect with their understanding of intention? Recall that a long Piagetian tradition examined children's understanding of intentions in the context of moral judgment (Piaget, 1932). The standard conclusion was that young children are relatively slow to acknowledge the relevance of intention to moral judgment, focusing instead on the gravity of the consequences as the primary index of the seriousness of the misdemeanor. More recent research, especially in the context of theory of mind, has sought to assess children's understanding of intention in its own right. The link with moral judgment and moral responsibility has not been forgotten, but it is no longer so evidently center stage.

One important finding is that, contrary to the impression that might be gained from the older Piagetian literature, preschool children are able to distinguish between acts that are deliberate as compared to acts that are intentional. More specifically, when 3-year-olds engage in actions that go wrong; for example, if they inadvertently mispronounce a word in trying to repeat a tongue twister, they appropriately judge that the actions were not done "on purpose" (Shultz, 1980). However, it is also likely that 3-year-olds get by with a relatively simple, desire-based notion of unintended action, judging outcomes that are desirable as intended and outcomes that are undesirable as unintended (Astington, 1991). Thus, it is important to probe the extent to which young children realize that desires and intentions do not always coincide. For example, I can intend to do many chores that I do not want to do, and I can want to visit far-off places that I have no current intention of visiting.

To explore children's ability to make this distinction, Feinfeld, Lee, Flavell, Green, and Flavell (1999) presented 3- and 4-year-olds with stories in which the pro-

tagonist's desire and intention were different. For example, in one story, the protagonist wants to go to one place (e.g., to the mountain) but, on mother's instructions, intends to go to a different place (e.g., to the football field). However, because of a mistake by the bus driver, the protagonist ends up where he wanted to go and not where he intended. Four-year-olds performed quite systematically—they realized that the protagonist was trying and expecting to get to one place (e.g., the football field in the example just given) but wanted to go to a different place (e.g., the mountain). By contrast, 3-year-olds were much less systematic. Although they were generally accurate in identifying the protagonist's preference, they were much less accurate in indicating what he was trying and expecting to do. Moreover, even when they did identify the protagonist's intention correctly, they often added that the protagonist also intended to reach the other, more desirable goal. As Feinfeld et al. (1999) point out, one conceivable interpretation of these findings is that 3-year-olds have some difficulty in acknowledging the role that thinking and believing plays in the formulation of an intention. More specifically, intentions are generally formed with the belief—sometimes false—that one's plan can be executed (Moses, 1993). In the next section, we look in detail at children's understanding of belief.

Beliefs

A great deal of research effort has been devoted to documenting and probing children's developing understanding of belief, and notably false belief. Indeed, the false-belief task has been the favored task for the refinement and testing of various competing accounts of the child's theory of mind. For that reason, I use this section to serve a double purpose—to review the extent to which there is an emerging empirical consensus regarding the major landmarks in the child's understanding of belief, and to provide an initial evaluation of those competing theories.

Three main tasks have played a role in the effort to assess children's understanding of belief. First, in the unexpected displacement task, a protagonist, having put an object in one place, is unaware of its transfer to a new place during a brief absence, and on his or her return, expects it to be where it was originally put. Children are asked to say where the protagonist will look for the object—in the new or the old place (Wimmer & Perner, 1983). Second, in the deceptive container task, children

discover that a familiar container (e.g., a Band-Aid box) contains some unexpected content (e.g., stamps), and are asked—in the face of this unexpected discovery—to indicate (a) what they originally thought to be inside the container and (b) what someone looking at it for the first time would think is inside it (Gopnik & Astington, 1988; Perner, Leekam, & Wimmer, 1987). Finally, in the appearance-reality task, children are shown a misleading object—for example, a sponge shaped and painted to look like a rock; they examine it, discover its true identity, and are then asked both about its real and apparent identity (Flavell, 1986). As will be clear from this brief description, all three tasks turn on the fact that a protagonist, lacking full perceptual access to the object or situation in question, comes to, or might come to, an erroneous conclusion. Children are asked to diagnose the protagonist's erroneous conclusion, despite their current knowledge of the true facts.

Wellman, Cross, and Watson (2001) recently carried out a helpful meta-analysis of a large number of different studies covering all three types of task. They asked how performance changed with age and how it varied as a function of various potentially influential factors such as whether the child was actively involved in the displacement or switch or just a spectator. They obtained support for a very robust age-change between 3 and 5 years. At 30 months, children are more than 80% incorrect; at 44 months, they are 50% correct; and by 56 months, they are approximately 75% correct. Thus, children's performance shifts from being systematically below chance (at 41 months and younger) to systematically above chance (at 48 months and older). Moreover, the age change is quite stable across various conditions of testing. It is unaffected by whether children are questioned about what a protagonist thinks or asked to predict the protagonist's belief-based behavior. It emerges whether the target person is a story character, a puppet, or a real adult. It emerges whether the protagonist holds a false belief about an object's location or its identity. Finally, it is unaffected by whether children are asked about their own false belief or that of another person.

Wellman et al. (2001) did find that certain factors help or hinder accurate performance. For example, an explicit indication that the protagonist is being tricked or deceived, active participation by the child in performing the critical object switch or change of location, or an explicit cue (verbal or pictorial) regarding the protagonist's belief are all factors that help children to diagnose belief more accurately. Finally, the elimination

of the target object (e.g., in the unexpected displacement task, the removal of the desired chocolate from the old location together with its consumption—as opposed to its transfer to a new location) helps children diagnose the protagonist's search accurately. Nevertheless, as Wellman and his colleagues underline, each of these factors tends to help (or hinder) younger children and older children alike. There was no indication, for example, that younger children solve the false-belief task when it involves deception, whereas older children solve it irrespective of whether deception is involved. Rather, deception was a helpful factor across the entire age range. Similarly, the presence of the target object proved a hindrance across the entire age range. Thus, none of these factors do much to alter the observed gradient of improvement with age. In particular, there is no factor—or set of factors—that serves to unmask the competence of 3-year-olds and enables them to perform like 5-year-olds—or even to perform at above chance levels.

Armed with these empirical conclusions, Wellman et al. (2001) spell out plausible implications for theory. First, they note that the consistent age change, together with the failure to uncover a set of conditions under which 3-year-olds perform systematically above chance, undermines a family of theories implying that children have an innate, or early, capacity to understand false belief (Fodor, 1992; German & Leslie, 2000; Leslie, 2000). Such accounts have generally implied that such early understanding can be unmasked provided the child is tested under optimal conditions, notably conditions that minimize or eliminate various information-processing constraints. Yet, the meta-analysis failed to identify such conditions.

Second, they argue that even if room is made for the impact of information-processing constraints—particularly those identified by various executive function accounts (Carlson & Moses, 2001)—the fact that a consistent age change appears whether such constraints are maximized or minimized strongly suggests that some kind of conceptual change takes place between 3 and 5 years. The improvement that they consistently note cannot be exclusively attributed to the lifting of information-processing restrictions but probably implies the attainment of some type of conceptual insight.

Let us pause to consider each of these two claims in turn. Is it—as Wellman et al. (2001) conclude—time to abandon a nativist, modular stance toward the understanding of belief in the wake of overwhelming empirical evidence for conceptual change? As Moses (2001)

points out in a level-headed commentary, such a move might be a bit premature. First, as Wellman et al. (2001) concede, there are no studies of 3-year-olds in which all of the four optimizing conditions that they themselves identify have been brought together. It is feasible that such an optimal conjunction would lift the performance of 3-year-olds above chance. Second, it is important to keep in mind the fact that research on false-belief understanding has—need it be said?—focused on the understanding of false belief. Yet, there are many cases where we are called on to understand someone's belief without knowing whether the belief is true or false because an accurate reading of reality is simply unavailable. Beliefs about the future fall into this category, as do many beliefs about the past. As an experimental illustration, consider a fascinating study conducted by Wellman and Bartsch (1988). They asked children to predict where the protagonist would look for his or her lost dog given that (a) the protagonist thought it was in place X; (b) the child participating in the study thought it was in place Y; and (c) the actual location of the lost dog was yet to be determined. Three-year-olds did very well in this task—much better than in a variety of closely matched conditions in which the nature of reality was not indeterminate. Thus, 3-year-olds predicted that the protagonist would be guided by his belief. Arguably, these findings need further confirmation. Can we be certain, for example, that 3-year-olds are not simply eliding the distinction between where the protagonist wants the dog to be—and where the protagonist thinks the dog is? Future studies might be aimed at setting up a clearer contrast between the protagonist's desire (or hope) and the protagonist's belief (or expectation). For example, the protagonist might hope that his dog has run off toward the park rather than the (dangerous) highway but nonetheless believe that the dog has actually gone toward the highway rather than the park. Still, the findings of Wellman and Bartsch (1988) definitely point to a way of escaping from the vast edifice of false-belief studies toward the less explored territory of what might be called indeterminate beliefs. Such an escape might ultimately offer succor to the nativists by showing that 3-year-olds do possess a useful, working notion of belief, even if they undeniably have trouble in understanding false beliefs.

What of the second conclusion reached by Wellman et al. (2001) that a conceptual change takes place between 3 and 5 years? This is a reasonable conclusion at this point in the research program. Still, it is worth un-

derlining three important caveats. The first caveat is that even if a conceptual change is involved, the meta-analysis is not much help in deciding among various different candidates for the nature of that conceptual change, as Wellman and his colleagues concede. Thus, each of the following three candidates remains viable. First, it could be argued that what is emerging is a concept of belief—no more and no less. This is essentially the position adopted by Wellman himself (Bartsch & Wellman, 1995) together with various like-minded colleagues (Gopnik & Wellman, 1994). On this account, the period between 3 and 5 years marks the construction of a second major pillar of our everyday theory of mind. Children below the age of 3 years have a good understanding of desires and by the age of 5 years they have an understanding of desires, beliefs, and their relationship. Second, it could be argued that the emerging concept of belief is actually better seen as an insight into the way in which beliefs are formed on the basis of access to particular sources (Wimmer & Hartl, 1991; Wimmer & Weichbold, 1994). This focus on children's understanding of the sources of belief is plausible because—as noted earlier in describing the three classic tasks used in false-belief research—the protagonist's incomplete perceptual access is critical to his or her false belief. Third, it is feasible to claim that the child's emerging insight into the nature of belief is part of a larger conceptual insight into various representational media, of which the mind is only one example, albeit a prominent one. In setting out this claim, Perner (1991, 1995) underlines the following puzzle—which he takes to be a major conceptual hurdle for the child. Consider an out of-date road map; it shows a forest beside Highway 1. You know that the forest has long disappeared and a large housing estate has been built in its place. Nevertheless, you also appreciate that someone to whom you lend the map might mistakenly drive along Highway 1 expecting to see the forest. You understand, therefore, that the map—despite its misrepresentation of reality—can nonetheless be read as an accurate representation of reality. According to Perner, it is this conflicting function—misrepresenting while being taken to accurately represent—that stymies the 3-year-old in thinking about beliefs—or any medium, be it a map, a photograph, or a signpost that purports to represent reality accurately while not actually doing so.

The second caveat concerning the claim that a conceptual change occurs between 3 and 5 years is that even if any one of the three types of conceptual change

just described were to emerge as the most convincing account, we still need to understand the underlying engine of development. To make this point more explicit, let us suppose that the belief-focused account advocated by Wellman and his colleagues turns out to be the most convincing. This would still leave entirely open the question of how children come to construct such a concept. For example, is it by virtue of their firsthand experience of holding a belief, of acting, thinking, and talking in accord with that belief, and then discovering that the belief can still turn out to be false? Alternatively, is it explicable in terms of the modification of an increasingly untidy and nonpredictive desire-based theory? Or is it by virtue of hearing people's (false) beliefs articulated in language? The meta-analysis gives very few clues to help resolve these questions—although it is worth noting that one factor—the provision of an explicit cue, such as a verbal statement of the protagonist's belief—was one of the factors that boosted performance.

The third and final caveat concerns the future of research on the false-belief task. Consider the problem of conservation. Few, looking back at the various conflicting interpretations of that age change, would claim that we now have a definitive understanding of why or how it takes place. One plausible conclusion from the plethora of inconclusive research is that cross-sectional experimental analysis is just not potent enough to uncover the dynamics of developmental change. Moreover, in the case of conservation, it was far from clear what experiences in the child's everyday environment might promote development. Hence, even when training studies were conducted and were effective, their relevance to conceptual change in everyday life, outside of the laboratory, was unclear. Does this mean that research on false belief will fade away, in much the same way as has research on conservation? One optimistic sign is that investigators are turning much more actively to a consideration of the type of variation in children's everyday life that promotes understanding. The child's language ability and the conversational environment to which the child is exposed are emerging as very important factors. I return to the role that language might play in promoting the understanding of belief in the context of an analysis of individual differences.

Perception, Knowledge, and Source Monitoring

False-belief tasks, and the conceptually related appearance-reality task, it was noted, turn on the child's real-

ization that perceptual access is a key to accurate knowledge. In the standard unexpected displacement task, the story protagonist ends up with a false belief because he or she was not present to witness the displacement. In the deceptive container task, the child (or some other person) has not witnessed the surreptitious replacement of the standard contents. In the appearance-reality task, the child has to identify what someone might conclude about the properties or identity of an object, in the absence of comprehensive perceptual access; for example, someone who has just looked at, but not touched, a sponge painted to resemble a rock, might take it to be a genuine rock—until they poke it.

Alongside this focus on what children understand about the consequences of blocked or restricted perceptual access, it is important to ask whether children also appreciate the consequences of appropriate perceptual access. A variety of related but distinct questions present themselves. Do children realize that appropriate perceptual access usually leads to knowledge? Can they distinguish among the various different sources of perceptual knowledge—seeing, hearing, touching, and so on? Do they differentiate between such perceptual sources and learning via the testimony of others? Finally, when do they realize that the judgment of someone with appropriate perceptual access should generally be trusted? As we shall see, these questions all speak to the wider issue of when and how children come to be insightful seekers and gatherers of information.

Three- and 4-year-olds are well able to report when someone can and cannot see an object (Flavell, Shipstead, & Croft, 1978) and they can position a doll so that it will not be seen by two doll policemen (Hughes & Donaldson, 1979). Young children also realize that seeing yields knowledge. For example, several experiments have established that 3- and 4-year-olds realize that someone who has looked into a box will know its contents, whereas someone who has picked it up but not looked inside will not know its contents (Pillow, 1989; Pratt & Bryant, 1990).

Children might conceptualize perceptual contact in an all-or-none fashion. Thus, they might assume that any kind of perceptual contact yields knowledge. Alternatively, they might have a more refined notion of perceptual contact, realizing, for example, that visual inspection is needed to identify an object's color but manual inspection is needed to identify its hardness. O'Neill, Astington, and Flavell (1992) found a shift with age from a more global to a more refined understanding

of perceptual input. Thus, 3-year-olds were poor at judging that color has to be judged by looking, whereas hardness is best gauged by manual inspection. Five-year-olds, by contrast, were much more accurate at realizing that our senses can provide modality specific information. O'Neill and Chong (2001) extended this conclusion to all five senses: Three-year-olds were quite inaccurate in both saying and showing how they had determined, for example, the smell of a bubble bath—even when they had just copied the experimenter and smelled the liquid in question. Four-year-olds were much more accurate.

A similar development appears to occur with respect to children's differentiation between perceptual and nonperceptual sources of information. Gopnik and Graf (1988) informed 3-, 4-, and 5-year-olds about the contents of a drawer in three different ways: Children looked in the drawer, were told about the contents, or were given a clue. They were then asked how they knew the contents. Although 3-year-olds performed above chance, the performance of 5-year-olds was almost perfect. Moreover, even if 3-year-olds were correct on an immediate test, they were prone to forget their source in a delayed test.

Nevertheless, 4- and 5-year-olds do display a certain degree of amnesia about how they have come to know various facts (Taylor, Esbensen, & Bennett, 1994). Thus, whether they are reminded of a fact that they already know (e.g., that tigers have black stripes) or introduced to a fact that they do not know (e.g., tigers' stripes provide camouflage) both age groups, especially the 4-year-olds, often claim immediately afterward that they have known both facts "for a long time." Control procedures have established that children can judge time intervals in other contexts, for example, in assessing whether they have received a gift that day or "a long time ago."

Summarizing these various studies, it appears that 3-year-olds can differentiate between those who have been supplied with information about an object—for example by looking into a box—and those who have no information about it at all. At the same time, they are poor at distinguishing among different sources of information. Thus, they are prone to confuse perceptual and nonperceptual routes (such as being told or making an inference), and they often fail to differentiate among particular perceptual routes, such as touching, looking, and smelling. Five-year-olds perform much more accurately on all these source-monitoring tasks—but, as noted, they have some difficulty in pinpointing the time of the learning experience.

It is important to note that all of these tasks call for children to reenact, to verbally identify, or to pinpoint in time their reliance on some particular source such as looking or telling. Whitcombe and Robinson (2000) showed that 3- and 4-year-olds are better at what might be described as procedural or online source monitoring. In their study, children were given limited or inappropriate perceptual access to an object—for example, they could only see a small red patch of a larger picture, or they could only feel an object inside a tunnel, and therefore not properly identify its color. Having ventured nonetheless to state the identity of the object, an adult with fuller or more appropriate access to the object proposed a different identity. When children were asked for a final judgment, they tended to yield to the better-informed adult. Moreover, when the roles were switched—so that the children were better informed than the adult—they tended not to yield. By implication, children were tracking who had better perceptual access and they either revised—or retained—their initial judgment in an appropriate fashion. Despite this accurate source monitoring at a procedural level, the familiar pattern of inaccuracy reappeared when children were asked to indicate the source of their final judgment. For example, children who had appropriately revised their initial judgment when the adult was better informed often made the mistake of saying that they knew the object's identity because they had seen or felt it.

One interpretation of this type of accurate procedural source monitoring is that children follow a simple stay or shift rule. Specifically, they might stay with their own judgment if they have had a vivid and determinate perceptual encounter with the object but shift to the informant's judgment if they have not. Thus, if they have been able to inspect a whole picture and establish that it is a strawberry—or look inside a tunnel and establish the identity of an object located inside it, children stay with their own judgment. If, however, they have only glimpsed part of the object or tried to identify its color by feel alone—and ended up by making a guess—they revise their judgment if another is offered.

On this argument, procedural monitoring would involve, at best, some sensitivity to the determinacy or certainty of one's own perceptual encounters but it would not call for any monitoring of another informant. Robinson and Whitcombe (2003) tested this skeptical interpretation in a follow-up study. Children made an essentially uncertain judgment about an object, given their restricted perceptual access. They then heard an adult make a different judgment—sometimes on the

basis of better access but sometimes on the basis of equally restricted access. If children yield to another judgment whenever they are uncertain, they should have yielded just as often whether or not the adult was better informed. They did not. Children were much more likely to adopt the adult's counterclaim when he or she was well-informed. In the future, we may expect to see more research intended to tease out the differences between "explicit" and procedural source monitoring. When children are uncertain, it is a useful strategy for them to seek and rely on information from someone else. Still, their reliance ought to be tempered by some sensitivity to how well-informed their interlocutor is. The findings of Robinson and Whitcombe (2003) suggest that even 3-year-olds have some competence at this type of fine-tuning.

Reviewing these diverse studies, it is evident that children's accuracy in identifying the source of a piece of information improves with age. Between 3 and 5 years, children improve in their identification of one perceptual channel as compared to another, and they improve in identifying information based on perception versus testimony. At the same time, 3- and 4-year-olds appear to keep a surprisingly watchful eye on their informants. They defer to an informant who is better informed but resist one who is not.

Emotion

A great deal of research on emotional development has adopted what we might think of as the "continuity" position. Guided by Darwin's emphasis on the similarities between human beings and animals in the origins and function of the expression of the emotions, this research tradition has approached emotional development in terms of the key issues of the production and comprehension of nonverbal signs of emotion—especially in the face. I reviewed some of the key findings from this research tradition earlier.

However, there is an important aspect of emotional development that this approach ignores. First, young children can communicate about emotion in language. No other species has that capacity—and there is good reason to keep in mind the possibility that that capacity transforms the emotional lives of human beings as compared to other species. Second, as I describe later, young children increasingly interpret both their own emotional experiences and those of other people in the light of their larger theory of mind. Again, that capacity calls

into question the Darwinian "continuity" project, at the very least if it is taken to offer a comprehensive analysis of emotional development.

When do children start to put feelings into words and when do they begin to interpret emotions in relation to other mental states? Two and 3-year-olds already make references to basic emotions such as feeling happy, sad, and scared (Wellman, Harris, Banerjee, & Sinclair, 1995). They tend to talk mainly about their own emotions but references to those of other people, as well as those of stuffed animals and dolls, are also apparent. Moreover, they refer to likely future emotions and to emotions felt in the past. Thus, they talk about emotion in a referential and descriptive mode rather than an expressive mode. To clarify this distinction, consider the expressive terms: "Ouch," "Yuck," or "Oh!" These terms can be used to express a current emotion of the self but they cannot be readily used to identify a non-current emotion or one belonging to another person. Wittgenstein (1953) proposed that children's early emotion talk is acquired and used in the expressive mode. However, close analysis of children's comments on other people and their references to noncurrent emotion shows that that is not the case. More generally, it would be wrong to see children's early emotion talk as a supplement to some preexisting nonverbal system for the expression of emotion. The evidence suggests that it is an altogether different mode of communication—it is descriptive, discursive, and referential.

When children refer to an emotion what do they have in mind? They might be referring only to the outward signs of the emotion—the tears or the smiles—or they might be referring to the experiential changes that an emotion generally entails. Wellman et al. (1995) found some indications that preschoolers differentiate between the experience of emotion and the actions and expressions that frequently accompany emotion. They also found that children think of emotions—unlike pains—as intentional states directed at an object or target. They realize that people are sad *about* something, afraid *of* something, or mad *at* someone. Here, we do see an important continuity with children's interpretation of facial expressions. Recall that experiments on social referencing have established that toddlers in the 2nd year realize that an adult's emotion is directed at a particular target—they do not treat it as a diffuse mood change.

Granted that young children talk about emotion with apparent sophistication, do they do so in an accurate

and appropriate fashion? More specifically, does the way in which they would describe an emotionally charged episode coincide with the description that an adult might supply of the same event? To explore this issue, Fabes, Eisenberg, Nyman, and Michealieu (1991) observed preschoolers aged 3 to 5 years in their day-care centers, and they approached bystanders following an emotional incident to ask for a description of what had happened. Three-year-olds gave an account of the target child's emotion that matched an adult observer's about two-thirds of the time and 5-year-olds did so about three-quarters of the time. For example, "She's sad because she misses her Mom," or "She's mad because she thought it was her turn."

How do children come to provide such accurate descriptions? One explanation that has appealed to various investigators (Lewis, 1989; Russell, 1989) is that children learn the typical script for any given emotion. They come to realize that there is some kind of standard elicitor (e.g., frustration in the case of anger; the unexpected in the case of surprise) together with an accompanying expressive and gestural pattern. When they see key features of the script, they identify the emotion accurately. The script-based analysis is consistent with the fact that preschoolers are quite good at describing the elicitors that would provoke various basic emotions such as sadness and fear (Trabasso, Stein, & Johnson, 1981). Such situational knowledge becomes richer and more differentiated as children get older so that they can describe situations likely to evoke more complicated emotions such as disappointment, relief, and jealousy (Harris et al., 1987).

There is, however, one important limitation of the script concept. It focuses on the external circumstances and observable behaviors that make up an emotional episode but it ignores the subjective appraisal that is frequently involved. What any given individual deems to be a frustration or surprise depends on the desires and beliefs that they bring to a situation. Are children sensitive to the crucial role played by these subjective appraisals? With this question in mind, Harris, Johnson, Hutton, Andrews, and Cooke (1989) asked 4-, 5-, and 6-year-olds to watch a naughty monkey who offered various animals either a nasty surprise (e.g., he gave the elephant whose favorite drink was coke a coke can with milk inside) or a nice surprise (e.g., he gave the horse whose favorite snack was peanuts a chewing gum packet with peanuts inside). Children were asked to say how the recipient of these gifts would feel both before and after

discovering the contents of the container. As might be expected, all three age groups understood the role of desires: They judged that the recipient would feel happy if he eventually found his favorite drink or snack but sad otherwise. For the question about how the animal would feel *before* discovering the surprise contents, there was a marked age change. The youngest children mostly attributed to the animal an emotion based on the actual contents of the container—ignoring the animal's mistaken belief about those contents. By contrast, the oldest children mostly did the reverse—they attributed an emotion based on the animal's mistaken belief—ignoring the actual contents. By implication, all the children realized that the animal's emotion would depend on his desires—as indexed by their answer to the question about how the animal would feel on discovering the actual contents—but their appreciation of the role of beliefs underwent a steep improvement with age.

At first sight, these results fit the pattern that has repeatedly emerged in other analyses. Children understand the role of desires well before they understand the role of beliefs. There is, however, a major deviation. The youngest group, with a mean age of 4 years, was quite poor at diagnosing the animals' emotions with reference to their (mistaken) beliefs. Moreover, only about half the 5-year-olds were correct. It was only among the oldest group of children, with a mean age of 6 years, that the majority was correct. Yet, as we noted in the discussion of children's understanding of belief, children generally understand a variety of false-belief tasks at around 4 to 5 years of age. Thus, even if 4- and 5-year-olds accurately predict a person's thoughts, actions and utterances on the basis of his or her beliefs, they continue to have difficulty in predicting a person's emotions on the basis of his or her beliefs.

Several subsequent studies have supported this intriguing conclusion. In a series of four experiments, Hadwin and Perner (1991) showed that children could appreciate a story character's mistaken belief before they made use of this knowledge to make attributions of surprise. For example, 5-year-olds were at chance in attributing surprise, whereas all but one child correctly judged the protagonist's false belief. Only by 6 years of age did a significant majority of children make correct belief-based attributions of surprise. A similar lag emerged for the attribution of happiness.

Bradmetz and Schneider (1999) replicated the same lag across five experiments and across two emotions (fear and happiness). Almost half the children ranging

from 3 to 8 years appreciated the false belief held by the protagonist but still made the incorrect emotion attribution. For example, when given a version of the story of Little Red Riding Hood, children frequently realized that Little Red Riding Hood mistakenly thinks it is her grandmother in the bed but then went on to say that she was afraid—and invoked the wolf to explain her fear, for example, “Because it is a wolf!” or “Because the wolf wants to eat her.” However, no child made a correct emotion attribution but failed the false-belief test. Thus, Bradmetz and Schneider (1999) document a robust lag between understanding belief and understanding the emotion that would be caused by that belief.

Finally, de Rosnay and Harris (2002) compared children’s performance on a story version of the nasty-surprise task (involving an animal puppet mistakenly expecting his favorite food) with their performance on a filmed version (involving a child mistakenly expecting to be reunited with his or her mother after an absence but actually encountering a stranger). In two experiments, children frequently erred on both the story and the film task by incorrectly identifying the protagonist’s emotion, despite correctly identifying the protagonist’s belief.

These various studies indicate that an appreciation of the role of beliefs in the elicitation of emotion is consolidated at around 6 years of age. This is not because 4- and 5-year-olds fail to understand beliefs, including false beliefs. There is a large body of evidence to show that they do—as described earlier. Indeed, as just stated, even in the same study, children will accurately diagnose a protagonist’s belief but fail to diagnose the concomitant emotion.

It is tempting to argue that such a lag is not surprising—children frequently grasp a concept without realizing all its implications. However, the puzzle is actually more acute. As described earlier, once children understand false beliefs, they immediately appreciate the implications for action. Thus, we do not find 3- and 4-year-olds who say that Maxi thinks his chocolate is where he left it but proceed to claim that he will search in the place to which it has been moved. Stated differently, recall that the meta-analysis reported by Wellman et al. (2001) showed that children solve the false-belief problem at approximately the same age whether they are quizzed about a protagonist’s thoughts or actions.

To summarize, the two central pillars of children’s theory of mind—desires and beliefs—are each relevant

to their understanding of emotion. Moreover, in line with a large number of other findings, children acknowledge the key role of desires before they acknowledge the role of beliefs. An important unanswered question is why they are so slow to acknowledge the role of beliefs in causing emotion. No existing account of the child’s theory of mind offers a satisfactory explanation of this puzzle.

So far, I have discussed children’s attribution of so-called basic emotions: fear, anger, sadness, and so forth. Can the same focus on children’s understanding of beliefs and desires also explain children’s attribution of more complex emotions, notably those emotions that are frequently designated as social, such as guilt and pride? My reading of the evidence is that children need to consider not only a person’s desires and beliefs but also the way in which they assess themselves, and assume that others will assess them, in relation to various standards. Children who neglect these social considerations will fail to attribute guilt, pride, shame, and so forth in an appropriate fashion.

Earlier research on moral judgment by Piaget (1932) and by Kohlberg and his colleagues (Colby, Kohlberg, Gibbs, & Lieberman, 1983) analyzed children’s developing conception of why such standards should be upheld. However, these analyses did not focus directly on children’s attribution of guilt as a consequence of any failure to live up to those standards, the issue examined by Nunner-Winkler and Sodian (1988). They found that 4- and 5-year-olds consistently claimed that a story protagonist who had deliberately lied, attacked, or stolen from another child would feel happy. They justified this attribution by noting that the outcome—as seen from the point of view of the perpetrator, at any rate, was positive. He or she had, for example, stolen something desirable or successfully pushed another child off the swing. By contrast, children around the age of 8 years claimed that the protagonist would feel bad or sad and they explained their attribution by reference to the misdeed or the protagonist’s bad conscience. By implication, young children are oblivious to feelings of guilt—this insouciance has come to be known as the “happy victimizer” phenomenon. It warrants analysis because, as Arsenio and Kramer (1992) point out, most adults would not have expected such a stance (Zelco, Duncan, Barden, Garber, & Masters, 1986) and it raises the possibility that attempts to prompt children to be guided by their conscience may be fruitless, at least in the preschool years.

Various explanations of this marked age change can be ruled out. First, there is no evidence that young children think of hitting, stealing, and lying as acceptable. They judge them as bad—and they maintain that these actions would still be bad in hypothetical communities with no rules or punishment for such actions (Smetana, 1981). Indeed, Keller, Lourenco, Malti, and Saalbach (2003) confirmed that younger children are just as likely as older children to judge the protagonist's actions to be wrong. More generally, these findings underline the fact that developmental changes in children's moral judgment—the focus of the earlier research by Piaget and Kohlberg—do not offer an adequate explanation for age changes in the attribution of guilt.

Second, it might be that older children are more inclined than younger children to focus on the likelihood of punishment for such a misdeed. Indeed, being older, they might reasonably expect more chastisement. Analysis of children's justifications lends no support to this interpretation either. When older children attribute bad feelings to the protagonist they scarcely ever explain that attribution by reference to punishment (Keller et al., 2003; Nunner-Winkler & Sodian, 1988).

A third possibility is that older children are more aware than younger children of the distress of the victim. Again, this seems unlikely because, as noted earlier, harm and distress are important factors leading preschoolers to judge certain actions as wrong (Davidson, Turiel, & Black, 1983; Smetana, 1985). Indeed, Arsenio and Kramer (1992) obtained direct evidence to rule out this interpretation. They asked children to comment on how the victim as well as the wrongdoer felt after a misdeed. The familiar age change emerged for attributions to the wrongdoer—whereas children in all age groups acknowledged that the victim would feel bad.

A fourth possibility is that children vary with age in their interpretation of the question. Maybe younger children assume that they are being asked to say how someone performing such a misdeed would *actually* feel—and conclude reasonably enough that a delinquent who hits and steals from other children would feel no remorse. By contrast, older children may assume that they are being asked to say how someone *ought* to feel. If this argument is correct, we might expect younger children to refer to bad feelings more often if they were asked how they themselves would feel. Keller et al. (2003) examined this prediction but found little support. Younger children were more likely to claim that they themselves

would feel bad as compared to a story protagonist. However, the same effect emerged for older children—so that the greater overall tendency of older children to attribute more guilt remained.

The most plausible explanation of the happy victimizer findings is that there is a major shift in how children conceive of actors—including themselves. Preschoolers typically see people as agents who aim to get what they want and feel happy or sad depending on whether they have done so. Older children are more likely to see people as agents who assess actions, including their own, against normative and moral standards; if their actions meet those standards, they may feel proud but if they fall short they may—and indeed should—feel guilty or ashamed (Harris, 1989). Indeed, we may push this analysis a little further. Arguably, older children see everyone—victims as well as wrongdoers—as part of a moral order. In line with that proposal, Arsenio and Kramer (1992) found that older children are more likely to explain the feelings of victims and wrongdoers in relation to moral considerations. Making the same point differently, younger children—as we have seen—know that misdeeds cause a victim distress; what older children may appreciate, in addition, is that such distress is compounded by a sense of injustice on the victim's part.

One reasonable yet troublesome objection to this general line of argument runs as follows. It might be argued that young children do feel guilt. To the extent that they feel guilt, they must appraise their actions in relation to normative standards, including moral standards. Some recent evidence appears to point firmly in that direction. Kochanska, Gross, Lin, and Nichols (2002) found that through the preschool years, preschoolers show a relatively stable tendency toward nonverbal displays of discomfort following a mishap; mothers' ratings of their child's proneness to guilt showed moderate correlations with such displays; and children who displayed more discomfort were more likely to abide by adult-imposed rules. If preschoolers actually do feel guilt, why are they prone to claim that wrongdoers will feel good rather than bad?

I think the most plausible answer to this question is a familiar one. The fact that children enter into a given mental state is no guarantee that they can diagnose that state in themselves or attribute it to others. We have already seen that this is the case for belief. Young children hold beliefs, including false beliefs. Nevertheless, it takes some time for them to recognize and attribute

such beliefs. Young children can also display emotions that are based on a mistaken appraisal of a situation—alarm at an intruder when there is none or surprise at an unexpected outcome. Again, it takes time for them to recognize and attribute such belief-based emotions. In the same way, children can feel guilt but may take time to recognize and attribute it. More specifically, children may know that they have done something wrong, and feel badly as a result, but in the absence of an interpretation of why they feel as they do, they may not recognize themselves as feeling guilty—even though observers would reasonably do so. This lag between the emergence of a psychological process in the child and the child's capacity to recognize and attribute such a process is not confined to guilt. For example, children may hesitate as they read an anomalous sentence but when subsequently asked about whether there was something they did not understand, they will fail to recognize their comprehension problem (Harris, Kruithof, Meerum Terwogt, & Visser, 1981). Thus, we need not postulate an active process of repression or denial to explain children's lack of insight and awareness. It is a normal developmental process.

In conclusion, the fact that preschool children display overt signs of guilt is no guarantee that they can make sense of what they feel after a wrongdoing or accurately attribute guilty feelings to another person. In future research, it will be fascinating to examine this claim in more detail. It will be important not only to observe displays of emotion in young children but also to ask them what they feel. If the preceding analysis is correct, preschoolers will often display emotions but deny any such feelings, whereas older children will be better placed to recognize how they feel.

Thoughts, Memories, and the Stream of Consciousness

Most adults share a variety of assumptions about the waking mind. We accept that it spontaneously generates a ceaseless flow of thoughts and feelings—what William James (1890) referred to as the “stream of consciousness.” This flow is deemed to be partly controllable—we can turn our mind to a particular plan or problem that we need to finalize—but there are also intrusive thoughts that come unbidden. Emotional concerns can have an especially dramatic influence on the stream of consciousness. Guilty ruminations over what we might have done differently, apprehension in the face

of uncertainty, excitement about a potential success can all serve as attractors that redirect the flow of thought for varying lengths of time. Finally, we recognize that the contents of consciousness are limited—we cannot concentrate on two conversations at once or think concurrently about two unrelated problems. This limited capacity of consciousness is in some ways problematic—it means that when an emotionally charged thought intrudes, it is likely to interrupt, and even redirect the stream of consciousness. At the same time, it is a balm; in times of distress or anxiety, we can find solace by temporarily focusing on, and becoming absorbed in, some alternative activity, whether it is a book, a film, or an interesting conversation.

What do young children understand about these various aspects of our mental lives? Do they share adult assumptions about the ceaseless and partially controllable nature of the stream of consciousness? Research on this topic was spasmodic in the 1980s but is beginning to gather momentum—with important implications for the use of introspective self-reports from children in clinical settings. In a series of studies, Flavell and his colleagues have shown that preschoolers have a radically different view of our inner life from adults (Flavell, Green, & Flavell, 1993, 1995). For example, preschoolers do not consistently attribute any mental activity at all to someone sitting quietly or even to someone engaged in an activity such as reading or talking. This is not simply a problem in attributing mental activity to other people. Preschoolers are generally poor at acknowledging that they themselves have just been thinking and poor at saying what they have been thinking (Flavell et al., 1995). For example, after 5-year-olds had been asked by the interviewer to think about where they kept their toothbrush, they often denied that they had been thinking or acknowledged thinking but failed to mention either a toothbrush or a bathroom. Consistent with these findings, preschoolers are also often unaware of their ongoing inner speech (Flavell, Green, Flavell, & Grossman, 1997). In addition, when 5-year-olds were asked to try to have no thoughts at all for about 20 seconds, the majority claimed that they had succeeded. By contrast, the majority of 8-year-olds not only reported some mental activity but also reported specific thoughts (Flavell, Green, & Flavell, 2000).

How should this limitation be interpreted? Arguably, preschool children are providing accurate reports on their inner life but this does not seem likely. Especially when they have been prompted to reflect on a given

topic (e.g., where their toothbrush is kept) it seems plausible to assume that they have actually done so; it also seems unlikely that they can keep their minds empty for 20 seconds at a stretch. An alternative interpretation is that preschoolers have a faulty theory of the way that the mind works. They do not yet subscribe to the folk theory adopted by adults. Rather than thinking of the mind as a homunculus or processing device that is constantly active, they construe the mind as a container that may or may not house thoughts and ideas at any given moment. Although this explanation seems plausible, it is probably not the whole story. After all, older children are not only more likely than younger children to acknowledge that thinking is continuous but also to identify particular thoughts that they have had. By implication, children improve in their recognition skills. As the stream of consciousness goes by, they can increasingly identify specific mental contents borne along by that stream.

When stated in this manner, it is reasonable to ask whether certain mental contents might be more easily spotted than others. For example, despite their limited introspective ability, preschoolers might be better at picking out those mental states that have an especially vivid or intrusive aspect. Some findings lend support to this idea. For example, preschoolers can report with apparent accuracy on their ability to imagine an object in motion (Estes, 1998; Estes, Wellman, & Woolley, 1989). Indeed, the report by Estes et al. (1989) points to the intriguing possibility that preschoolers might be able to discover the way that their mind functions—and come to more accurate conclusions—in the context of a dialogue with adults. They found that 3- and 4-year-olds, who had at first balked at imagining a pair of scissors open and close, reported that they had successfully done so, when further prompted by the experimenter.

Preschoolers also show some appreciation of the quality of our mental life when asked about emotion. For example, even 4-year-olds acknowledge that an intense emotional reaction will wane over time. They make that claim whether the initial emotion is positive or negative and with respect to their own emotional experience as well as that of story characters. Moreover, children make the same claim in different cultures—for example, whether they are growing up in the West or in China (Harris, Guz, Lipian, & Man-Shu, 1985). Children might be simply espousing a folk theory and not accurately reporting on their own phenomenology but a plausible conclusion from these systematic findings is that the waning of intense emotion is a universal experi-

ence, acknowledged and understood by young children everywhere.

However, as adults we realize that our emotions do not always dissipate in a steady fashion. We are vulnerable to flashbacks and reminders that override, however temporarily, the underlying pattern of dissipation. Do young children understand such intrusive flashbacks? In an initial investigation of this question, children were asked about a story character who woke up on the day after an emotionally charged experience, and either started thinking about the experience again, or alternatively had forgotten about it (Harris et al., 1985). Six-year-olds claimed that the character would feel happier thinking about a positive experience rather than forgetting about it, but would feel happier forgetting about a negative experience rather than thinking about it. Four-year-olds were less systematic. They reached similar conclusions to the 6-year-olds for the positive experience but did not appear to grasp the benefits of forgetting a negative experience.

In a more extensive investigation of the same issue, Lagattuta, Wellman, and Flavell (1997) asked 3- to 6-year-olds to listen to stories in which the protagonist experienced a sad event and, subsequently, encountered a reminder. Children were told that the story character felt sad in the presence of a reminder and questioned to check if they were able to explain that the reminder had led the protagonist to think back to the earlier, sad event. The majority of 5- and 6-year-olds were able to articulate such explanations; but this was rare among 4-year-olds. Nonetheless, in a follow-up study in which the cues were identical to (and not just associated with) items involved in the initial event some 3-year-olds also provided such explanations, especially after they were explicitly asked whether the character was thinking back to the past event.

Finally, we may ask whether children have any appreciation of the limited capacity of consciousness. In an interview study with 8- and 13-year-old boys who had newly entered a boarding school and were sometimes feeling homesick, some tacit appreciation of that limit often emerged in their discussion of coping strategies (Harris, 1989). More specifically, boys often talked about the way in which absorbing activities helped them to stop thinking about home. For example, one 8-year-old explained: "I would try and forget all about it (home) or try and get my mind off it with going to play with my friends . . . or getting stuck into work or something like that." Another explained: "Well if you were in the

dorms, you could read a book; if the lights were out you could try and get to sleep; if you were in the middle of a lesson just occupy yourself. [Interviewer: What does that do?] Well, once you get started and you're really doing it, then you forget about being homesick and don't really think about it."

In summary, it is evident that children make rapid progress during the early school years in understanding the flow of consciousness. Whereas preschoolers seem to have little insight into the continuous nature of that stream, older children realize that the stream is more or less ceaseless. They also increasingly understand the way in which one type of mental content intrudes on—and for better or worse may displace—another. Such findings raise interesting questions about children's grasp of the complicated nature of mental control. At some level, we adults assume that we can control our mental processes—for example, we can choose to concentrate on this or that topic. At another level, we also recognize that our self-control is partial—even as we concentrate, we cannot dictate the ideas that we generate and we cannot suppress intrusive and irrelevant thoughts. What children understand about this delicate issue remains to be explored.

LATER DEVELOPMENTS AND MATURE FUNCTIONING

Research on the child's theory of mind has focused mainly on young children. The way in which that theory is carried forward or radically revised in later years has been much less studied. However, there are some issues that have attracted attention. In this section, I discuss three notable examples.

Understanding Doubt and Uncertainty

To the extent that 4- and 5-year-olds appreciate that someone with a mistaken belief effectively holds, and will act on, an inaccurate representation of reality, it is tempting to assume that children of this age appreciate that our everyday construal of reality is a question of interpretation: What one person represents as true, another person may deny. Indeed, some theorists have proposed that the onset of false-belief understanding marks the onset of what might be called an interpretive theory of mind.

Early dissent from this position was voiced by Michael Chandler (1988). He argued that such a conclusion overstates the young child's achievement. The false-belief task—and its close cousins such as the appearance-reality task or the level 2 visual-perspective-taking task—calls for the child to understand that the belief formed by a given protagonist depends critically on the history of his or her perceptual access to the situation under consideration. More generally, granted knowledge of that history, it is possible to predict what belief the person will arrive at. For example, knowing that the protagonist in the false-belief task failed to observe an object's unexpected displacement, it is possible to predict his or her mistaken belief that the object remains in its earlier location. Similarly, knowing that someone has only looked at—and not yet touched—a piece of sponge that has been fashioned and painted to resemble a rock, it is possible to understand that he or she will be misled by its visual appearance.

As Chandler emphasizes (Carpendale & Chandler, 1996; Chandler, 1988), however, there are many cases in which knowledge of a person's perceptual history does not fully constrain the predictions that can be made about his or her beliefs. Consider a familiar ambiguous stimulus, such as the illustration of a duck-rabbit that is found in introductory psychology textbooks. Two observers looking at this picture may draw different conclusions about what is depicted. To that extent, the setup resembles the standard false-belief or appearance-reality setup. However, knowing the person's perceptual history does not yield a prediction of which interpretation he or she will reach regarding the ambiguous figure. Similar remarks are applicable to ambiguous utterances. If there are three blocks, one blue and two red, children who are told to look under the red block might differ about which of the two red blocks they think is intended. Yet, knowledge of their individual perceptual histories will be of no assistance in deciding which child will opt for which block.

Carpendale and Chandler (1996) found that children's understanding of the impact of such perceptually ambiguous information emerged more slowly than their understanding of perceptually inaccessible information. More specifically, 5-year-olds who did well on a standard false-belief task, and could explain why the central protagonist had a different belief from the other story character (given his or her lack of perceptual access to the unexpected displacement), could rarely explain why two children looked at an ambiguous picture or hearing

an ambiguous message would reach different conclusions. Eight-year-olds, however, performed much better. They explained the belief divergence in terms of the ambiguous nature of the stimulus. They realized that it was hard to predict which of the two interpretations any given observer would adopt although they also realized that other, more deviant interpretations—for example, that the ambiguous duck-rabbit illustration depicted an elephant—were unlikely. Chandler and his colleagues make a good case for distinguishing between children's understanding of information that is inaccessible and their understanding of information that is ambiguous. Even if 5-year-olds understand that some information is inaccessible, they are puzzled by the fact that some information is ambiguous.

Indeed, the cautionary conclusion reached by Carpendale and Chandler (1996) can be extended further. Some beliefs are relatively straightforward judgments about observable objects or events and such beliefs may well go wrong when perceptual access is blocked, but it is clear that we hold many different kinds of belief and we form those beliefs in various ways. For example, we also hold beliefs about what is right and wrong, about the past and the future, and about a large number of theoretical and metaphysical entities. In none of these cases, do we arrive at our beliefs by a simple act of perceptual observation. Given this "disunity" of belief, it is appropriate to ask whether children's sensitivity to disagreement among individuals varies from one belief domain to another.

Evidence in support of this variation has been reported by Wainryb and her colleagues (Wainryb, Shaw, Langley, Cottam, & Lewis, 2004). They found that 9-year-olds show considerable sensitivity to the type of belief that they were invited to consider. For example, with respect to relatively straightforward moral beliefs—such as whether it is acceptable to hit or steal—9-year-olds generally insist that only one stance is right and they also insist that dissent is not acceptable. However, with respect to factual matters, although they again insist that only one stance is right, they are more tolerant of dissent. Finally, with respect to uncertain issues whether in the realm of fact or taste, they acknowledge that more than one stance could be right and that more than one stance is acceptable. Even 5-year-olds show some emerging sensitivity to these various domains of belief but, in line with the results of Carpendale and Chandler (1996), they are less sensitive to the potential ambiguity or uncertainty of certain issues.

Thus, instead of allowing that opposing judgments might both be right, they tend to claim that only one belief can be right.

The acknowledgment that more than one stance toward a given issue could be right is a clear recognition of uncertainty. However, children might adopt two different attitudes toward uncertainty. On the one hand, they might conclude that competing claims are equally valid and that there is no way to adjudicate between them. For example, in the case of ambiguous figures or taste preferences, one individual's subjective appraisal is as good as another's. On the other hand, children might recognize that in some domains competing claims are not equally meritorious. Insofar as they come to acknowledge ambiguity and uncertainty, do children generally adopt the first stance—treating all competing claims as more or less equal? Alternatively, do they show some appreciation of the second stance—recognizing that rational adjudication among competing claims is possible? The answer to this question is obviously important from an educational point of view. Any genuine understanding of debate—whether in science, politics, morality, or history—critically depends on the realization that competing claims are *not* equally valid and there are various criteria for their adjudication, depending on the domain in question.

Some evidence points to a pessimistic conclusion. When preadolescents have been assessed for their understanding of competing knowledge claims, they rarely acknowledge that such claims can be compared and evaluated. For example, Kuhn, Cheney, and Weinstock (2000) presented children, ranging from 10 to 17 years, and adults with competing claims in various domains and asked participants to say whether only one claim was right—and in those cases where each claim was acknowledged as having some merit to say whether it was possible to judge one as superior. Across all participants, the most frequent response pattern was to acknowledge that more than one claim might be right but to deny that adjudication was possible. Even when the claims pertained to the physical world (e.g., the structure of atoms or the functioning of the brain), less than half of the adult participants acknowledged that one could be judged superior; among the youngest age group interviewed (10-year-olds), only 20% acknowledged that adjudication is possible. Only among a specialist group of adults (all doctoral students in philosophy) was there universal acknowledgment that competing claims about the physical and social world are open to adjudication.

More encouraging results have emerged from studies in which children have been invited to consider the type of evidence that might resolve a given empirical question. For example, Sodian, Zaitchik, and Carey (1991) told children aged 6 to 9 years a story about two brothers who were trying to figure out whether a mouse in their house—which they had not been able to see—was big or small. Children were shown two boxes, one with a large opening, the other with a small opening and asked what the brothers could conclude if either one or the other box was baited with cheese, left out during the night, and checked in the morning to see if the cheese had been eaten. More than half of the 6- to 7-year-olds and the large majority of the 7- to 9-year-olds (a) suggested leaving out the box with the small opening, (b) understood the implications of the cheese being either gone or still there in the morning, and (c) realized that leaving out the box with the big opening would be inconclusive. Similar results emerged in a parallel study. Most children judged that inviting an aardvark to find buried mild-smelling food would test the sensitivity of its sense of smell but burying strong-smelling food would produce only inconclusive results. Indeed, children of this age understand how evidence bears not only on the properties of a given individual but also on the properties of a class or set. Six- and 7-year-olds realized that different patterns of evidence about how hard various tennis rackets (differing in size, shape, and strings) could hit the ball could be used to evaluate not only the rackets that were tested but also what type of racket to buy in the future (Ruffman, Perner, Olson, & Doherty, 1993). Note, however, that these are all questions that have definite answers, once the necessary observations have been made. For example, the mouse is big or small, not both. Similarly, size of tennis racket either does or does not affect how hard the ball can be hit. If the issue is acknowledged as one where each of the competing views may have some validity (e.g., competing views about how the brain functions), children, as well as many adolescents and adults, are unlikely to report any possibility of determining their relative merits.

Although children in their study did well in understanding the implications of various sorts of evidential test suggested by the interviewer, Sodian et al. (1991) also observed that few children were able to generate a conclusive test themselves. More generally, it is almost certainly easier to recognize the implications of evidence once it is provided than to think about what evi-

dence would be informative and ways to gather it. This gap between evidence evaluation and evidence seeking may explain, at least in part, why preadolescents often conclude that empirical claims cannot be adjudicated. They have difficulty in conceiving of the type of evidence that would be decisive. For example, when asked whether it is possible to adjudicate between different accounts of the way that the brain works, many children—and indeed many adults—may not know what type of evidence would be informative.

In summary, young children understand that beliefs may diverge when observers differ in their perceptual access. They do not, however, immediately appreciate all the various ways in which beliefs may diverge. In particular, they are slower to understand the way that ambiguous or uncertain information may be differentially interpreted. Moreover, when the existence of uncertainty is acknowledged, children—and even some adults—show some signs of being overwhelmed. They are likely to conclude that it is impossible to adjudicate among beliefs. Still, elementary school children can often differentiate between decisive and inconclusive evidence when such evidence is explicitly presented to them. Further analysis of adolescents' sensitivity to this central issue in epistemology is presented by Kuhn and Franklin (Chapter 22, this *Handbook*, this volume).

Understanding Second-Order Beliefs and Nonliteral Utterances

An old idea in social cognition is that development is marked by an increasing ability not simply to take the perspective of another person, as exemplified by the standard false-belief task, but to contemplate multiple, potentially intersecting perspectives. For example, Selman (1980) claimed that it was not until approximately 10 years of age that children began to articulate not only the distinct perspectives of particular actors in a given social situation but also the perspective that one actor might have toward the perspectives of other actors. In theory-of-mind research, the most direct analysis of this developmental trend has focused on the second-order false-belief task. Extending their pioneering studies of the standard false-belief task, Perner and Wimmer (1985) introduced a more complex, second-order task in which children were called on to assess what one actor would believe about the beliefs of another actor. For example, children heard a story in which one actor did not

realize that a second actor knew about an unexpected change of location; their task was to diagnose the first actor's mistaken belief about the second actor's belief. Perner and Wimmer (1985) found that children could solve the problem at around 6 to 7 years of age, well beyond the age at which the standard false-belief task is mastered but still in advance of what might have been expected on Selman's role-taking theory.

Subsequent research by Sullivan, Zaitchik, and Tager-Flusberg (1994), showed that most kindergarteners are able to manage the second-order task if simpler stories with a deceptive context are used. Still, as we saw with the standard task, even if thematic changes alter the absolute level of difficulty, this need not compromise the claim that there is a developmental improvement in the ability to handle the second-order task.

The difficulty of the second-order task is especially evident among children with autism. Recall that most children with autism, even those with a relatively advanced mental age, fail the standard false-belief task. Baron-Cohen (1989) focused on the minority of children with autism who pass that standard task. When such children were tested on the second-order task—Baron-Cohen found a severe impairment even among those who were in their teens.

In an interesting analysis, Happé (1993) proposed that success on the second-order task might be connected to the understanding of figurative speech, particularly irony. She went on to show that subjects with autism and with mild learning disabilities who failed the second-order task did indeed have difficulty understanding ironic remarks. For example, when presented with a vignette in which a parent said "Nice job!" to a child who had made a mess while doing a household chore, children with autism were inclined to focus on the literal meaning of the remark and to interpret it as a compliment.

Follow-up work by Happé (1994) showed that the interpretation of stories containing nonliteral utterances was a sensitive diagnostic tool in assessing the social cognitive impairments of mature subjects with autism. Performance on the stories was closely related to performance on theory-of-mind tasks, although even those subjects who managed to pass all the theory-of-mind tasks showed impairments on the more naturalistic story materials relative to normal controls.

In summary, research on the child's theory of mind has concentrated on the establishment of basic building

blocks: children's developing understanding of desire, belief, and emotion. Some investigators, however, have taken up a more traditional theme of research on social cognition: the ability to take multiple perspectives. Various studies show that the understanding of beliefs about beliefs is mastered at around 6 years of age by normal children—but considerably later, if at all, by children with autism. Competence on these so-called second-order tasks turns out to be linked in an intriguing fashion to another aspect of social cognition—the ability to appropriately interpret nonliteral utterances, notably irony. That said, difficulty in interpreting such remarks turns out to be a persistent impairment of subjects with autism, even among those who do well on both first- and second-order tasks.

Measures of Reflective Functioning among Adults

A great deal of research on the social cognition of adults has been conducted with little reference to developmental theory. Research on so-called reflective functioning among adults constitutes an important exception to that generalization. Both in its conceptualization and in its empirical yield, this line of research retains important links to developmental research. I briefly review some of the key findings.

In an influential study, Main, Kaplan, and Cassidy (1985) administered an adult attachment interview (AAI) in which they asked 40 middle-class mothers to reflect on, and describe, their relationships with their mothers during infancy and childhood. Memories of rejection, illness, and separation were probed as well as reasons for the parents' behavior. A link emerged between maternal reflections on their childhood attachments and the type of relationship that mothers had with their own children. "Autonomous" mothers offered a balanced and consistent account of their childhood relationships; they tended to have securely attached children. "Dismissing" mothers often devalued their childhood relationships, had difficulty in recalling them, and seemed unaware of inconsistencies in their account; they tended to have insecure-avoidant children. "Preoccupied" mothers were often caught up in their childhood memories, recalled conflictual relationships, and had difficulty in providing a coherent, integrated account; these mothers tended to have insecure-ambivalent children.

Subsequent research has lent considerable support to the claim that such reflections predict the kind of relationship that parents establish with their children. In a meta-analysis, Van IJzendoorn (1995) found a strong relationship between the parents' attachment, as measured by the AAI, and the nature of their children's attachment, as measured by standard instruments such as the Strange Situation or the Attachment Q-sort (AQS). This relationship emerged for fathers but more strongly for mothers. As noted by Van IJzendoorn (1995), the findings are impressive in that the two measures are quite different—reflective discourse for the AAI and the coding of behavioral responses for the Strange Situation and the Attachment Q-sort.

Several other findings are worth stressing. First, although performance on the AAI calls for a good deal of reflective discourse, classification appears to be independent of verbal IQ (Bakermans-Kranenburg & Van IJzendoorn, 1993). Second, in line with the assumption that it is the parent who influences the child rather than the reverse, a similar predictive relationship emerges even if parents are interviewed prior to the birth of the child (Benoit & Parker, 1994; Fonagy, Steele, & Steele, 1991).

How exactly should we interpret this intriguing link? One possibility is that the nature of mother's early experience is critical. According to this "early experience" interpretation, mothers vary during their childhood in the way that they are mothered; that differential early experience eventually affects the way that they come to reflect on the past during the AAI, and it also affects the way that they relate to and nurture their own children. An alternative possibility is that the AAI is an index not so much of what mothers actually experienced as children but of their current capacity to reflect in a coherent fashion about intimate relationships. According to this "current reflective capacity" interpretation, mother's psychological sensitivity—as indexed by her discourse during the AAI—is linked to the way that she construes—and mothers—her child.

It is too early to adjudicate between these two alternatives. Still, it is worth noting that we may be able to do so in the future. Recent longitudinal research indicates that attachment in infancy can be a good predictor of performance on the AAI during late adolescence (Hamilton, 2000) or early adulthood (Waters, Merrick, Treboux, Crowell, & Albersheim, 2000). Nevertheless, in a sample of disadvantaged families who experienced high rates of stressful life events, no such predictive link

from infancy to late adolescence was found (Weinfeld, Sroufe, & Egeland, 2000). Similarly, disruptive effects of stressful life events, notably divorce, on continuity from infancy to late adolescence were also reported by Lewis, Feiring, and Rosenthal (2000). With respect to the latter two samples—where no relationship between early attachment and current performance on the AAI was found—it is possible to ask which measure is the more important for the prediction of later parenting—particularly the type of attachment that such adolescents will form with their own children. The early experience interpretation implies that early attachment would be the stronger predictor, whereas the reflective capacity interpretation implies that performance on the AAI would be the stronger predictor.

Beyond the question of whether it is the mother's past experience or her current reflective capacity that is important, it is worth noting that we continue to have a relatively weak understanding of how exactly characteristics of the mother influence the child's attachment. Maternal sensitivity has traditionally been emphasized by attachment theorists, but existing measures of such nonverbal responsiveness probably fail to capture the entire spectrum of transmission from mother to infant (Van IJzendoorn, 1995). Recent research by Meins and her colleagues offers a way to broaden our assessment of that spectrum and promises to make connections with the concept of reflective functioning (Meins, Fernyhough, Fradley, & Tuckey, 2001). These investigators assessed maternal sensitivity in the usual fashion using the scale devised by Ainsworth, Bell, and Stayton (1971), but they also assessed maternal "mind-mindedness"—mothers' tendency to comment appropriately on the ongoing mental states of their infant. As expected, maternal sensitivity was correlated with infants' attachment security, as measured at 12 months but mind-mindedness proved to have an independent and somewhat stronger relationship to attachment security.

In summary, parents' comments on their own intimate relationships are a good predictor of the type of relationship that parents form with their infants. In particular, mothers who offer a psychologically coherent and balanced account of their childhood relationship with their own mother as well as mothers who comment appropriately and accurately on their infants' current mental states are likely to have infants who display a secure attachment. This striking relationship between psychological discourse on the part of the mother and emotional security on the part of the infant should en-

courage continuing collaboration and dialogue between two relatively distinct research communities—those who focus on social cognition especially as indexed by psychological discourse and those who focus on early attachment.

HOW DO HUMANS DIFFER FROM OTHER NONHUMAN PRIMATES IN THEIR THEORY OF MIND?

As noted earlier, the initial impetus for research on theory of mind came from research on primatology. In that context, the possible role of language was not highlighted in any obvious way. Indeed, if we think about the classic false-belief task, it is not inconceivable that a languageless creature such as a chimpanzee could solve it. After all, it calls for an appreciation of the way in which an observer might have incomplete perceptual access to the true state of affairs. That appreciation does not necessarily call for any linguistic ability. It could be based on observation of an agent's lack of perceptual access at some given moment. As it happens, subsequent research with primates, notably chimpanzees, has mostly produced negative results when they have been tested on variants of the false-belief task (Call & Tomasello, 1999). In addition, despite an initially enthusiastic compilation of case notes from the field, suggesting deliberate deception among chimpanzees, doubts surfaced about the extent to which such ploys, deceptive though they might be, really did depend on a calculation of just what the dupe would falsely believe (Heyes, 1998). Perhaps, for example, they were guided by some past experience of the risks associated with acting in particular ways in full view of a rival or competitor.

In addition, three other streams of experimental research have suggested that chimpanzees are quite restricted in their psychological inferences. First, they seem to have a limited understanding of the link between seeing and knowing. They generally beg for food indiscriminately from humans who either can or cannot see them (Povinelli & Eddy, 1996), and they fail to realize that someone who has seen an event is likely to know more about it than someone who has not (Povinelli, Rulf, & Bierschwale, 1994). Second, chimpanzees do not seem to interpret fairly simple gestures or cues indicating a source of food. For example, if they know that food has been hidden in one of two boxes, and a trainer either gazes at, points to, or places a marker on the baited box,

chimpanzees typically choose randomly as if unable to "read" the trainer's action as a helpful communicative act (Call & Tomasello, 2005). Third, although chimpanzees appear to transmit tool-using techniques from one to another, so as to engender a form of local "culture" (Whiten, Goodall, McGrew, et al., 1999), this form of social transmission might not involve any systematic analysis of the intentions that underlie the model's actions (Tomasello, 1996)—it might rest instead on a more superficial observation of motor actions or of ensuing outcomes.

Nevertheless, the most recent evidence has led to a more positive assessment of the chimpanzee's mind-reading capacity. First, chimpanzees do display an ability to monitor one another's orientation and intended actions, at least in competitive contexts. For example, Tomasello, Call, and Hare (2003) have tested chimpanzees in the following situation. A subordinate and a dominant watch from separate rooms as food is placed in each of two locations, one open and one partially screened, in a central area. The subordinate can see where each piece of food is placed. The subordinate is also able to observe the range of the dominant's visual access and can observe that the dominant has seen the food at the open location but not at the screened location. The two animals are released into the central area, with the subordinate being given a brief head start. Under these circumstances, the subordinate appears to nicely calculate what the dominant has and has not seen. The subordinate heads for the food location that is visible only to her, thereby avoiding the risk of head-on competition with the dominant at the other food location. A variety of more pedestrian interpretations can be ruled out. For example, the subordinate is not reacting to the dominant's overt behavioral choice because the subordinate's food preference is manifest before the dominant's door has been lifted. Nor do subordinates show a generalized preference for food at a partially screened location: When tested in the absence of a dominant, they show no such preference.

In a series of follow-up studies, the subordinate's analysis of the dominant's history of perceptual access was analyzed. There were two partially screened locations. When both the subordinate and the dominant watched food hidden at one of these locations, the subordinate approached that location less often than when only the subordinate had seen the hiding. By implication, the subordinate remembered what the dominant had and had not seen and avoided the food source if the

dominant knew about it. Again, plausible alternative interpretations can be ruled out. For example, it is not the case that subordinates steer clear of a food source that any dominant has monitored. Thus, if one dominant saw the hiding but a different dominant is present when an opportunity to retrieve the food arises, the subordinate shows less avoidance. By implication, the subordinate not only realizes and remembers that a food source has been spotted by a dominant but also realizes that such privileged access is available to one individual and not others. Summing up, these experiments indicate that chimpanzees realize that conspecifics have a particular field of vision, can see things in that field, and will act on what they have seen.

Tomasello et al. (2003) suggest that the more flexible, psychological analysis that they have uncovered is probably tied to larger features of chimpanzee social behavior. In their natural habitat, chimpanzees do compete for food, but they rarely, if ever, indicate food to another that they themselves could take. Thus, their ordinary living conditions promote sensitivity to the states and intentions of a competitor rather than the states and intentions of a collaborator or benefactor.

It is interesting to note that dogs do display such sensitivity to a benefactor. For example, unlike chimpanzees, domesticated dogs take advantage of communicative acts by their trainers when searching for food (Hare, Brown, Williamson, & Tomasello, 2002). This proclivity appears to be the product of selective breeding practices. It is not found among all members of the canine order—for example, wolves show no such sensitivity. Nor is early socialization in the company of human beings a critical factor. Puppies that have had little contact with human beings are also sensitive to human signals. Overall, the evidence is consistent with the claim that selection pressures operating over successive generations of domestic dogs have led to a robust island of social cognition. Needless to say, no such selection pressures have operated on chimpanzees, despite the fact that they are receptive to human domestication in certain respects.

Should we conclude then that chimpanzees' sensitivity to the knowledge state and likely future actions of a dominant is a very local awareness, tied quite narrowly to contexts in which there is competition for food between conspecifics? Such a conclusion would be premature. In an ongoing series of experiments, Call and his colleagues find that chimpanzees differentiate between a human trainer who is ostensibly unable to hand over

some food (e.g., he cannot extract it from a tube or accidentally drops it) as compared to a human trainer who is unwilling to hand over food (e.g., he proffers the food but teasingly withdraws it). Faced with the unwilling as opposed to the incompetent trainer, they are more likely to display signs of impatience by banging on the cage or quitting the test area (Call, Hare, Carpenter, & Tomasello, 2004). Thus, chimpanzees do have some ability to read intentions in noncompetitive contexts.

How then should the strengths and limitations of chimpanzee social cognition be described? Tomasello and his colleagues propose that chimpanzees can “go a bit below the surface” of ongoing action. They grasp the fact that bodily and head orientation toward a given target can predict subsequent approach to that target. Similarly, they grasp the fact that ongoing signs of goal-directed behavior—including unsuccessful attempts—are good clues to subsequent actions (Tomasello et al., 2003). At the same time, they emphasize that there are currently no clear indications that chimpanzees can penetrate deeper—to understand, for example, the way in which an agent might deliberate and plan before acting, especially in collaboration with a group member (Tomasello, Carpenter, Call, Behne, & Moll, 2005). Thus, even if chimpanzees do read one another’s perceptual states and intentions in noncompetitive as well as competitive situations, there is little or no evidence that they have the capacity to engage in planned cooperation. In line with this conclusion, Hare and Tomasello (2004) report that chimpanzees performed much more skillfully in a food-finding task if the task is structured as competition rather than cooperation. On this view, the divide between chimpanzee and human child has to do with both the depth and richness of psychological understanding in the two species and the differential capacity for cooperative endeavors.

Povinelli and Vonk (2003) are skeptical that any analysis in terms of merely gradualistic or quantitative differences captures the full extent of the gap between chimpanzee and child. They propose instead that at some point in human evolution the capacity that we share with our primate cousins—to go below the surface features of particular actions—was ramped up to a qualitatively different mode of apprehension. Specifically, they argue that we human beings have an almost ineluctable tendency to assume that actions are caused by internal mental states. In turn, we regard mental states as having an ontologically distinct status from the actions that they guide. On this view, chimpanzees may “go below the surface” but never conceptualize a gen-

uinely mental substrate, whereas human beings invariably go much below the surface and infer a qualitatively distinct set of states. Indeed, so powerful is that inferential tendency that we human beings are prone to apply it—mistakenly—to our otherwise similar primate cousins, particularly chimpanzees. Povinelli and Vonk (2003) go on to argue that the food competition experiments reported by Tomasello and his colleagues do not allow us to decide between a lean and a rich interpretation of the strategies displayed by the chimpanzee subordinate. Maybe the subordinate is attributing visual experience and knowledge to the dominant but maybe the subordinate is using a much less sophisticated form of behavioral extrapolation: “Don’t go after food if D was present and oriented toward it when it was placed in position; such an orientation is a good cue that D will go after the food.”

The resolution of this debate in primatology is not likely to be rapid or straightforward (Povinelli & Vonk, 2004). Meantime, developmental psychologists may rejoice that the testing of human children is made a great deal easier by the fact that it is possible to talk to them about mental states, to ask them to make predictions about mental states, and to assess the degree to which they voice explanations in terms of mental states. In a later section, I explore the extent to which language is not only a means for the more sensitive assessment of the child’s social cognition but also an intrinsic part of human social cognition.

IS THERE A UNIVERSAL CORE TO THE HUMAN THEORY OF MIND?

In arguing for a universal core to the human theory of mind, stable across diverse cultures, Fodor (1987) observed, “There is, so far as I know, no human group that doesn’t explain behavior by imputing beliefs and desires to the behavior. (And if an anthropologist claimed to have found such a group, I wouldn’t believe him.)” As Avis and Harris (1991) noted, Fodor might have couched his incredulity in less hypothetical terms. In a classic monograph on the Dinka of southern Sudan, the Oxford social anthropologist Godfrey Lienhardt (1961) asserted just such an absence of mentalistic explanation: “The Dinka have no conception which at all corresponds to our popular conception of the ‘mind’ as mediating and, as it were storing up the experiences of the self. . . . What we should

call the ‘memories’ of experiences, and regard therefore as in some way intrinsic to the person . . . appear to the Dinka as exteriorly acting upon him” (p. 149).

The available evidence tends to bear out at least part of Fodor’s proposition. First, Wierzbicka (1992) has suggested that all human languages contain terms that roughly refer to wanting, thinking, and knowing. Second, cross-cultural studies have shown that children from radically different cultural backgrounds understand false beliefs even if the age of mastery is variable. Children growing up in industrialized centers of Western Europe, North America, and Asia solve the false-belief task at around 4 to 5 years of age (Wellman et al., 2001). Much the same age of mastery emerged in a more wide-ranging comparison of children attending urban preschools in India, Thailand, Canada, and Peru as well as a village preschool in Samoa (Callaghan et al., 2004). On the other hand, Vinden (1999) found that Mofu children from Northern Cameroon and Tolai children from Papua New Guinea could generally solve false-belief tasks only at around 7 years of age. Vinden also tested Tainae children in Papua New Guinea, but a variety of problems—including the reluctance of young children and females to be tested and difficulties in formulating one of the key test questions in the vernacular—render the results hard to interpret. The potentially crucial role of language was highlighted in another study reported by Vinden (1996). She tested 4- to 8-year-old Junín Quechua children growing up in a remote Quechua village in Peru. Most children passed an appearance-reality task—although there was a clear improvement with age. However, most children failed to solve false-belief tasks even when the same materials were used as for the appearance-reality task. They could usually say that an object that looked like a rock was really a sponge, but they often erred in saying what they had thought the object was before they touched it and what a newcomer would think it was before touching it. However, in Junín Quechua, “What would he think” is rendered by a phrase meaning (roughly) “What would he say.” Thus, Junín Quechua children may have been unfamiliar or uncomfortable with the phrasing of the false-belief questions.

Summing across these studies, there is persuasive evidence from many different settings that children come to an understanding of false belief by about 5 years of age. Nevertheless, some reports indicate that children do not master the standard task until about 7 years of age—or persist in failure even beyond that age. For the moment, caution is needed in interpreting delayed mastery.

As acknowledged by Vinden (1996), language difficulties may play an important role. Studies of Western children provide convergent evidence of the critical role of language and there is every reason to expect that language will be equally important in non-Western settings.

How do children from different cultures fare on other mental-state tasks? With respect to emotion, we saw in an earlier section that children readily link particular situations with particular emotions and then gradually realize that individual desires and eventually beliefs may modulate a given individual's reactions to a situation. Only a limited amount of research has examined this claim in a cross-cultural context, but the scattered findings lend some support to the universality thesis. For example, Harris et al. (1987) asked children in Europe and a remote village of Nepal to describe what situations would be provoked by various emotions. Children in both settings suggested appropriate elicitors for various basic emotions. Vinden (1999) found that Mofu and Tolai children could predict from about 5- or 6-years that someone would be upset by an unexpected loss—not finding some fruit where it had been left.

Avis and Harris (1991) showed that most Baka 5-year-olds growing up in the rain-forests of Southeast Cameroon understood that someone approaching a pot and wrongly believing it contained food would be happy before lifting the lid but sad afterward. Tenenbaum, Visscher, Pons, and Harris (2004) observed a similar understanding of belief-based emotion among Quechua children ranging from 8 to 11 years. However, Vinden (1999) found little evidence for the understanding of belief-based emotions among the Mofu or Tolai.

Harris and Gross (1988) reported that children in Western Europe, North America, and Japan all come to differentiate felt and expressed emotion at around 6 years of age. Sissons Joshi and MacLean (1994) obtained similar findings among children in India. For the time being, we do not know whether and how children from a preliterate community come to make that distinction but like the concept of false belief, the concept of hidden, unexpressed emotion seems a good candidate for universality.

In sum, although linguistic obstacles have sometimes led to inconclusive results, children growing up in non-Western settings, including traditional rural villages, acquire an understanding of belief at roughly the same age as Western children. They can also identify what situations will provoke particular emotions and use that knowledge to anticipate how someone will feel. Some

children in these setting also understand belief-based emotion. Regarding various other aspects of mental state understanding, we have, as yet, no evidence. In particular, there has been very little exploration of the possibility that certain basic concepts—for example the distinction between expressed and experienced emotion and the incessant flow of consciousness—are elaborated in culture-specific ways. Certainly, the existing evidence for some degree of cross-cultural stability in the acquisition of key concepts should not be taken to mean that there is no cultural variation in the way that these concepts are put to work and elaborated (Harris, 1990; Lillard, 1998, 1999).

CHILDREN WITH AUTISM

Research on the normal development of a theory of mind was given an important boost in the United Kingdom by a related program of research on children with autism. In 1985, Baron-Cohen, Leslie, and Frith reported that only 20% of a group of children with autism passed a variant of the false-belief task compared to approximately 80% of normal children and children with Downs syndrome of comparable mental age. Leslie (1987) proposed a theoretical explanation by arguing that the well-known limitations in pretend play that are one of the diagnostic signs of autism reflect an innate, modular deficit in the conceptualization of various mental states including belief as well as pretence. My aim here is not to provide a comprehensive review of the syndrome of autism but rather to describe ways in which children with autism depart from—and thereby highlight—the standard pattern of development.

Subsequent research moved rapidly ahead in confirming that children with autism do have a wide-ranging difficulty in grasping false beliefs. First, even if some children with autism succeed in passing variants of the standard task, they frequently fail more complex versions that call for an understanding of beliefs about beliefs (Baron-Cohen, 1989). Second, children with autism are poor at deliberately creating a false belief by lying. For example, even if prompted to mislead a thief but help a friend, they tend to naively help both. This is not due to any insurmountable tendency to be cooperative. When prompted, they are able to act selectively by physically blocking the thief but helping

the friend (Sodian & Frith, 1992). Third, children with autism show just the type of problems with emotion understanding that would flow from a difficulty in understanding beliefs. Whereas they perform quite well in grasping familiar links between situations and emotions (realizing, for example, that a birthday generally provokes happiness but a loss provokes sadness), they perform much less well than controls matched for verbal ability in understanding belief-based emotions (Baron-Cohen, 1991).

Nevertheless, the temptation to conclude that children with autism provide an instance of cognitive development with the theory-of-mind module neatly excised should be resisted. First, in line with normal children, the degree of difficulty that children with autism display on standard false-belief tasks is correlated with their language ability. Thus, autistic children with a verbal mental age of 6 to 7 years have approximately a 20% probability of passing the false-belief task, whereas those with a verbal mental age of 11 to 12 years have approximately an 80% probability of passing (Happé, 1995). Indeed, children with autism could be said to need a greater verbal ability than normal children to achieve the same theory-of-mind result. After all, among normal children a verbal mental age of 4 to 5 years is sufficient to yield a high probability of passing the standard false-belief task.

Second, the apparently clear-cut difference between children with autism and children with some other mental handicap such as Down's syndrome in performance on the false-belief task turns out to be less clear than it originally appeared. More specifically, mentally handicapped children also display a lag, albeit one that is less marked, than that shown by children with autism (Yirmiya, Osnat, Shaked, & Solomonica-Levi, 1998).

Third, there is increasing evidence that children with autism perform quite well on tasks that call for an understanding of other allegedly central concepts for a theory of mind: desire and perception. Tan and Harris (1991) showed that children with autism assert, and re-assert, their desires—even in the face of an interlocutor who initially thwarts them. In addition, longitudinal studies of the spontaneous language production of children with autism show that despite a paucity of references to the cognitive states of knowing and thinking, they do often refer to desires and perceptions (Tager-Flusberg, 1993). Finally, children with autism perform quite well on visual perspective-taking tasks (Hobson, 1984; Reed & Peterson, 1990).

One potential interpretation of these findings is that children with autism follow the same developmental road map as normal children but at a much slower pace—a proposal made by Baron-Cohen (1989). By implication, their problems do not reveal a modular excision but rather an abnormally slow rate of growth in such a module. This interpretation is consistent with the fact that many children with autism do eventually pass the false-belief landmark and with the fact that a minority even comes to an understanding of beliefs about beliefs. It is also consistent with the observation that children with autism have no particular difficulty in talking about their own desires or those of other people. After all, there is solid evidence that the understanding and discussion of desires emerges early in the course of normal development (Bartsch & Wellman, 1995; Harris, 1996; Tardif & Wellman, 2000)—before an understanding and discussion of beliefs. Arguably, children with autism show no obvious delay on the earliest landmarks of a theory of mind but do so increasingly—as their slowed rate of development dictates.

However, this simple delay-based account runs into difficulties if we take a look at so-called precursors or early indices of a theory of mind. If children with autism perform more or less normally with respect to desires, we might expect them to perform without difficulty on all co-occurring or antecedent indices of a theory of mind. Yet, they display clear limitations in three areas: (1) the development of joint attention, (2) engagement in pretend play, and (3) concern for others in distress. I briefly take up each of these in turn.

As discussed earlier, normal infants start to show joint attention behaviors in the 1st year of life. By either following or directing the attention and gaze of another person, they establish a triadic relationship comprising the self, the other person and an object of mutual attention. Children with autism show important restrictions in joint attention (Mundy, Sigman, & Kasari, 1993). Indeed, longitudinal research has suggested that deficits in joint attention are an important early marker for a likely later diagnosis of autism. Baron-Cohen, Allen, and Gillberg (1992) targeted a group of 18-month-olds who had an older sibling with autism and who on genetic grounds therefore were at risk themselves. A small number of these children showed deficits in both joint attention and pretend play; follow-up studies confirmed that these children did go on to receive a diagnosis of autism. Finally, there is no evidence that these difficulties with joint attention are eventually overcome, as one might expect on a

developmental delay hypothesis (Klin, Jones, Schultz, & Volkmar, 2004).

One of the defining features of autism—ever since Kanner's original description of the syndrome—has been a limitation in pretend play. Later experimental analysis has revealed that children with autism are not completely deficient at pretend play. First, with prompting, they engage in simple object-directed pretense (Lewis & Boucher, 1988). Second, if asked to watch an adult engage in object-directed pretense—for example, a pretend pouring or pretend squeezing—they perform competently in working out the likely pretend consequences (Kavanaugh & Harris, 1994). Nevertheless, even if the findings indicate a basic competence for both the production and comprehension of pretense, they also indicate persistent restrictions on fertility and generativity (Harris & Leevers, 2000; Jarrold, Boucher, & Smith, 1996; Lewis & Boucher, 1995). Moreover, as noted earlier, a delay in the onset of pretense, in combination with deficits in joint attention, appears to be an early marker for autism (Baron-Cohen et al., 1992).

Finally, children with autism differ from normal children and mentally retarded children in their responses to the distress of others. When an adult feigns distress or pain, children with autism are less likely to attend to the distressed person, more likely to remain engaged in toy play, and less likely to display concern. This finding has emerged among toddlers with autism (Sigman, Kasari, Kwon, & Yirmiya, 1992) and persists into adolescence (Sigman & Ruskin, 1999).

Taken together, these findings indicate that children with autism do not simply exhibit a delay in the acquisition or onset of an otherwise normal theory of mind. They show early difficulties with joint attention, pretend play, and empathic concern that appear to be quite persistent. Yet, they also show relatively normal progress on an aspect of a theory of mind (notably the understanding of desires) that is generally taken to emerge after the onset of joint attention, pretend play, and empathic concern. These findings imply that the gradual confluence that we see in normal children, more specifically the joint recourse to beliefs and desires in explaining behavior, may bring together two initially separate ontogenetic streams. Stated differently, the findings from autism suggest that the acquisition of a theory of mind is not a single, indivisible process. Children with autism understand some parts of the puzzle but not others.

INDIVIDUAL DIFFERENCES IN PRETEND PLAY AND THEORY OF MIND

As noted in the discussion of autism, Leslie (1987) argued that children's ability to engage appropriately in pretend play, either alone or with a partner, implies that they understand the mentalistic nature of pretense. He further argued that this alleged capacity for meta-representation sets the stage for an understanding of belief. Various commentators have concluded that Leslie's rich analysis of early pretense is wrong (Currie, 1998; Harris & Kavanaugh, 1993, pp. 75–76; Jarrold, Carruthers, Smith, & Boucher, 1994; Nichols & Stich, 2000; Perner, 1993).

Two persuasive objections have emerged: one conceptual and the other empirical. First, contrary to Leslie's analysis, young children could surely engage in pretense even if they did not possess any insight into the mental state of pretending. After all, there is a great deal of evidence that children can hold a belief—including a false belief—well before they show any signs of understanding beliefs as mental states. Toddlers might construe pretense play as a special form of action rather than a special mental state. So, they might think of the pretend action of pouring tea (e.g., the lifting and tilting of an empty teapot) as a special type of action—one that resembles genuine pouring in the motor gesture involved but which is also different in being directed at make-believe tea as opposed to real tea. To see the thrust of this alternative analysis, consider our appreciation of what a mime artist is doing. We see him peel an invisible banana, lift it to his mouth, and bite it. We readily conclude that he is now eating the banana but we do not need to consider the process of mental representation that might be taking place in his mind. It is enough for us to see him directing familiar gestures at an imaginary banana. Similarly, toddlers might construe pretend gestures as familiar actions directed at imaginary props.

The second objection is empirical. Studies indicate that even 4-year-olds, let alone toddlers who are just starting to engage in pretense, do not systematically appreciate that certain mental states are a necessary condition for particular pretend acts. For example, they do not realize that knowing that a kangaroo hops is a necessary condition for pretending to hop like a kangaroo (Joseph, 1998; Lillard, 1993; Sobel, 2004).

However, even if we accept these two arguments against the particular theoretical analysis advanced by

Leslie, it is still plausible that a relationship does exist between the capacity for pretend play and the eventual understanding of belief. One supportive point, noted by Leslie (1987) and corroborated by a good deal of subsequent research, is that even if children with autism are not incapable of pretend play they do show restrictions in generativity and they often show a marked delay in their understanding of false beliefs. It is tempting to see some connection between these two problems. Further evidence for such a connection has emerged more recently from the study of normal children. For example, the frequency of joint proposals (e.g., "You have to stay in my arms" or "Let's make cookies") and of role assignments in the course of pretend play (e.g., "You be mommy") are correlated with children's performance on theory-of-mind tasks (Astington & Jenkins, 1995; Jenkins & Astington, 2000). Similar findings have emerged from other studies (Schwebel, Rosen, & Singer, 1999; Taylor & Carlson, 1997; Youngblade & Dunn, 1995).

It is worth emphasizing, however, that in these various studies, although measures of joint pretend play or role-play correlate with measures of performance on theory-of-mind tasks (typically false-belief and/or appearance-reality tasks), the same does not hold for other aspects of pretense. For example, there is no consistent evidence that the amount of pretense, the diversity of pretend themes, the impersonation of a machine, or engagement in solitary pretend play correlates with performance on theory-of-mind tasks. Thus, role-play, but not pretend play in general, is associated with the understanding of belief (Harris, 2000).

In the next section, the evidence for a strong link between language ability and theory of mind will be reviewed. Granted that relationship, it is appropriate to ask if the relationship between pretend play and theory-of-mind understanding holds up if we take into account the possible contribution of children's language ability. As it happens, this possibility was examined in all the studies cited earlier. In each case, the relationship between pretend play and theory of mind was maintained even when language ability was controlled for, with language ability variously measured in terms of vocabulary, mean length of utterance (MLU), or syntax (Harris, 2005).

In summary, there is a good deal of evidence showing a correlation between children's pretend role-play and their performance on standard theory-of-mind tasks.

That correlation holds up when another potent predictor of children's theory-of-mind performance—their language ability—is taken into account. How should we explain this relationship? Given the objections raised earlier against Leslie's analysis, we need to look elsewhere. Indeed, Leslie's analysis would predict the understanding of belief to be correlated with pretense in general rather than role-play in particular. The findings just reviewed suggest instead that pretend role-play is linked to children's performance on standard theory-of-mind tasks. This link can be interpreted as support for simulation theory, which assumes that the solution to classic theory-of-mind tasks can be reached via a form of role play, in which one's own current situation and knowledge are temporarily set to one side (Harris, 2000). Still, it must be acknowledged that the link between role-play and theory-of-mind performance rests for the moment on correlational data only. Indeed, in one recent correlational study, there was some indication that earlier false-belief understanding predicts later role assignment and joint proposals rather than the reverse (Jenkins & Astington, 2000). Moreover, there have been no intervention studies to assess whether training in role-play leads to better performance on standard theory-of-mind tasks. Nonetheless, we do have the suggestive findings of an earlier research tradition (Smilansky, 1968) showing that educational programs in dramatic play have beneficial effects on children's social cognition in general.

THE RELATIONSHIP BETWEEN LANGUAGE AND THEORY OF MIND

As discussed at various points throughout this chapter, human beings can observe other people's facial expressions and bodily posture for clues to their future intentions. Nonetheless, human beings, unlike any other species, can also talk to each other about their thoughts and feelings. A probable hypothesis is that children's understanding of thoughts and feelings varies with their opportunities to engage in such conversation (Harris, 1996, 1999). There are now four lines of evidence that converge on that claim. First, children's language ability has proved to be a consistent and potent predictor of their performance on assessments of mental-state understanding. Second, children deprived of ordinary access to everyday conversation, notably deaf children,

exhibit a marked delay in their understanding of mental states. Third, parental language that is rich in references to mental states appears to improve children's performance on standard theory-of-mind tasks. Finally, intervention studies that make heavy use of language and explanation produce clear gains in understanding. I discuss key findings from each of these four areas and then ask in more detail about the theoretical implications.

Accuracy in the attribution of beliefs and emotions is strongly correlated with language skill among both normal children and children with autism (Cutting & Dunn, 1999; Happé, 1995; Pons, Lawson, Harris, & de Rosnay, 2003). One possible interpretation of that correlation is that children's early understanding of mental states facilitates the development of language. Recent investigations of early word learning have shown that young children notice what their conversation partner is attending to, or has in mind, when he or she introduces a new word and they use that information to decode the intended referent (Baldwin & Moses, 2001; Waxman & Lidz, Chapter 7, this *Handbook*, this volume). Arguably, children who are particularly sensitive to their interlocutor's thoughts and attitudes might be at an advantage in building their vocabularies or in decoding complicated utterances.

However, longitudinal research does not support this line of interpretation. Astington and Jenkins (1999) assessed the language ability and theory-of-mind performance of a group of preschool children on three successive occasions over a period of 7 months. Theory-of-mind performance was not a predictor of subsequent gains in language. However, language ability at the initial assessment proved to be a good predictor of subsequent improvement in theory-of-mind performance. Thus, children who had superior language skills at the beginning of the study—particularly in the domain of syntax—made more progress in their subsequent conceptualization of mental states. Similar findings were reported by Watson, Painter, and Bornstein (2001) over a longer period of time. Children's language ability at 24 months was a good predictor of their theory-of-mind performance at 48 months.

Further strong evidence that language facilitates the acquisition of a theory of mind has emerged from the study of deaf children. Deaf children perform poorly on standard theory-of-mind tasks compared to hearing controls. This difficulty is not attributable to deafness per se. Deaf children who learn to sign fluently in early childhood—typically deaf children born into a family

with a deaf adult who is a fluent signer—perform at a level similar to that of hearing controls. By implication, it is the delayed access to language and communication—which is typical of deaf children of hearing parents—that impairs performance (Peterson & Siegal, 2000).

Still, two different interpretations of that impairment are feasible. Arguably, those deaf children who are slow to enter into conversation and communication are at a disadvantage in processing the narrative that is normally used to pose a theory-of-mind problem. Alternatively, deaf children do understand the test narrative well enough. Their difficulty arises because they have a genuine difficulty in understanding mental states and notably beliefs. Support for the second alternative was obtained by Figueras-Costa and Harris (2001). Even when deaf children were given a nonverbal test of false belief, one that made minimal demands on their verbal comprehension, they still performed poorly. Moreover, Woolfe, Want, and Siegal (2002) found a delay among late-signing deaf children when they used a pictorial rather than a verbal test of false-belief understanding. Thus, late-signing children appear to be genuinely delayed in their conceptualization of beliefs. It is not that they have difficulty in grasping a verbal test procedure.

Families vary in terms of the conversational environment that they offer a young child. Three recent studies indicate the contribution that the mother's language style makes to children's mental-state understanding. Meins, Fernyhough, Wainwright, Das Gupta, Fradley, and Tuckey (2002) asked whether mothers' *mind-mindedness*—the proclivity to treat their infant as an individual with a mind of its own influences later theory-of-mind understanding. To assess mind-mindedness, they identified comments by mothers that were appropriately geared to their 6-month-infants' current focus of attention and demeanor—for example "You know what that is, it's a ball" or "You're just *teasing* me." The frequency of these mind-minded comments predicted children's success on a composite theory-of-mind measure more than 3.5 years later. Ruffman, Slade, and Crowe (2002) found that mothers' mental state language during picture-book sessions at earlier time points in the child's 4th year predicted children's later theory-of-mind performance at later points in that same year. The reverse pattern did not hold—thus, earlier theory-of-mind performance by the child did not predict mother's later pattern of discourse. Finally, in an assessment of 5- to 6-year-olds, de Rosnay, Pons,

Harris, and Morrell (2004) found that mothers' mentalistic descriptions of their child and the child's own verbal ability were positively associated both with correct false-belief attributions and with correct belief-based emotion attributions. Moreover, mothers' mentalistic descriptions predicted children's correct emotion attributions even when the sample was restricted to those who had mastered the simpler false-belief task.

Taken together, these correlational studies suggest that mothers whose conversation is rich in psychological references promote their children's mental state understanding; there is little evidence for the reverse direction of influence. It also looks as if mere loquacity on the part of the mother is not sufficient to promote mental state understanding. Ruffman et al. (2002) found that it was specifically mothers' mental state discourse rather than other aspects of their conversation (e.g., descriptive or causal talk) that predicted children's theory-of-mind performance. Moreover, aspects of the mother-child relationship that might be thought to play a role proved to have little independent impact on mental-state understanding. In particular, the nature of the child's attachment proves to have no predictive significance—once the mother's discourse is taken into account (de Rosnay, Harris, & Pons, *in press*; Meins et al., 2002). Finally, mothers' psychological orientation has a sustained influence. It is evident not only among 3-year-olds but also among 6-year-olds. Her influence definitely reaches beyond the standard index of children's developing theory of mind, namely false-belief understanding.

Confidence in correlational findings is always boosted when they can be supplemented by intervention studies. Two recent interventions are especially informative. Lohmann and Tomasello (2003) gave 3-year-olds who failed a standard test of false belief various types of training. The most effective combined two factors: (1) the presentation of a series of objects—some of which had a misleading appearance (e.g., an object that looked initially like a flower but turned out to be a pen); and (2) verbal comments on what people would *say*, *think*, and *know* about the perceptible properties and the actual identity of these objects. Hale and Tager-Flusberg (2003) obtained similar results. In one intervention, children discussed story protagonists who held false beliefs; in a second, they discussed story protagonists who made false claims. In each case, children were given corrective verbal feedback if they misstated what the protagonists thought or said. Both interventions

proved very effective in promoting 3-year-olds' grasp of false belief.

These two studies confirm that conversation about people's thoughts or claims has a powerful effect on children's understanding of belief. One additional finding underlines the critical role of conversation. When Lohmann and Tomasello (2003) gave children a series of misleading objects but offered minimal verbal comment, the impact on children's mental state understanding was negligible.

These four lines of research, from different laboratories using diverse techniques on a heterogeneous sample of children all confirm a reasonable intuition: Children's own language competence and their access to conversation, especially conversation that deals explicitly with mental states, promotes their theory of mind. This convergence is one of the most exciting developments in recent research on theory of mind and confirms the vigor of the field (Harris, de Rosnay, & Pons, 2005).

TAKING STOCK

Research on the child's theory of mind has been conducted primarily in the cognitive-developmental tradition: the child is seen as a thinker trying to explain, predict, and understand people's thoughts, feelings, and utterances. Less attention has been paid to the consequences of such social cognitive skill for the child's social and intellectual relationships. Below, I briefly review research that begins to address these two lacunae. I discuss the way in which children's understanding of mental states affects their peer relations and their trust in the claims made by other people. I then attempt to take stock of how—after more than 25 years of intense investigation—we should conceptualize the understanding of mind that we see emerging in young children.

Social Cognition and Peer Relations

Insofar as children gradually acquire a theory of mind, it is reasonable to ask about the implications of these conceptual changes for children's wider social behavior. Investigators who have examined this issue have focused on the possibility that children with more advanced social cognition will perform better on various measures of social interaction, particularly with peers.

This predicted link has emerged in several studies of preschool children. Denham, McKinley, Couchoud, and Holt (1990) examined the relationship between preschoolers' accuracy on an emotion-attribution task and their popularity amongst peers. Children with a better understanding of the causes of emotion were more popular with peers, even when the effects of age and gender were controlled. In a study of "hard-to-manage" children, aged 3 and 4 years, Hughes, Dunn, and White (1998) found that poor understanding of emotion was linked to various interpersonal difficulties (e.g., anti-social behavior, aggressiveness, restricted empathy, and limited prosocial behavior), whereas Dunn and Cutting (1999) found that 4-year-olds' with a good understanding of emotion cooperated and communicated more effectively with a close friend during play. Finally, in a longitudinal study of 4- and 5-year-olds, Edwards, Manstead, and MacDonald (1984) found that accuracy in identifying the expression of emotion was correlated with popularity one or 2 years later, even when initial popularity was taken into account.

A similar link between emotion understanding and peer relationships has emerged among school-aged children. Dunn and Herrera (1997) found that 6-year-olds' ability to solve interpersonal conflicts with their friends at school was predicted by their emotion understanding at the age of 3 years. Cassidy, Parke, Butkovsky, and Braungart (1992) reported a positive relationship between children's emotion understanding and their popularity with peers during the 1st year of obligatory schooling. Finally, in a study of 11- to 13-year-olds, Bozacki and Astington (1999) found a positive relation between emotion understanding and social skills as judged by teachers.

These various findings strongly suggest that the understanding of mental states and notably the understanding of emotion facilitates children's interactions with peers both before and during the school years. These are correlational findings, and short of proving the link by means of an intervention study, we cannot be certain of the exact causal relationship. Nevertheless, the link between competence at the identification and analysis of emotion and later peer relationships is encouraging.

On a more cautionary note, Cutting and Dunn (2002) found that there are costs as well as benefits to superior social cognition. Five-year-olds were assessed during their 1st year at school for their sensitivity to teacher criticism. Children's understanding of false belief and

mixed emotions measured 1 year earlier—when they were in preschool—proved to be a good predictor of their sensitivity. More specifically, children who showed a better understanding of thoughts and feelings in preschool were likely to derogate their ability, when asked to imagine receiving criticism from a teacher for a minor error. As Cutting and Dunn (2002) point out, these findings raise important questions about the longer-term impact of social cognitive skills. On the positive side, they may indeed help children to navigate the playground and peer relationships more effectively. At the same time, they may render children more vulnerable to the inevitable slings and arrows of social life, including interactions with teachers.

Social Cognition and Trust

For the most part, investigators have neglected a domain in which children's social cognition is likely to have far-reaching implications: their credulity with respect to other people's claims. Consider the dictum of the Scottish Enlightenment philosopher, Thomas Reid (1764/1970): "In a word, if credulity were the effect of reasoning and experience, it must grow up and gather strength, in the same proportion as reason and experience do. But if it is a gift of nature, it will be the strongest in childhood, and limited and restrained by experience; and the most superficial view of human life shows, that the last is really the case, and not the first" (pp. 240–241). Is there evidence that children become less credulous with age? One of the central findings in theory-of-mind research is that most normal children beyond the age of 4 years realize that sincere claims and beliefs may be false. It would be reasonable to expect that insight to render children less credulous.

Indeed, recent findings confirm that preschoolers do increasingly display selective trust and doubt in the claims made by particular people (Clément, Koenig, & Harris, 2004; Harris & Koenig, in press; Koenig, Clément, & Harris, 2004). When preschoolers are presented with two informants, one of whom makes various claims that the child knows to be true but the other makes either false claims or confesses ignorance, they subsequently trust the hitherto reliable informant but doubt the hitherto unreliable informant. For example when shown an unfamiliar object and offered different names for it by the two informants, children trust the hitherto reliable informant.

Two developmental phases are apparent in children's selective trust (Koenig & Harris, 2005a). Three-year-olds trust a hitherto reliable informant—by seeking information from her and endorsing her claims—and doubt a self-confessedly ignorant informant. They are less selective when invited to choose between a reliable informant and an inaccurate informant. Four-year-olds are selective in both cases: They trust a reliable informant and they doubt not only an ignorant informant but also an inaccurate informant. Arguably, 4-year-olds, attribute inaccurate claims to an informant's mistaken beliefs and adopt an appropriately skeptical stance toward that person's later assertions.

Beyond the particularities of the age change in trust and doubt, these findings call attention to the way that children use their emerging theory of mind to make trait attributions in the cognitive sphere. After a brief exposure to a distinctive pattern of reliability on the part of particular informants, preschoolers anticipate that those informants will continue to differ in terms of their future epistemic reliability. In some ways, there is nothing remarkable about this result. Attachment theory has long insisted, and provided evidence for, the claim that infants can gather and retain information about a caregiver's past emotional availability and use that to forecast how he or she will respond in the future. However, attachment theory has generally emphasized the infant's ability to anticipate a class of overt behaviors on the part of a caregiver—particularly, the caregiver's physical availability and emotional responsiveness. The findings on selective epistemic trust suggest that preschoolers are capable of a deeper type of attribution. They do not base their trait attributions on particular regularities in the overt behavior of their informants—at the behavioral level, mistaken claims have nothing in common with one another. Rather, they base their predictions on regularities in the psychological status and more specifically the epistemic reliability, of their informants (Koenig & Harris, 2005b).

Further evidence that preschoolers are able to assess the epistemic reliability of their informants and do not just focus on behavioral regularities emerged in a study that examined the scope of children's attributions. As in prior experiments, 3- and 4-year-olds were presented with two informants. One proved reliable in that she named a set of familiar objects accurately; the other informant, by contrast, proved unreliable in that she admitting to not knowing the names of any of the objects.

Subsequently, children were shown various novel objects and asked if they knew what they were for. Once they had acknowledged not knowing, children were prompted to seek help from either of the informants. In addition, each informant then offered a different demonstration of what to do with the object. Finally, children were asked to provide their own demonstration. As in previous studies, children were selective: They tended to ask for help from, and trust the help supplied by, the reliable as opposed to the unreliable informant. Thus, after witnessing the differential reliability of the informants in the verbal sphere, children made a relatively global assessment of their epistemic reliability. They displayed selective trust in the information that the two informants provided in the nonverbal sphere of object use (Koenig & Harris, 2005a).

Granted that children increasingly display selective trust and doubt in particular informants how exactly is that selectivity established? We may envisage two different mechanisms. In line with the thrust of Reid's dictum, children might start off by trusting every informant on first encounter. To the extent that informants continue to prove reliable (e.g., say nothing that contradicts what the child knows already and respond appropriately to questions) children would retain—but not add to—their initial stock of trust in that informant. However, whenever informants prove unreliable—by acknowledging ignorance in response to questions or by saying something the child knows to be false—children would accumulate doubt. On this account, selectivity is brought about by growing doubt with regard to unreliable informants rather than by any increment in trust.

Consider, however, a reasonable alternative. Arguably, children add to their stock of trust in an informant whenever he or she makes a claim that the child knows to be correct. Thus, children would be much more likely to believe the claims of familiar as compared to unfamiliar informants. Familiar informants—unlike unfamiliar informants—would generally have ample opportunities to prove themselves trustworthy. On this account, selectivity is brought about by cumulative trust in reliable informants rather than by any increment in doubt.

The first model fits the intuition that a person's false assertions are more distinctive—and make a deeper impression on us—than their true assertions. For example, an evidently false statement by a politician can dramatically undermine their reputation for probity. The second

model fits a different intuition, namely that young children are especially likely to trust the claims of familiar caregivers more than those of relative strangers. Whichever model ultimately proves correct, it is clear that the development of children's epistemic trust is a tractable but neglected domain of research in social cognition. To the extent that theory-of-mind research has shown how young children attribute mental states, the stage is set for understanding how they make different attributions to different individuals depending on their past history.

Emerging Contours in the Child's Theory of Mind

In this final section, I highlight selected major findings and draw them together into a larger conceptualization of the child's theory of mind. Four such findings stand out. First, if we study the progressive steps that children take in understanding mental states, there is now ample evidence that certain mental states are mastered more easily and in advance of others. One particularly robust finding from normal children is that they can conceptualize and talk about individuals' goals and preferences before they can conceptualize and talk about individuals' epistemic states of knowledge and belief (Bartsch & Wellman, 1995; Tardif & Wellman, 2000). A second, emerging finding from the primate literature is that chimpanzees are able to monitor the perceptual states and the associated goals of conspecifics (Tomasello, Call, & Hare, 2003), yet we have no comparable evidence showing that chimpanzees are capable of understanding beliefs (Call & Tomasello, 1999). A third finding from the study of autism is that despite their well-established difficulty in understanding beliefs (Happé, 1995; Yirmiya, Osnat, Shaked, & Solomonica-Levi, 1998), children with autism show no major impairment in understanding perceptual states (Reed & Peterson, 1990) or desires (Tager-Flusberg, 1993; Tan & Harris, 1991). A fourth finding from the study of deaf children echoes the pattern established for children with autism: Deaf children born into a non-signing family display a marked lag in the understanding of beliefs (Peterson & Siegal, 2000) but no detectable lag in understanding perceptual states (Peterson, 2003) and frequent references to desires (Rieffe & Meerum Terwogt, 2000).

A plausible implication of these various findings is that even if investigators often talk in terms of having—

or lacking—a theory of mind, it is more appropriate to acknowledge a bifurcation: The understanding of perceptual states and goals can be achieved despite the handicaps of autism, despite restricted access to language as in the case of deaf children—and indeed despite the absence of any access to language, as in the case of nonhuman primates. By contrast, as discussed in an earlier section, the understanding of beliefs varies with language ability and with access to conversation. Why should there be this schism? My own speculation, set out elsewhere (Harris, 1996, 1999, 2005) and briefly elaborated here, is that among normal children, there are various mind-reading abilities that are probably part of our primate heritage: The ability to detect goals and to monitor perceptual states is part of that heritage, even if we have not yet fully established the degree of variation in the primate order. However, from approximately 2 to 3 years of age, a uniquely human capacity begins to emerge, notably the capacity to enter into conversations that are primarily aimed at the exchange of information. Broadly speaking, in the earliest stage of language acquisition, a great deal of early conversation by young children is instrumental. It is aimed at extralinguistic goals such as the regulation of the interlocutor's attention, perceptual states, and goals. Thus, the interlocutor is invited to pay attention to particular objects and events and to help with particular projects. The topic of conversation is closely tied to objects, events, and possibilities embedded in the immediate situation and there is minimal displacement from the here and now.

However, in the 3rd year of life, there are various signs that the exchange of information via conversation becomes an end in itself rather than a way to regulate ongoing action and to achieve instrumental goals. Children increasingly talk about absent entities and past events (Fivush, Gray, & Fromhoff, 1987; Morford & Goldin-Meadow, 1997; Snow, Pan, Imbens-Bailey, & Herman, 1996). They increasingly seek information by posing questions—not only to facilitate an ongoing plan—but also to gather information about things that they happen to see and hear (Lewis, 1938; Przetacznik-Gierowska & Likeze, 1990; Snow et al., 1996). Finally, when a request is misunderstood, they offer clarification even in circumstances where the request has been granted and clarification serves only an epistemic purpose rather than an instrumental goal (Shwe & Markman, 1997).

In conversations where information is exchanged about absent objects and noncurrent events, any two in-

terlocutors will rarely share exactly the same knowledge base or perspective. Effective conversation therefore depends on the ability of each interlocutor to acknowledge that divergence and to allow for it in conveying what they know, think, and feel about the topic in question. Indeed, many of the speech acts of ordinary conversation—conveying information, asking a question, querying an assertion, or issuing a denial—all turn on the fact that different interlocutors have different perspectives. Studies of nonegocentric communication by preschoolers suggest that they display an early sensitivity to such variation (Menig-Peterson, 1976; O'Neill, 1996; Sachs, & Devin, 1976; Shatz & Gelman, 1973; Wellman & Lempers, 1977).

These comments underline the fact that cooperation that is directed at some practical goal typically has a different set of ground rules from conversation. In the context of pragmatic cooperation, partners can frequently act on the assumption that they share a common goal and a common set of beliefs about how to attain that goal. In the context of conversation, by contrast, differences in perspective and belief, and the acknowledgment and articulation of such differences, are of vital importance for the success and coherence of the conversation. Indeed, the voicing of shared beliefs and common knowledge scarcely amounts to a conversation at all. This key feature of conversation leads to the reasonable expectation that children who often participate in conversation—especially conversation that involves an exchange of viewpoints rather than the negotiation of a pragmatic goal—are likely to perform better on those theory-of-mind tasks that call for an understanding of differences in knowledge and belief. As discussed in an earlier section, there is now ample evidence for this prediction. Deaf children who have access to a native signer in their home perform better on standard false-belief tasks than deaf children who lack such access (Peterson & Siegal, 2000). Children with caregivers who frequently talk about what particular individuals think and know also do well on standard false-belief tasks (Ruffman et al., 2002). Finally, experimental interventions in which such viewpoints are articulated serve to promote false-belief understanding (Hale & Tager-Flusberg, 2003; Lohmann & Tomasello, 2003).

In conclusion, an intriguing irony emerges as we look back over the past 25 years. A major inspiration for research on theory-of-mind was an experiment not with children but with a chimpanzee, Sarah (Premack

& Woodruff, 1978). If my analysis is correct, however, cumulative research increasingly reveals that the type of goal understanding that Sarah displayed has a very different phylogeny and ontogeny from the belief understanding that human children display. Goal understanding is connected to the analysis and pursuit of practical activities. Belief understanding is intimately connected with the ability to engage in conversation with no practical end in sight.

My guess is that we have yet to appreciate just how far children live in different conversational worlds. Not only do families vary in the extent to which they enunciate and discuss conflicting psychological reactions, they also vary in the extent to which they enunciate and discuss conflicting moral, scientific, religious, and historical claims. Moreover, just as family discourse has an impact on children psychological understanding, so it is plausible that family discourse has an impact on children's epistemological understanding. In any given domain, some children will be sensitized to the way that divergent claims can be adjudicated but others will scarcely recognize that alternative claims exist.

Universality versus Cultural Specificity of Drawing Schemas	879
Does Drawing Skill Improve Linearly with Age?	880
MUSIC	881

Participation in the arts is central to human behavior. The earliest humans made art and traces of artistic ability can be seen in nonhuman animals. The arts are critical to the development of cognitive, social, and affective capacities in children and are included in the *Handbook* for the first time in the present edition.

I review the developmental course of the comprehension and production of two major nonverbal art forms, drawing and music, focusing on typical development in the absence of formal training. Research on individual differences and on giftedness in the arts is not covered (but see Moran & Gardner, Chapter 21, this *Handbook*, this volume for a discussion of giftedness). Unfortunately, almost all of the research on drawing and music has been conducted in Western settings, with a few exceptions (reviewed here).

Research on drawing has focused on production whereas research on music has focused on perception. This asymmetry, reflected here, may be due to the fact that the earliest music children produce is song rather than notated compositions. Songs are fleeting, while drawings are permanent and thus perhaps more amenable to study.

For each art form, I consider the following questions:

- What does an investigation into the evolutionary roots of this art form tell us?

Evolutionary Base	882
Historical and Theoretical Approaches	883

Producing Music through Song: Major Milestones in Development	891
Does Musical Skill Improve Linearly with Age?	893
CONCLUSIONS	895
REFERENCES	895

- What historical, theoretical, and methodological approaches have been taken in the study of this art form?
- What are the major milestones in the development of comprehension and production of this art form?

For both drawing and music, I also consider one of the most enduring and provocative questions in the developmental study of the arts—whether development improves linearly with age, or whether some artistic abilities decline with age or are U-shaped, with young children responding more like adult artists than older children. This question is far more acute with respect to the arts than for logical, mathematical, scientific, or moral reasoning, where linear development is the normal expectation.

DRAWING

Drawing is a complex activity that involves motoric, perceptual, and conceptual skills, including the use of schemas and rules specific to pictures (Gombrich, 1977; Thomas, 1995). Adults with no special training in drawing are able to translate a three-dimensional scene into a recognizable two-dimensional representation. While their drawings may not look highly skilled or accurate,

their accomplishment is impressive: They can represent objects in a recognizable manner even though there is little actual similarity between a real-world scene and its small two-dimensional representation.

Pictures pervade our lives—we see them not only in art museums but also in magazines, billboards, cereal boxes, and so on. Pictures can be nonrepresentational (as in designs, abstractions) or representational, and, if the latter, they can be either realistic or nonrealistic. Nonrealistic representations are as easily recognized as realistic ones (witness cartoons, caricatures, and children's drawings). When we read a picture as a work of art (e.g., rather than as a diagram or scientific illustration), we attend to aesthetic properties—specifically we attend to what the picture expresses (properties not literally present such as sadness, agitation, loudness), the style of the work (the artist's individual handprint), and its composition (the organization of its parts and its balance or lack thereof; Arnheim, 1974; Goodman, 1976).

We can speculate about the evolutionary base of the visual arts from what we know about early human art as well as nonhuman capacities in picture-making and picture-responding.

Evolutionary Base

The drawings of the earliest humans, from over 30,000 years ago, are extraordinarily realistic, capturing the fluid contours of the animals they hunted. Cave paintings have been likened in skill to the most highly prized human drawings (e.g., to drawings by Picasso). Cave art testifies to the drive to create art in humans: The earliest humans crawled through tunnels into deep recesses in caves to paint. The function of cave art has been debated (was it to encourage hunters? was it religious?) and we will only be able to speculate on this question. Perhaps the function was purely aesthetic, perhaps it was ritualistic, most likely it was polyfunctional. We also will never know what proportion of the population was able to draw in this way.

The visual arts extend to the nonhuman realm but only in a very limited manner. Apes and monkeys can recognize two-dimensional depictions of objects (Davenport & Rogers, 1971; Zimmerman & Hochberg, 1970; but see Winner & Ettlinger, 1979). Chimps have shown a sense of visual balance: Given a page with a small figure off-center, chimps added marks in a location that balanced the marks (Schiller, 1951). Morris (1967) gave painting materials to Congo, a laboratory chimp, and

noted certain resemblances between Congo's spontaneous paintings and those by very young children. Paintings by chimps in the laboratory have been confused with abstract expressionist paintings, though surely the intentions behind the chimp and adult works were not comparable (Hussain, 1965). Chimps trained in sign language have shown the ability to make a rudimentary drawing and then, using sign language, label the object drawn, revealing an understanding that a mark on a page can stand for something in the three-dimensional world (R. Gardner & Gardner, 1978; Patterson, 1978). And when Premack (1975) gave three chimps a photograph of a chimpanzee head with the face blanked out and offered them the cut out eyes, nose, and mouth, one of the three chimps was able to place these parts in correct position. But the fact remains that no nonhuman animals draw spontaneously, and even when given drawing and painting materials, chimps make only nonrepresentational marks (with the possible exception of those trained in sign language). The achievements of humans in the realm of visual arts are far more impressive, even in infancy.

Historical and Theoretical Approaches

Psychologists have long been fascinated by the oddities of children's drawings when compared to those of even untrained adults. Why do children act out their scribbles as they draw and then give the resulting lines a name that looks nothing like what is drawn? Why do children all over the world today draw humans as "tadpole" figures (a circle with arms and legs radiating out of it, and two eyes) when they know that people don't look like this? Why were two-eyed profiles, such as that in Figure 20.1a drawn by nineteenth-century but not twentieth-century children? Why do they show one object behind another as if the object in front were transparent, as in the "transparent" boat in Figure 20.1b? Why do they draw objects in the same scene from mixed viewpoints, showing, for example, trees "folded out" from both sides of a street, as in Figure 20.1c?

The study of children's drawings began at the end of the nineteenth century with the rise of the field of child development. Early investigators include Barnes (1894), Hall (1892), Kerschensteiner (1905), Lukens (1896), Luquet (1913, 1927), Maitland (1895), Ricci (1887), Rouma (1913), and Sully (1895); for reviews, see H. Gardner (1980), Golomb (2002, chap. 2), and Strommen (1988). Drawings (like language) were seen as a reflection of de-

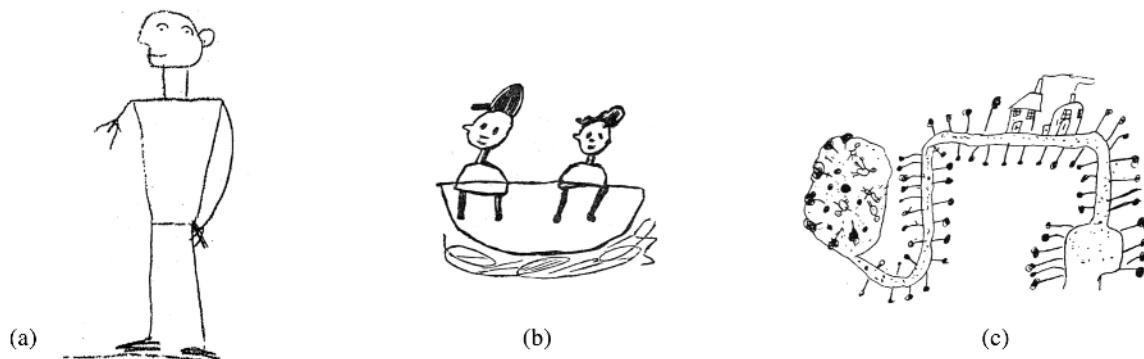

Figure 20.1 Odd features of children's drawings. velopmental stages, and parents, psychologists, and educators began to collect children's markings and to create descriptive taxonomies of drawing stages. The many oddities of children's drawings were seen as deficiencies reflective of children's immaturity and indicative of their incomplete or oversimplified concepts of the objects they were drawing.

The French art historian Luquet (1913, 1927) proposed three phases in the development of realism—a claim that remains influential yet controversial. At ages 3 to 4, Luquet theorized, children are in the phase of synthetic incapacity, or failed realism, in which they are unable to capture the spatial relationships among objects. From 5 to 8, children are in the phase of intellectual realism in which objects are depicted in canonical (stereotypical) position rather than from the particular viewpoint of the child drawing. At this phase, he argued, children draw what they know rather than what they see. Drawings are based on children's internal models (i.e., a table top is drawn as a rectangle because the child *knows* it to be rectangular; a near object appears transparent because the child shows what she knows to be behind it; a cup is always shown with handle even if the handle is not visible because the child *knows* cups have handles).

After age 9, according to Luquet, children enter the phase of visual realism. Now they draw what they see, basing their drawings on how things look from a single viewpoint, even if this means distorting an object by making it partially occluded or by altering its shape (e.g., drawing a table-top as a parallelogram despite knowing it is in reality a rectangle).

Piaget and Inhelder's (1956) studies of children's drawings were influenced by Luquet (1913, 1927), and exemplify this "deficiency/progressing toward realism" tradition. They saw the development of drawing as guided by the child's developing understanding of space. Following Luquet, they described a progression characterized at age 3 to 4 by synthetic incapacity in which children draw bounded objects (e.g., a closed circle) but ignore size and shape. Children at this age draw the human figure as a tadpole, and this figure was understood by Piaget and Inhelder to reflect not deficient perception but deficiencies in spatial representation. From age 4 to about 7 or 8, children were said to enter the stage of intellectual realism where they draw what they know not what they see. At the concrete operational stage, children were said to be able to draw in a realistic way, reflecting their understanding of Euclidean geometry and their emergence from spatial egocentrism. Piaget and Inhelder argued that at this stage the child could represent the third dimension (through occlusion and perspective). Thus, they saw drawing stages as progressive and assumed the desired endpoint to be visual realism. However, few concrete operational age children are able to draw in correct perspective (Willats, 1977), making it difficult to assume a close tie between concrete operational reasoning and realism in drawing (see Golomb, 2004, chap. 4, for further discussion of this issue).

The assumption that children's drawings become increasingly realistic with development led to the use of children's drawings as measures of intelligence, with

higher scores for more detail and more accurate alignment of parts and proportion (Goodenough, 1926; Harris, 1963). Piaget and Inhelder's (1956) description of the shift from intellectual to visual realism, and their assumption that the oddities in children's drawings reflect what children *know* about an object rather than what they *see*, pervaded theories of children's drawings for many years. But as will be shown later, the assumption that the errors children make in their drawings are direct windows into their level of conceptual understanding is wrong. Even adults know far more about an object that they can show in a drawing: We can recognize our errors but simply have not acquired the rules for drawing complex objects or scenes (Golomb, 1973; Morra, 1995; Thomas, 1995). Such a view also reveals a Western-centric assumption of realism as the end state in the history of art. This assumption is misguided because the earliest human art (the art in the caves) is exceptionally realistic and because many cultures did not develop realistic art.

Although the study of children's drawings began with the emergence of the study of child development, this topic was gradually relegated to a minor area of developmental psychology. Just compare the number of developmental psychologists who study memory, language, and number versus those who study drawing. By the 1970s, children's drawings went unmentioned in many developmental textbooks (Thomas & Silk, 1990).

Freeman's (1980) experimental approach to children's drawings helped to revive the study of child art and to bring this study into the arena of cognitive developmental research. Freeman argued that children's drawings reflect production problems rather than conceptual limitations. For example, he argued that tadpole figures, which appear to have no body, stem from the strategy of drawing in linear fashion from head to legs. This causes children to fall prey to the serial order effect, remembering the first and last items of a list (head, legs) but forgetting the middle (trunk). Hence, his "production deficit" hypothesis of children's drawings diverges from Piaget and Inhelder's (1956) view that drawings reflect deficiencies of spatial representation.

Willats's (1995) information-processing theory of picture production (based on Marr's, 1982, theories of the visual system) also brought the study of child art into the arena of experimental cognitive development. Both Willats and Freeman (1980) distinguished between object-centered descriptions (in which shapes are not distorted) and viewer-centered descriptions (in

which shapes are distorted to show how they look rather than how they actually are). What develops, for Willats, is a set of different drawing systems, from topological relations to various kinds of projection systems, with the final one being linear perspective. He also argued that denotation systems develop with two-dimensional regions first standing for volumes and later for surfaces of objects, and with one-dimensional lines ultimately standing for edges and contours. Willats's and Freeman's view that drawings develop from object-centered to viewer-centered descriptions parallels Piaget's view of the movement from intellectual to visual realism. Willats stands out however in his focus on the acquisition of drawing-specific rules for the emergence of visual realism.

In striking contrast to the deficit models of children's drawings was a more positive view put forth by artists and art educators at the beginning of the twentieth century. These artists and educators championed the striking resemblance between child art and emerging styles of Western art—impressionism, cubism, abstract expressionism—and organized exhibitions of child art (Fineberg, 1997; Golomb, 2002; Viola, 1936). Artists such as Kandinsky, Klee, and Picasso used child art as sources of inspiration for their own art (H. Gardner, 1980; Golomb, 2002). Arnheim (1974), the leading spokesperson for the aesthetic view, argued that children's art had its own aesthetics and was not just a sign of children's underdevelopment. He pointed out that many of the distortions and oddities found in children's drawings (e.g., fold-out drawings, lack of depth, transparencies) can be found in non-Western art (Paleolithic, Egyptian, South Sea Island, Kwakiutl Indian art, or pre-Renaissance Western art), showing us how many ways there are to represent and how much tolerance we have for lack of realism (cf. Deregowski, 1984, pp. 120–122). Arnheim (1974) argued that children's drawings are not failed attempts at realism but instead are intelligent solutions to the problem of depicting a three-dimensional world on paper. Arnheim interpreted children's drawings as graphic "equivalents" that are clear and readable and no more "deficient" than nonrealistic art produced by adult artist throughout the centuries.

A serious limitation of much of the experimental research on children's drawing to be reviewed later is the focus on how children represent geometric forms (e.g., copying cubes). Moreover, experimental studies have often used artificial tasks instead of analyzing properties of children's spontaneous drawings. Hence, many

studies yield drawings very different from ones that children produce on their own. For instance, asking children to draw a cup positioned so that the handle is not visible may test whether they incorrectly make the occluded handle visible, but children probably would not choose to draw a cup from observation in their spontaneous drawing. These experimental approaches typically ignore the “aesthetics” of children’s drawings and their ecological validity has been challenged (Costall, 1995). As is discussed later, studies of the development of music comprehension have also been criticized for using artificial stimuli rather than real pieces of music. However, studies using artificial tasks are useful because they test hypotheses about the limits of the child’s capacities.

We turn now to a consideration of how children develop the ability to make sense of pictures, followed by a consideration of how they develop the ability to produce pictures.

Picture Recognition, Comprehension, and Preference: Major Milestones in Development

Understanding pictures requires that one recognize pictures as representations. Understanding pictures also requires the ability to perceive the illusion of the third dimension in a two-dimensional picture, as well as the ability to perceive aesthetic properties of pictures. The development of these abilities is reviewed here, followed by a consideration of children’s aesthetic sense—as measured by the kinds of pictures preferred at different ages.

Understanding the Representational Nature of Pictures: Four Components

The representational information carried by pictures is far more impoverished than information available in the ordinary environment: Objects are smaller than in real life, color is frequently lacking, and edges of objects are often represented by lines despite the fact that objects in the real world do not come with outlines. In addition, pictorial information is contradictory: Certain depth cues suggest the third dimension, while other information (e.g., from binocular and motion parallax) shows the surface of the picture to be flat.

Understanding the representational nature of pictures is four-part: A person must recognize (1) the *similarity* between a picture and what it represents, (2) the

difference between a picture and what it represents, (3) the *dual reality* of a picture as both a flat object and a representation of the three-dimensional world, and (4) the fact that pictures are made with intentionality and are to be interpreted. Infants are excellent at the first two understandings while the third and fourth kinds develop later.

Recognizing the Similarity between a Picture and What It Represents.

Infants need no special instruction in reading pictures, even when these are small black-and-white line drawings (Hochberg & Brooks, 1962), which is a finding consistent with Gibson’s (1979) view that pictures convey the critical information available from the world. Hochberg and Brooks kept their child from seeing any representational images until the age of 2, and then presented him with pictures of familiar objects such as a shoe or key (drawings, then black-and-white photos). The child labeled the pictures correctly, showing that no one needed to teach him to recognize objects represented in pictures. Later research with infants has confirmed this finding (Daehler, Perlmutter, & Myers, 1976; DeLoache, Strauss, & Maynard, 1979; Dirks & Gibson, 1977; Fagan, 1970; Fantz, Fagan, & Miranda, 1975; Field, 1976; Rose, 1977; Ruff, Kohler, & Haupt, 1976). Twelve-month-olds can even recognize line drawings of common objects when much of their contour has been deleted (Rose, Jankowski, & Senior, 1997). Thus, understanding what a picture represents is an untutored skill, in contrast to understanding what a word stands for—an understanding that must be learned because words have an arbitrary rather than iconic relationship to their referents.

The fact that adults in cultures without pictures can, with some effort, read what pictures represent helps to confirm the conclusion from infant research that all one needs to recognize what a picture represents is experience with the actual objects represented (Deregowski, 1989; Deregowski, Muldrow, & Muldrow, 1972; Jahoda, Deregowski, Ampene, & Williams, 1977; Kennedy & Ross, 1975). The exception are those pictorial schemas that are highly conventional (such as the depiction of a flying bird by a W-type shape), and thus, like words, require learning (Nye, Thomas, & Robinson, 1995).

Recognizing the Difference between a Picture and What It Represents.

Are young children realists when it comes to pictures? Piaget argued that children confuse the sign with the thing signified, referring to

this trait as “realism” (Piaget, 1929). If children are realists, they should succeed at recognizing what a picture represents but fail to distinguish a picture from its referent. In one sense, children are *not* realists about pictures. Infants discriminate between photographs and their referents between 3 to 6 months of age (Beilin, 1991; DeLoache, Pierroutsakos, & Uttal, 2003; DeLoache, Strauss, & Maynard, 1979); and 3- to 4-year-olds can readily sort pictures from objects (Thomas, Nye, & Robinson, 1994). For a review of such early pictorial competence, see DeLoache, Pierroutsakos, and Troseth (1996).

But in another sense, children *are* realists about pictures. Despite their ability to discriminate pictures from objects, they sometimes see pictures as “substandard” versions of real objects possessing some of the properties that only the real objects possess (Thomas, Nye, & Robinson, 1994). Ninio and Bruner (1978) described one child who, between 8 to 18 months of age, tried to manipulate pictured objects. Pierroutsakos and DeLoache (2003) described 9-month-olds manually exploring pictures of objects as if they were the real thing. This behavior occurred despite infants’ ability to select the actual object when given a choice between the pictured versus real object (DeLoache, Pierroutsakos, & Uttal, 2003). By 19 months, the infants had stopped grasping at pictures and now pointed to them.

But even preschoolers can become confused. Beilin and Pearlman (1991) gave 3- and 5-year-olds pictures of objects such as a rattle along with life-size photos of the same objects and asked them about the physical and functional properties. Three-year-olds had some difficulty with these questions, especially those about physical properties, sometimes believing, for example, that a picture of a rattle makes a noise when shaken. They had less difficulty with functional properties, usually realizing that one cannot eat a picture of an ice cream cone, for example. Five-year-olds had no trouble with either type of question, and among the 3-year-olds, errors were made only by some. From this study it would appear that by the age of 3, most children are no longer pictorial realists.

Still, young children are not completely clear about the relationship between a picture and what it represents. They believe that a picture shares the fate of its referent, showing that they have not completely separated picture from referent. Beilin and Pearlman (1991) asked the same 3- and 5-year-olds what would happen to a picture of a flower if the real flower it depicted were altered and found that children think that

the picture would change too (though this kind of response was more prominent among the 3- than the 5-year-olds). Zaitchik (1990) reported similar results when she showed 3- and 4-year-olds a toy duck on a bed and took a Polaroid photograph of the duck. Children then saw the toy duck go into a bath and were asked to predict what the photograph would show. Forty percent said that the photograph would show the duck in the bath. The finding that an already completed picture changes to match a subsequent change in its referent was replicated by Charman and Baron-Cohen (1992), Leekam and Perner (1991), Leslie and Thaiss (1992), and Robinson, Nye, and Thomas (1994), though it is not clear whether children believe that the picture actually changes as the referent changes or whether they simply confuse the properties of picture and referent due to forgetting. Thus, there remains support in the domain of picture perception for Piaget’s claim that young children are realists.

Recognizing the Representational Status of Pictures. Children under 2.5 years of age do not grasp that a picture *stands for* its referent. Callaghan (1999) showed 2-, 3-, and 4-year-olds several balls differing in size and features. The experimenter held up a picture to show which ball should be dropped down a tunnel. Two-year-olds could not use the pictures as symbolic objects and thus selected balls randomly rather than selecting the one that matched the picture. Sometimes they even put the picture down the tunnel instead of the object, showing that they treated the pictures as objects.

By 2.5 years, children can understand the representational status of pictures. DeLoache (1987) showed children color photos of a room, each indicating where a toy was hidden in the actual room. The experimenter pointed to one of the photos to show the child where to search for a toy hidden in the room. Children aged 2.5 years could use the photos to find the toys, showing that they recognized the photos as representational objects. However, they could not find the hidden toy in the actual room when their cue was a scale model of the room with a hidden toy in the model. The contrast in findings led to the conclusion that children cannot treat a scale model as both an object and a symbol because they can’t stop thinking of the model as an object. In contrast, they can treat a picture as a symbol because a picture is primarily only a representation and not an object.

However, Callaghan (2000a) has found that children do not fully understand the symbolic nature of pictures until age 3: Under age 3, children rely on verbal labels

to mediate the matching of picture with referent. Further evidence for incomplete understanding comes from DeLoache (1991) who showed that 2.5-year-olds can be fooled into treating pictures as objects and hence fail to see them as symbols. When a miniature dog was hidden behind a photo of a chair (to indicate where the dog could be found in the room), children failed to retrieve the dog from behind the chair. In this condition, they treated the photograph as an object and could not use it as a clue to the location of the toy (see also Dow & Pick, 1992).

Children can actually succeed on DeLoache's (1991) task simply by attending to what the picture represents. Attending to the dual identity of a picture (i.e., recognizing that a picture of a flower is both a flower and a flat piece of paper) is not tested by her task and remains more difficult for children. Thomas, Nye, and Robinson (1994) showed children an actual flower, a color photo of a flower, and a plastic replica of a flower and asked them to label and handle each one. The alternative identity of the plastic and pictured flower was then explained (e.g., it does not really grow in the ground), and children were then asked an appearance question (Does it look like a flower?) and a reality question (Is it really a flower?). Four-year-olds made some errors when asked about the plastic and pictured flower, and most errors were realist ones in which they confused the representation with the referent (saying it both looked like a flower and was a flower).

Thus, while infants recognize pictures, it is not until at least 4 years of age that children fully understand the symbolic nature of pictures and grasp the dual identity of a picture. Some children under age 4 believe that a picture has some of the nonvisual properties of its referent and that a picture changes as its referent changes; some also confuse the picture with its referent when asked to consider both of the picture's identities. These errors could be due to a difficulty holding in mind two interpretations of the same input (Flavell, 1988) or to being confused by the experimenter's questions. Errors might also be the result of how adults talk to children about pictures: We assume an understanding of (and gloss over) the dual identity of pictures, referring to a picture of a horse, for example, as simply "a horse" (Nye, Thomas, & Robinson, 1995). The way out of this confusion may be simply through learning—through experience with pictures.

Acquisition of an Intentional Theory of Pictures.

Full understanding of pictures requires the realization

that pictures are made by someone with a mind. The "artist" interprets what is seen and puts it on paper. Thus, beauty is not directly transferred from world to paper but is a matter of the artist's interpretation of what he or she sees. Moreover, the beholder too has a mind, and this affects how the picture is perceived (Freeman, 1995; Gardner, Winner, & Kircher, 1975).

Snippets of understanding the intentional basis of pictures can be seen in 3-year-olds. Bloom and Markson (1998) asked 3- and 4-year-olds to draw a lollipop and a balloon and both drawings looked the same. Later children were asked to label each, and they used their prior intentions to label each picture. Similarly, 3-year-olds were more likely to label a drawing as a picture of something if told that the picture was drawn intentionally rather than a result of spilled paint.

Richert and Lillard (2002) found that children under age 8 are easily confused about the role of the artist's intention in determining what a picture represents. Even if they are told that an artist had no knowledge of a certain object, if the drawing produced looks like that object, children say that this is what the artist was drawing. Parallel findings were reported by Richert and Lillard in another representational domain—that of pretense: Children under age 8 did not realize that one cannot pretend to be a rabbit if one has never heard of a rabbit.

Studies have not pinpointed what causes the emergence of understanding of the role of intention in drawing. However, one likely catalyst is the experience of having one's own drawings misinterpreted, which could lead children to reflect about how their intentions determine the meaning of their drawings. Another possible mechanism of change is children's developing general ability to introspect (Flavell, Green, Flavell, & Grossman, 1997).

Freeman and Sanger (1993) found that subtle misunderstandings about the role of the artist in picture making persist until adolescence. When children were asked whether an ugly thing would make a worse picture than a pretty thing, most 11-year-olds said yes (revealing a belief that beauty flows directly from the world to the picture), but most 14-year-olds said no (they said that whether the picture is pretty or not depends on the artist's skill). Thus, the older children recognized that the artist determines whether a picture is beautiful. These findings about pictures are but one of many manifestations of a developmental progression in epistemological understanding by which children gradually come to understand that knowledge has its origin not only in

the external world but also in the mind (see Kuhn & Franklin, Chapter 22, this *Handbook*, this volume).

Perceiving Depth in Pictures

To perceive depth in a picture, one must overlook three kinds of cues that indicate that the picture is flat. First, binocular disparity is a cue resulting from small differences in how a scene looks to each eye. The farther away an object, the less disparity between the two views. In a picture, objects meant to appear far away are the same distance from our eyes as objects meant to appear near, which is why binocular disparity tells us that the two objects are on the same plane. Second, binocular convergence is a cue given by the fact that our eyes converge on what we focus on. For near objects, the angle of convergence is greater than for distant objects. This angle of convergence is interpreted by the brain as information about distance. But when we look at a picture, the angle of convergence is identical for images meant to be near and far in the picture because all of the objects are on the same flat picture plane. Third, motion parallax is a cue yielded by moving our head as we view a scene. When we do so, nearer objects are displaced faster than farther ones. But when we move our head in front of a picture, near and far represented objects move at the same rate, declaring the surface to be flat.

These three cues tell us that a three-dimensional scene is three-dimensional, and that a picture is only two-dimensional. How then do we perceive depth in two-dimensional pictures? We do so by ignoring these cues in favor of pictorial depth cues. These include occlusion (near objects partially occlude far ones), linear perspective (receding lines converge toward a vanishing point), size diminution (distant objects are smaller than near ones of the same absolute size), relative height (distant objects are drawn farther up on the picture plane), and texture gradients (textures get denser in the distance).

Infants perceive depth in the three-dimensional world when the nonpictorial cues of motion parallax and binocular cues are available, but they fail to read depth in pictures (Bower, 1965, 1966; Campos, Langer, & Krowitz, 1970). Children between the ages of 2 and 3, however, can judge which of two houses in a picture is farther away using either occlusion cues or the cue of relative height (Olson & Boswell, 1976). The addition of the linear perspective cue of converging lines did not result in improvement in children's pictorial depth perception for 3- to 5-year-olds, who still relied on occlusion and relative height (Olson, 1975). Some studies have

shown that children as old as age 5 can use relative height as a depth cue only in combination with other depth cues, such as partial occlusion (M. Hagen, 1976), or in a context showing the position of the objects with respect to the vanishing point in the picture (Perara & Cox, 2000). For other studies on pictorial depth perception in children, see Olson, Pearl, Mayfield, and Millar (1976); Wohlwill (1965); and Yonas, Goldsmith, and Hallstrom (1978).

While children as young as age 3 can use certain cues to judge whether one object is farther than another in a picture (relative depth judgment), the ability to determine precisely how far away a pictured object is meant to be relative to others develops later. Children as old as age 7 are less accurate than adults on such tasks (Yonas & Hagen, 1973). Even adults fail to make precisely accurate metric judgments about pictures: We read pictures as flatter than they should be read given the pictorial cues (Hagen, 1978). Perhaps the binocular and motion parallax cues that show the picture to be two-dimensional dilute the pictorial cues that yield the three-dimensional illusion.

Cross-cultural evidence suggests that the ability to read depth in pictures is not a skill that requires prior exposure to pictures. Children and adults in cultures with little or no exposure to pictures representing depth can read pictures as representations of three-dimensional scenes (Hagen & Jones, 1978; McGurk & Jahoda, 1975), despite Hudson's (1960) earlier claims that they could not. Like the ability to recognize what is represented in a picture, the ability to perceive depth in a picture may develop simply as a function of experience perceiving the actual world.

Perceiving Aesthetic Properties of Pictures: Expression, Style, and Composition

Most research on the perception of pictures has focused on the perception of representation (the same is true of research on drawing, as is shown later, where researchers focus on the development of the ability to represent). However, a few studies have examined sensitivity to nonrepresentational, aesthetic aspects of pictures—in particular to expression, style, and composition. Detection of these features calls on skills quite different from those required to perceive representational properties of pictures.

Expression. Pictures can express properties they do not literally possess. They can express nonvisual properties (loudness) and moods, doing so via represen-

tational content (a dying tree expresses sadness) or formal properties (dark colors express sadness; note that the depiction of a sad face is a literal rather than an expressive way to depict sadness). Because expressive properties are not literally present in pictures, reading expression in pictures can be considered a form of metaphorical thinking, and expression in art has been referred to as "metaphorical exemplification" (Goodman, 1976).

On very basic tasks, identification of expression in visual forms has been shown to emerge very early and may rely on universal, innate sensitivities. Even babies (age 11 months) have some capacity to perceive cross-modal (visual-auditory) similarities that might underlie metaphors: They can match a dotted line to an intermittent tone (both broken), and a continuous line to a continuous tone (both smooth; Wagner, Winner, Cicchetti, & Gardner, 1981). Preschoolers are sensitive to the expressive properties of abstract (nonrepresentational) stimuli, such as angular lines versus softly curving lines and bright colors versus dark colors (H. Gardner, 1974; Lawler & Lawler, 1965; Winston, Kenyon, Stewardson, & Lepine, 1995), and to expressive properties of certain kinds of representational content (e.g., a dying tree as sad; Winston et al., 1995). Shown abstract paintings, 5-year-olds respond with the same mood labels as do adults (Blank, Massey, Gardner, & Winner, 1984; Callaghan, 1997; Jolley & Thomas, 1994) though studies conflict in their reports of which emotions are best recognized in pictures by young children. When directly questioned about the mood in a drawing, children (including non-Western ones) as young as age 4 are typically correct (Jolley & Thomas, 1995; Jolley, Zhi, & Thomas, 1998a). While children may incorrectly match a "happy" painting (as judged by adults) with an excited face, they do not match it with a sad face, thereby showing a sensitivity to the positive or negative valence expressed by the picture even if they miss the precise mood (Callaghan, 1997). Children make the same kinds of errors when perceiving emotions in faces (Russell & Bullock, 1985). And even 3-year-olds can reliably select paintings that express happy, sad, excited, and calm, but only after first seeing adults modeling these judgments in other paintings (Callaghan, 2000b).

On more challenging expression tasks, young children do not succeed. When simply asked to select an appropriate completion for a picture, one of which matched the mood in the picture (e.g., a wilted tree versus a blooming tree to complete a sad picture), children did not succeed until 10 to 11 years of age (Carothers &

Gardner, 1979; Jolley & Thomas, 1995). Here, no mention was made of mood. When Winner, Rosenblatt, Windmueller, Davidson, and Gardner (1986) asked 7-, 9-, and 12-year-olds to pair abstract and representational paintings on the basis of their expressive property, only the two older age groups performed above chance. This latter task was a challenge because the abstract painting was not labeled for the child as sad, happy, excited, or calm; instead, children had to discern the mood expressed in the abstract picture and then match it to the mood conveyed by the representational picture.

Style. Features that distinguish one artist's style from another are hard to define and include a wide variety of properties such as level of abstraction, texture, brush stroke, color, and light. Children's ability to detect style in works of art has been studied through paradigms in which children are asked to match works by the same artist. Whenever it is possible to match on the basis of representational content, representation trumps style (H. Gardner, 1970). Jolley, Zhi, and Thomas (1998b) showed Chinese and English children triads of pictures and asked them to match two of them. Matches could be made on the basis of color, subject matter, or what was referred to as visual metaphor (e.g., two different objects both broken). Both Chinese and English children matched on color at age 4 and on subject matter by age 7. Though metaphorical matches increased between 7 and 10, subject matter remained predominant at age 10.

In matching tasks in which the choices vary in style but not subject matter, preschoolers and even 3-year-olds can perceive which paintings are by the same artist, though they justify such matches only in global terms such as looking alike (H. Gardner, 1970; Hardiman & Zernich, 1985; O'Hare & Westwood, 1984; Steinberg & DeLoache, 1986; Walk, Karusitis, Lebowitz, & Falbo, 1971). When asked to pick out their own drawing from drawings by a range of children (all of the same subject matter and 3 months after having made the drawing), even 3- to 4-year-olds succeeded, showing that they recognized their own style. Five- and 6-year-olds even recognized their own drawings after a 1-year delay (Gross & Hayne, 1999).

In a more difficult style perception task, children were asked to complete a drawing by adding a person the way the artist would have done it (Carothers & Gardner, 1979). They were given a choice of two drawings of people, one of which used the same line quality as the target drawing. Six-year-olds chose at random, but 9-year-olds selected the completion in the appropriate style of line.

Thus, when only line quality was varied, 6-year-olds failed to match by style. This was a difficult task, however, because children were not directly asked to match by line quality.

Composition. Infants pay attention to the external contour of a pattern but not to the internal organization of its parts (Bond, 1972); sensitivity to the internal structure of a pattern develops gradually between the ages of 4 and 8 (Chipman & Mendelson, 1975). This was demonstrated by asking children to judge which of two patterns identical in external contour was simpler. The ability to look through the content of a painting to perceive its structure develops only by late childhood and early adolescence: When asked to sort groups of four paintings two of which had similar composition and two of which had similar content, classification by subject matter decreased with age with the main decline between ages 11 to 14, and classification by composition increased, with the main increase between ages 7 to 11 (H. Gardner & J. Gardner, 1973).

Taken together, studies of children's perception of aesthetic properties of pictures show that by age 3 or 4, children have the ability to perceive aspects of expression, style, and composition. However, when representational content is pitted against one of these nonrepresentational properties and competes for the child's attention, representation wins out and children ignore the aesthetic property.

Aesthetic Responses

Aesthetic responses to pictures depend on what is perceived in pictures. Little research has examined aesthetic reactions to pictures, and the research that has been carried out has been limited to the study of the kinds of pictures children *prefer*.

The Appeal of Realism. Parsons (1987) documented developmental changes in the bases of children's aesthetic preferences by interviewing children about their responses to different works of art. The 4- to 7-year-olds he interviewed liked abstract works as much as realistic ones. Between ages 7 to 10, children judged paintings as good only if they were realistic in form and color. In early adolescence (ages 10 to 14), expressive properties become more important than realism. By later adolescence, individuals begin to judge works by their social and historical context.

Parsons' (1987) study was carried out on only eight paintings and contained no statistical demonstration of a stage theory of aesthetic judgment. A more quantitative study by Linn and Thomas (2002) failed to find evidence for a stagelike progression in aesthetic preferences: From age 4 to adulthood, individuals used subject matter more often than any other property of a painting in explaining why they like it. Only for art students (who focused on the medium) was subject matter not the dominant criterion invoked, but even for them content was the second most often cited reason for liking a work. Even 2- and 3-year-olds show a preference for realism (McGhee & Dziuban, 1993). For other studies showing the appeal of realism for children, see Machotka (1966) and Rosenstiel, Morison, Silverman, and Gardner (1978).

Children prefer more realistic drawings of the human figure than they themselves can produce, and this finding holds for children at the scribbling stage on up to adolescence (Jolley, Knox, & Foster, 2000). Children also prefer perspective drawings that are more advanced than they themselves can produce (Kosslyn, Heldmeyer, & Locklear, 1977; H. Lewis, 1963). Thus, production lags behind preference (but see Brooks, Glenn, & Crozier, 1988, who found that preschoolers preferred drawings at their own level to drawings that were more complex).

The Appeal of Regularity. Two studies have examined preference for regularity and have shown that children respond positively to balance. Infants (12-month-olds) show a preference for vertical symmetry (symmetry across a vertical axis) over both asymmetry and horizontal symmetry (Bornstein, Ferdinandsen, & Gross, 1981). The preference for vertical symmetry could be due to experience in a visual environment dominated by such symmetry, especially the vertical symmetry of the face and body. And children ages 4, 6, and 10 prefer balanced drawings to unbalanced ones (Winner, Mendelsohn, & Garfunkel, 1981).

Eysenck and his colleagues also reported studies claiming to show a preference for regularity in childhood as well as adulthood, but what he studied was the ability to *distinguish* regular from irregular forms (Eysenck, Götz, Long, Nias, & Ross, 1984; Götz, Borisy, Lynn, & Eysenck, 1979; Iwawaki, Eysenck, & Götz, 1979). Eysenck devised a test consisting of pairs of nonrepresentational forms identical except for the fact that one member had been changed so that eight

artists considered the original to be superior in harmony, design, and “good gestalt.” People taking this test were told that one member of each pair had been deemed more harmonious by art experts. They were told to pick out the less harmonious design and were explicitly told that this was not the same as being asked to pick out the one they found more pleasant. Children from 10 to 17 were tested along with art students over 17 years of age, and no relation was found between “visual aesthetic sensitivity” and age or education. No effect of culture was found when children and adults from Japan, Honk Kong, and Singapore were compared to Westerners.

The work of Eysenck demonstrates that children at least after age 11 are near adultlike in their judgments of what counts as harmonious. However, had the instructions asked for preference, the results might have differed. Perhaps older children or those trained in art would show a greater preference for the irregular forms because they are more surprising.

Telling a Good Painting from a Less Good One. Children often prefer works other than those considered “great” by experts in art. Child (1965) showed 6- to 18-year-olds pairs of pictures similar in style and content but in each case one member of the pair had been judged aesthetically superior by art experts. Participants were asked which one they preferred. Between the ages of 6 and 11, children agreed with the experts only about a third of the time. Between 12 to 18 years, agreement with experts rose, but peaked only at 50% by the oldest age. That agreement never rose above 50% shows that young adults (age 18) do not hold the same aesthetic preferences as do experts in the arts, conflicting with Eysenck et al.’s (1984) claims for universality. These findings suggest either that training in the arts shifts the bases of aesthetic preferences, or that those who go into the arts have different preferences to begin with.

Conceptualizing Aesthetic Preference. Neither children nor adults believe that in the case of conflicting aesthetic preferences only one can be right (Kuhn, Cheney, & Weinstock, 2000). This finding was determined by asking children (8-, 10-, 13-, and 17-year-olds) and adults of various education levels to react to pairs of statements about aesthetic preference: one about paintings, one about music, and one about literature (e.g., Robin thinks the first painting they look at is better. Chris thinks the second painting they look at is better.

Can only one of their views be right, or could both have some rightness?). Those who said only one could be right were classified as absolutists; at no age, did absolutist views predominate (though these views were more common among 7- to 8-year-olds than among older children). Those who said both could be right were then asked whether one view could be better or more right than the other. Those who replied no were classified as multiplists in the aesthetic domain; those who said yes were classified as evaluativists. Most children and adults were multiplists, believing that two conflicting aesthetic preferences were equally right, thereby failing to distinguish aesthetic judgments from matters of personal taste. Only adults with expertise in the study of epistemology were evaluativists, believing that while both aesthetic preferences could be “right,” one could have more merit than another. Adolescents and adults were more likely to have become evaluativists in other domains than in the domain of aesthetic judgment and taste. Thus, they were more likely to respond as evaluativists when asked about conflicting value judgments (how bad lying is), conflicting judgments of truth about the social world (causes of crime), and conflicting judgments of truth about the physical world (composition of atoms). Yet, this finding could be a Western phenomenon. If children from a traditional society, such as China, were assessed, perhaps we would find them more likely to believe that one work of art can legitimately be judged as better than another.

Drawing: Major Milestones in Development

The milestones in the development of picture production are striking, and the oddities of children’s drawings have been characterized by some as indications of immaturity, but by others as indications that in some ways children are like artists.

Action Representations

The first milestone in drawing is the emergence, sometime between the ages of 1 to 2, of the kind of mark making we call scribbling. Using a large sample of preschool drawings, Kellogg (1969) described 20 basic kinds of scribbles (e.g., single curved line, roving open line, multiple loop line, and zigzag) as the building blocks of later representational drawings (but see Golomb, 1981, who was able to identify only two kinds of scribbles—circular loop and whirls, and repeated

parallel lines). According to Kellogg, children use the basic elements of scribbles to make progressively more controlled and complex forms. For example, a vertical and horizontal line together create a cross, which, when enclosed by a circle, becomes a “mandala”; when lines are drawn radiating out from the circle, the mandala becomes a sun or a tadpole human. Kellogg believed that representation emerges only after extensive practice with mark-making and only when adults respond to the child’s “meaningless” forms by pointing out a resemblance to objects in the world (e.g., showing the child how the circle with lines radiating out looks like a person). But studies show that children and adults with no previous drawing experience can, after one or two trials, arrive at drawings of humans that children in our culture achieve only after much practice with scribbling (Alland, 1983; Harris, 1971; Kennedy, 1993; Millar, 1975). Thus, scribbling may not be a necessary precursor to graphic representation (for a review of these claims, see Golomb, 2004, chap. 1). Figure 20.2 shows the first drawings of a 5-year-old boy from the South American Andes who progressed rapidly to human figures (Harris, 1971).

There is also reason to believe that scribbling itself has representational meaning. According to early views, scribbling (the very name suggests something messy and lacking in purpose) is a nonrepresentational activity that children carry out primarily for rhythmic, kinesthetic pleasure rather than for an interest in the marks their motor activity leaves (Kellogg, 1969; Lowenfeld & Brittain, 1964/1987; Piaget & Inhelder, 1956). Evidence that scribbling children are not just carrying out a pleasurable motor activity but are also interested in the marks comes from Tarr (1990), who showed that children pay close visual attention to the marks they make, and from Gibson and Yonas (1968), who showed that when children are given a pencil without lead (and thus with no mark-making capacity), scribbling comes to an abrupt halt.

In scribbles, the act of representation is sometimes carried out through symbolic action and language (Matthews, 1984, 1997, 1999; Wolf & Perry, 1988). Children symbolize an object’s motion as they draw (mimicking the action of a rabbit hopping; e.g., by making the marker hop along the page leaving dots and labeling each dot by saying “hop”; Wolf & Perry, 1988), but the resultant static marks do not capture the action and thus do not reveal to the naive eye what the child has intended to symbolize. Figure 20.3 on page 872 shows an action painting by a 2-year-old who moved the brush

in circular motions while labeling his painting an airplane. Matthews refers to these kinds of early representations as “action representations,” in contrast to later graphic representations where the final marks themselves reveal what they are intended to represent.

Action representations show us that even 2-year-olds grasp the concept that their own drawings are representational (this understanding emerges at about the same time as their understanding that pictures by *others* are representational, as reviewed earlier). A second indication of such representational awareness occurs when children give their scribbles names (called “romancing” or “fortuitous realism”; Gardner, 1980; Golomb, 2004; Gross & Hayne, 1999; Luquet, 1913, 1927). When asked what they have drawn, children ages 2 to 3 are more likely to give representational meanings to broken (angular) curves but to call smooth lines just “lines” (Adi-Japha, Levin, & Solomon, 1998). This finding may be due to a combination of two factors: (1) Broken curves create somewhat more closed forms; and (2) children may pay more attention to these kinds of lines because as they draw them they have to change direction intentionally. When children were asked to interpret scribbles by peers or their own scribbles produced several weeks earlier, they did not differentiate between types of line in this way. A third indication that 2-year-olds grasp the concept that drawings are representational is that they are able to draw recognizable representations of a human figure when the parts of the figure are dictated to them (called “guided elicitation”) and when asked to complete a partially drawn figure (Bassett, 1977; Cox & Parkin, 1986).

Graphic Representations

The first spontaneous graphic representations (ones that depict recognizable objects) emerge in typical children between 3 to 4 years of age (Golomb, 2004). Unlike action representations, graphic representations actually *look like* what they stand for. Even in cultures with almost no pictorial tradition, children make graphic representational drawings when asked by researchers to draw (Alland, 1983). Thus, children do not need to be instructed to arrive at graphic representation, nor do they first need models of representational drawings to do so.

Representing the Human Form. One of the first graphic representations children attempt is the human figure (Golomb, 2004). Children’s early attempts to represent the human figure have been described as “tadpoles” because these representations consist of a circle

with arms and legs (or just legs) emanating from it, as shown in Figures 20.4a and 20.4b. These figures appear to have heads but no trunks (Luquet, 1913, 1927; Piaget & Inhelder, 1956; Ricci, 1887), though Arnheim (1974) argued that the circle represented both head and body.

Children typically draw their first tadpole around 3 years of age (Cox & Parkin, 1986). Some remain in this phase for months, while others pass through this phase rapidly, moving on to more differentiated figures (Cox, 1993, 1997). Though tadpoles appear to have no trunks, Golomb (2004) showed that tadpoles do not reflect a limited understanding of the human body. For instance, when asked to construct a person out of given geometric shapes, only 2 out of 27 3-year-olds made tadpoles; when asked to complete a drawing consisting of a head with facial features, or when asked to model a person

out of Play-Doh, many of the same children who drew tadpoles included a trunk. Figure 20.5 shows drawings by a 4-year-old: When asked just to draw a person she drew an armless tadpole (the two figures on the left); when asked to draw a person with a tummy she drew a body (third figure from the left); and when asked to draw a person with a flower, she included a body and an arm. Thus, the task and the medium influence what is drawn. Tadpoles are not a printout of what the child knows about the human body; when it comes to the tadpole, the old adage that children draw what they know and not what they see has no support. They may not draw what they see, but their drawings do not tell us all that they know about what they draw.

According to Freeman's (1980) production deficit view of children's drawings, tadpoles are defective not because of the child's limited knowledge of the human form but rather because of children's planning and memory deficits. Freeman argues that drawing is a serially ordered performance. When children draw the figure, they begin with the head and end with the legs, forgetting what comes in the middle (trunk and arms), just as when remembering verbal lists we are more likely to remember the first and last word than those in the middle. But there are problems with this performance explanation. Experiments by Golomb and Farmer (1983) show that while children do draw the human starting at the top and moving down, 40% of the 3-year-olds also moved back up, adding arms, facial features, and so on. When asked to list the parts needed to draw a person, children were far more likely to include arms and a trunk than they were when asked to draw a person. As mentioned, when given global instructions (draw a person), 3- to 5-year-olds pro-

duced tadpoles, but when given more specific instructions (e.g., draw a person with a tummy, with a flower), these same children were able to add a torso and an arm (Golomb, 1981, 2004). And when children who spontaneously draw tadpoles were asked to construct a person out of cut out pieces of paper such as circles and rectangles, they often included a torso, showing that they are aware of the torso but just did not know how to include it in their spontaneous drawings (see also Bassett, 1977; Cox & Mason, 1998). Golomb (2004, p. 55) reports cases in which tadpole drawers scrutinized their drawings and criticized them, saying, for example, “The arms are wrong! They go here (points to the shoulders).” These findings fail to support Freeman’s position that failure to remember the trunk and the arms explains why these are omitted from tadpole humans.

Taken together, the evidence shows that defects of knowledge, memory, or understanding do not explain tadpoles. The tadpole is a simple, undifferentiated form that is, in Arnheim’s (1974) terms, a clear structural equivalent for a human reflecting the difficulty of the drawing task, but not reflecting all that the child can do when pushed, prodded, and stimulated by clever tasks and instructions.

Between the ages of 3 to 4.5, as children move from the tadpole to a “conventional” figure with a body differentiated from the head (Cox, 1993), they sometimes draw transitional figures in which the arms are attached to the legs (as in Figure 20.6) and with body features, such as buttons or stomach, sometimes placed between the legs (Cox & Parkin, 1986). The transition from tadpole to conventional figure is variable, with some children passing through a very short tadpole

Figure 20.6 Transitional figure with arms attached to legs.

phase, and others spending many months in this phase. Cox and Parkin found that children often produce tadpoles and conventional figures at the same time. While the mechanism of change from tadpole to conventional figure is not clear, it seems likely that children change when they want to make their drawings fit the model more accurately, and not as a function of seeing models by older children or of explicit instruction (Cox, 1993, 1997).

Early conventional figures are sometimes produced by adding a cross-line between the legs of a tadpole, thereby creating a body (Goodnow, 1977). More often, children draw two vertical lines from the head and join them with a horizontal line at the bottom, and then add two legs under this (Cox, 1997). Most, however, draw a rounded body stuck to the head by starting a line from the head and then bringing it back up again, as the 4-year-old did in Figure 20.7.

At first, children add features such as fingers or feet in a segmented manner, giving each body part its own space with no overlapping (Goodnow, 1977). However, after the age of 5 or 6, children become able to draw with a continuous contour line, as illustrated in Figure 20.8, a method referred to by Goodnow (1977) as “threading.” Cox (1993) found in her sample that 26% of 5- and 6-year-olds, 81% of 7- and 8-year-olds, and 96% of 9- and 10-year-olds drew figures with a continuous outline.

Typically, children (at least in the modern West) draw figures in frontal view but when given specific instructions that call for other orientations (e.g., draw a

man running), many children over five can draw people in profile (Cox, 1993). Figure 20.9 shows a profile drawing by my son at 5 years, 8 months when asked to draw from observation in an art class—he had only a side view of the person he was asked to draw. But even 4-

year-olds make clumsy attempts (e.g., simply leaving out one eye) to alter their figure when asked to draw people from the back or side (Cox & Lambon Ralph, 1996; Cox & Moore, 1994; Pinto & Bombi, 1996).

Realism

Because of the assumption of a universal trajectory from object-centered representation toward viewer-centered optical realism, the dominant question in the study of children's drawings has been how realism develops. Some researchers have asked why children do not at first draw realistically, using perspective (Costall, 1995). Such a question assumes that perspectival drawings are simply tracings of what we see if we could only look with an "innocent eye," and that something prevents children from drawing what they see. According to Sully (1895), an early student of child art, "the child's eye at a surprisingly early period loses its primal 'innocence,' grows 'sophisticated' in the sense that instead of seeing what is really presented it sees, or pretends to see, what knowledge and logic tell it is there. In other words his sense-perceptions have for artistic purposes become corrupted by a too large admixture of intelligence" (p. 396, cited in Costall, 1995, p. 18). A similar analysis was proposed by Bühler (1930), who believed that verbal labels interfere with the innocent eye. "As soon as objects have received their names, the formation of concepts begins, and these take the place of concrete images. Conceptual knowledge, which is formulated in language, dominates the memory of the child" (p. 114, cited in Costall, 1995, p. 18).

More recently, Freeman (1987) proposed a similar view, based on Marr's (1982) theory that the initial stages of visual processing give viewer-centered information about the perspectively distorted projected retinal image, followed by a translation into an object-centered description without the distortion. According to Freeman (1987) it is difficult to move from an object- to a viewer-centered description, because this requires "actively curbing normal perceptual habits" (p. 147, cited in Costall, 1995, p. 21). In short, knowledge gets in the way.

There is however no good reason to believe that children initially see the world in perspective. According to optical scientist Charles Falco, perspective is an unnatural consequence of a fixed lens locked into position pointing in a fixed direction and projecting an image onto a surface. We do not see in this way. Our eyes are constantly scanning a scene, providing our brains with

anything but a fixed perspective (Falco, personal communication, July 7, 2003). It is difficult to draw in perspective, and perspective was a late development in the history of Western art, made possible by the discovery of rules as well as inventions of external devices (e.g., looking at a scene with one eye through an aperture; viewing a scene with one eye through a plane of glass and tracing the scene on the glass) that help the artist adopt a single vantage point from which to draw (Gombrich, 1977; Radkey & Enns, 1987).

Also mistaken is the assumption that perspectively correct pictures are clearer than any other kind. Many nonperspectival pictures, such as cartoons, caricatures, and children's drawings, are highly informative because they capture perceptual invariants such as straightness, bentness, perpendicularity, convergence, symmetry, and so on (Costall, 1995; Gibson, 1973, 1979).

The Trajectory from Intellectual to Visual Realism. Luquet's (1913, 1927) and Piaget and Inhelder's (1956) claim that children do not draw what they see (visual realism) but instead what they know (intellectual realism), is consistent with a nineteenth-century demonstration by Clark (1897) who showed that 6-year-olds drew an apple with a pin stuck in it so that the pin (which the child knew was inside the apple) was visible inside the apple, which thus appeared transparent. Piaget and Inhelder (1956) demonstrated the same phenomenon by asking children to draw a stick shown either from a side view or a foreshortened end view. Children under ages 7 to 8 drew a line or long region for both orientations. It would have been correct to depict the foreshortened stick as a circle, and circles are just as easy for the child to draw as a straight line, but children's depictions of the foreshortened stick were presumed to reflect their knowledge that the stick was long.

Do children draw in an intellectually realistic way because their knowledge interferes or because they can't figure out how to translate a three-dimensional object into a two-dimensional representation? Evidence for the first of these explanations comes from a study showing that when children copied drawings of cubes, they drew much less accurately than when they copied designs, which were matched to the cubes in number of lines and regions (Phillips, Hobbs, & Pratt, 1978). When children knew they were copying a cube, their knowledge that a cube has square faces interfered with realism and they did not distort the faces of the cube by drawing them as parallelograms. Figure 20.10 shows the two models chil-

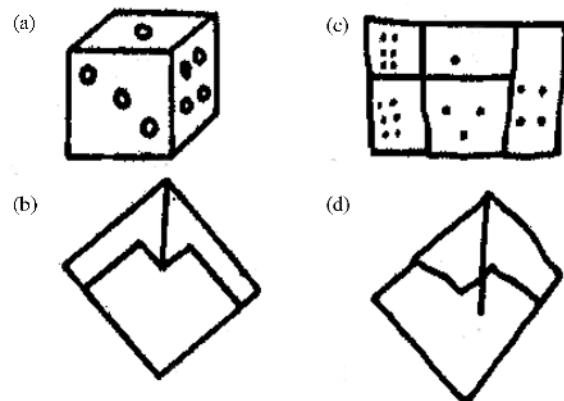

Figure 20.10 Children copy pictures of cubes more accurately than they copy designs. (a) Cube model that children copied. (b) Design that children copied. (c) Intellectually realistic copy of cube. (d) Visually realistic correct copy of design. *Source:* From "Intellectual Realism in Children's Drawings of Cubes," by W. A. Phillips, S. B. Hobbs, and F. R. dren were given to copy, and an example of an intellectually realistic copy of the cube and a fairly correct copy of the design. The fact that they were copying pictures of cubes rather than drawing from a three-dimensional model shows that in this case intellectual realism was not due to the difficulty of translating a three-dimensional image into a two-dimensional one because the drawing they were copying solved that problem for them. Presumably, their knowledge of a cube's actual shape interfered. Phillips, Hobbs, and Pratt (1978) suggest that young children have graphic-motor schemata for specific objects (e.g., when drawing a cube, they draw square faces). When they begin to draw a particular object, they select its corresponding schema; the observation of the object being copied then no longer influences the drawing.

There have been many demonstrations consistent with Luquet's (1913, 1927) original claim of a phase of intellectual realism followed by visual realism. One of the most often cited kinds of examples are X-ray or transparency drawings (Crook, 1984). For other research on children's development toward visual realism, see Barrett and Light (1976); Beyer and Nodine (1985); Bremner and Batten (1991); Bremner and Moore (1984); Chen (1985); Chen and Cook (1984); Colbert and Taunton (1988); Cox (1978, 1981, 1986); Crook (1985); A. Davis (1985); Freeman (1980); Ingram and Butterworth (1989); H. Lewis (1963); Light (1985);

Light and Humphreys (1981); Mitchelmore (1980); Nicholls and Kennedy (1992); Sutton and Rose (1998); Taylor and Bacharach (1982); Willats (1985); see Park and I (1995), for a review.

While there is ample evidence for intellectual realism in young children's drawings, we need not conclude that such drawings show us *all* that children know about the objects they draw. Young children are quite capable of producing viewer-centered drawings under certain conditions. For example, 6-year-olds who did not typically show occlusion were able to do so when they were asked to draw a toy policeman "hiding" behind a wall (Cox, 1981). Light and MacIntosh (1980) showed that when asked to draw a toy behind a glass, children drew the toy and glass side-by-side; when asked to draw a toy inside the glass, children drew realistically. While children under 7 to 8 draw cups with handles even when the handles are not visible (Freeman & Janikoun, 1972), they draw more accurately when asked to draw the cup exactly as it looks (Barrett, Beaumont, & Jennett, 1985; Barrett & Bridson, 1983; Beal & Arnold, 1990; Cox, 1978, 1981; C. Lewis, Russell, & Berridge, 1993; see also Cox & Martin, 1988). For a review of the conditions under which young children can produce viewer-centered drawings, see Sutton and Rose (1998). Thus, intellectual realism is best seen as a typical strategy rather than a full-blown stage.

Luquet (1927) argued that the shift to visual realism occurs because children recognize their drawings as failed in terms of realism and are therefore motivated to invent better methods. Piaget and Inhelder (1956, p. 178) argued, more plausibly, that the shift to visual realism occurred as a result of children becoming more aware of their own viewpoint. But Willats (1992, 1995) offers another explanation. He showed 4- to 12-year-olds a wooden figure holding a plate and asked them to draw it from both a foreshortened and nonforeshortened view. Four-year-olds made the same drawing from both views (showing that they were using object-centered descriptions that could be called examples of intellectual realism). But two-thirds of the 7-year-olds and almost all of the 12-year-olds changed their drawings in some way to show foreshortening, basing their drawings at least in part on what they saw. Willats reasoned that the foreshortened drawings were not a function of seeing more accurately but rather due to learning rules about line, rules specific to the graphic domain. His 4-year-olds drew single lines for arms (using lines to stand for

linear objects) and round regions for plates (using regions to stand for round objects); a third of the 7-year-olds used regions rather than lines for both arms and plates; 12-year-olds used lines to stand for the edges of both arms and plates (using line to stand for edge rather than object). Only when they used lines to stand for edges were children also able to foreshorten. Willats argues that it is wrong to describe this sequence as moving from drawing what one knows to drawing what one sees because there is no reason to think that 12-year-olds see edges more clearly than do younger children. Rather, children have learned the rule (specific to the graphic domain) of using lines rather than regions as scene primitives, and this rule allows them to foreshorten.

Further evidence that drawing development does not progress by increasingly careful observation of the natural world comes from B. Wilson and Wilson (1977, 1984), who argue that realism is gained when children acquire pictorial schemata. They showed that children are more apt to copy each other's pictures than to draw from life. They reported that drawings by children and adolescents in their samples were always derived from another picture the drawer had seen. Moreover children in different cultures use different formulae for drawing trees, suggesting that they are using different pictures as models (Wilson & Ligtvoet, 1992). These views are consistent with those of Gombrich (1977), who argued that even the most "realistic" artists use pictorial schemata derived from other pictures. All pictures are schematic, but schemata are more obvious in children's drawings because they have fewer schemes and are less able to modify them (Thomas, 1995).

In considering the development of realistic depiction, it is important to remember that even the most realistic picture contains infinitely less information than does the actual scene (Gombrich, 1977), and thus the creation and perception of pictures both always require the ability to infer. Our knowledge of what we are drawing plays some role in allowing us to represent an object pictorially; our knowledge of what is represented in a picture also plays a role in helping us recognize what is represented. As Phillips, Hobbs, and Pratt (1978) point out, recognizing a realistic line drawing of a cube as a solid object requires some measure of what might be called intellectual realism. Our knowledge of what is depicted helps us see the drawing as a cube. There is no pure visual realism operating independently of knowledge.

Representing Depth. Some of the studies reported earlier on the transition from intellectual to visual realism have shown children's difficulty in representing depth. Willats (1977, 1995) uncovered a series of stages that children go through as they acquire the graphic rules for creating the illusion of depth in a drawing. He asked children ages 5 to 17 to draw, from observation, a table with objects resting on it (Figure 20.11a). Five kinds of projective systems and five different sets of drawing rules for mapping objects onto the page were found. Drawings with no projection system were more common among the 5- to 7-year-olds than at older ages (Figure 20.11b). The most common strategy for 7- to 12-year-olds was to draw the table in orthographic projection,

in which the tabletop was drawn as a line with objects resting on it, with the third dimension completely ignored (Figure 20.11c). This is a visually realistic way of depicting a table, and captures the view from eye level. The most common strategy for 12- to 13-year-olds was to use vertical oblique projection (Figure 20.11d), which is a system used in Indian, Islamic, and Byzantine art and never taught in Western art classes. Here the vertical dimension on the page represents the third dimension in the scene (vertical lines represent edges receding into depth). Vertical oblique projection allows children to show their knowledge that a table top is rectangular, but the drawing is no longer visually realistic. Moreover, this system results in ambiguity because it does not

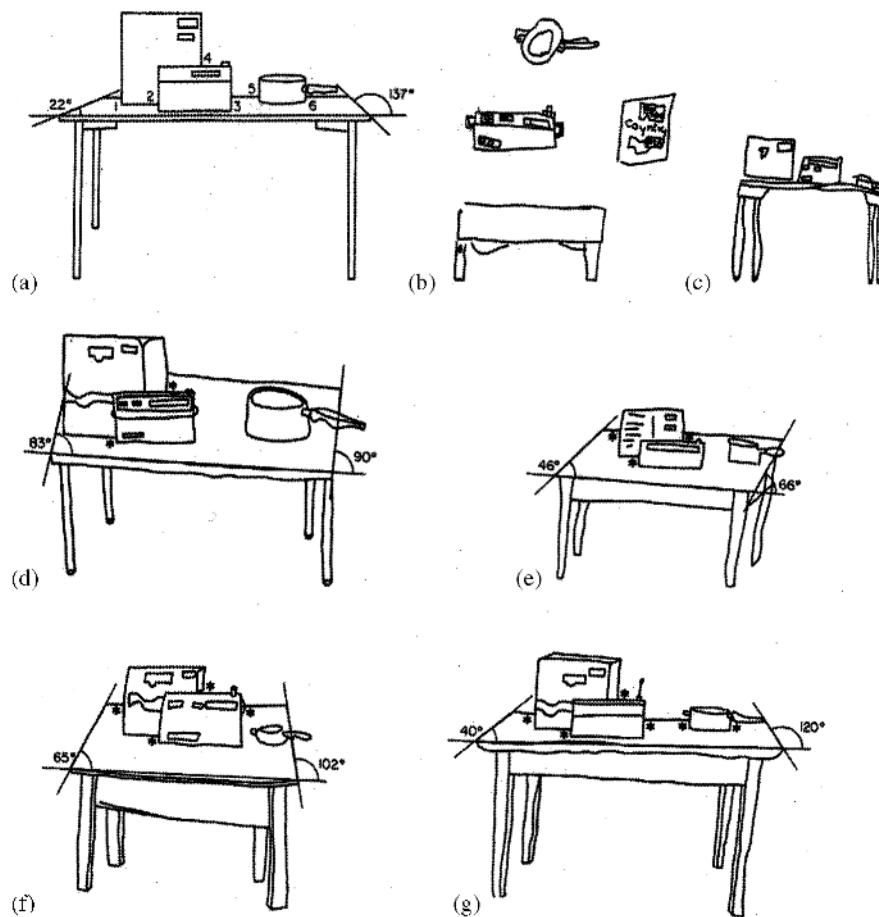

Figure 20.11 Drawings showing varying ways of depicting depth. (a) The tabletop children drew. (b) No projection system and objects float. (c) Orthographic projection with no indication of depth. (d) Vertical oblique projection where depth is ambiguously represented by vertical lines. (e) Oblique projection where depth is unambiguously represented by diagonal lines. (f) Naive perspective where lines converge but not at the correct angles. (g) Correct perspective. Source: From "How Children Learn to Draw Realistic Pictures," by J. Willats, 1977, *Quarterly Journal of Experimental Psychology*, 29, pp. 367–382. Reprinted with permission from the Experimental Psychology Society, <http://www.psypress.co.uk/journals.asp>.

disambiguate between high up versus receding into depth in the actual scene.

Only a minority of 13- to 14-year-olds figured out that one can resolve this ambiguity by using diagonal lines to indicate depth (Figure 20.11e; called oblique perspective—a system used in Asian art for centuries). Children using this system drew the tabletop as a parallelogram with diagonal lines representing edges receding into depth. The price they paid for creating a less ambiguous drawing is that they had to distort the rectangular shape of the table into a parallelogram. Forty percent of the drawings were in oblique projection, despite the fact that children rarely see drawings of this sort in illustrations.

The lines of true perspective drawings converge on a vanishing point; those of naive perspective do not converge sufficiently. Only a few children, between fifteen and a half and seventeen and a half, drew in naive perspective (Figure 20.11f); even fewer at this age drew in true perspective (Figure 20.11g). Consistent with Willats's findings, early collections of children's drawings included few perspective drawings even at adolescence (e.g., Kerschesteiner, 1905). Children in our culture do not naturally begin to draw in perspective, even though perspectival images are everywhere. Those who do draw in perspective have probably had training, or they are gifted in the visual arts (for descriptions of children gifted in drawing who figure out perspective early and essentially on their own, see Golomb, 2004, and Winner, 1996). Other studies of children learning to depict depth include Freeman, Eiser, and Sayers (1977); Light and MacIntosh (1980); Phillips, Innall, and Lauder (1985); Radkey and Enns (1987); and Reith and Dominin (1997).

Willats's stages show the complexity of the development of the ability to represent depth. The stages do not increase linearly in visual realism because the orthographic projections of stage 2 are actually more realistic than the vertical oblique projections that come next. Willats (1977) argued that perspective drawing develops not as a function of increasingly accurate observation of the world or of pictures, but rather due to the desire to reduce ambiguity. This view is consistent with Karmiloff-Smith's (1992) studies of children's overmarking in various domains (including drawing) to reduce ambiguity, and would explain the shift from vertical oblique to oblique perspective. Willats (1984, 1995) goes on to argue, in a manner that echoes Luquet (1927), that development away from object- to viewer-

centered descriptions occurs as children begin to notice that their drawings do not fully capture how the scene really looks and begin to judge their drawings self-consciously in these terms. Children invent increasingly complex systems when they become aware of the limitations of the system they are using.

Aesthetic Properties: Expression, Composition, Style, and Color

We know far less about aesthetic properties of children's drawings (e.g., expression, composition, style, color) than about representational properties, an imbalance that may reflect the assumption that the end state of visual art is realism.

Expression. While preschoolers' drawings appear expressive to adults, we cannot tell from spontaneous drawings whether the expressive properties are intentional. Some intervention is called for. When children were asked to draw a tree to complete a picture that was either gloomy (e.g., picturing a hunched-over figure with dark clouds overhead) or cheery (e.g., picturing a skipping person on a sunny day), they were unable to add expressively appropriate trees (e.g., drooping or dying tree versus blooming tree) until the age of about 11 (Carothers & Gardner, 1979). This finding would suggest that young children cannot intentionally express moods in their drawings. However, when instructions make it clear that children are to attend to expression, children succeed at a much younger age. This was shown in three studies. Asked directly to make a sad, happy, and angry tree, and a sad, happy, and angry line, even 4-year-olds succeed 37% of the time (Ives, 1984). In a study using equally explicit instructions, Winston et al. (1995) asked children ages 6, 9, and 12 to make a drawing of a tree that showed happiness, and one that showed sadness, adding that it did not matter if the tree looked like a real tree. Half of the children were given only a restricted set of colors (none of which could be used to represent a tree realistically), but all of which had been judged by young children to be either happy (e.g., yellow or orange) or sad (e.g., blue or purple). Children in this restricted condition were also told to make the tree without leaves or flowers, to maximize the chances they would use abstract properties to depict mood (e.g., color, line direction, size, or shape) rather than representational ones (e.g., a dying tree for sadness). Every child was able to use at least one strategy for expression. Older children were more likely than younger ones to

use abstract properties expressively, though in the restricted condition, 6-year-olds used color expressively as often as did the 12-year-olds. Finally, when asked to look at a representational picture showing a person in either a happy, sad, calm, or excited mood, to think about the mood shown (but without being given any verbal labels for the moods), and to select from two abstract pictures the one that was most similar in mood (e.g., happy versus sad for the happy or sad target; calm versus excited for the calm or excited target), children performed above chance by age 4 or 7 (but not by age 3 or 8; Winner et al., 1986).

Thus, we can conclude that when directly asked to show certain very basic moods in their drawings, preschoolers show some ability to do so; by age 6, children reliably show moods in their drawings when asked to do so; and when their color choice is restricted to colors that cannot be used representationally to depict certain objects, 6-year-olds can use the abstract property of color to express moods. These findings are consistent with ones reported earlier showing that preschoolers can, under certain conditions, *perceive* expressive properties.

Composition. Studies of compositional principles in children's drawings show a development toward order and balance (Golomb, 1987, 2004; Golomb & Dunnington, 1985). Golomb and Farmer (1983) analyzed compositional principles found in over 1000 drawings of about 600 children ranging from 3 to 13 years of age. The most primitive compositional strategy, seen only infrequently in the drawings of 3-year-olds, was an aspatial one in which figures were placed arbitrarily across the page. This strategy was followed by a proximity strategy in which objects were clustered together. Both of these strategies gave way to alignment and centering.

The alignment principle was seen as young as age 3, with objects partially aligned side by side along an imaginary horizontal axis. The alignment is only partial because objects still appear to float about in space. Partial alignment was used by 3-year-olds 55% of the time in Golomb's (2004) samples. By age 4, figures were aligned carefully and evenly across the horizontal axis. Five- and 6-year-olds continued this strategy, but clearly located the figures at the bottom of the page, with the empty space on top representing the sky, thus defining up and down (see also Eng, 1931).

The centering principle can be seen in drawings of 3-year-olds. The earliest use of centering consists of a sin-

gle figure placed in the middle of the page. This results in symmetry (recall that by 12 months of age children prefer vertical symmetry over asymmetry; Bornstein, Ferdinandsen, & Gross, 1981). Golomb (2004) found this kind of simple centering in 15% of 3-year-olds' drawings. By age 4, several figures may be balanced around the center (36% of 4-year-olds' drawings were centered). By age 5 and 6, symmetry was created by equal spacing of figures and repetition of elements. An increase in symmetry with age was also reported by Winner, Mendelsohn, and Garfunkel (1981).

Balance can also be achieved without symmetry, when different qualities counterbalance each other (e.g., a small bright form may be balanced by a larger pale form because brightness lends weight; Arnheim, 1974). This kind of "dynamic balance" was found by Winner et al. (1981) in 25% of drawings by children aged 4, 6, and 10. In contrast, dynamic balance was seen rarely by Golomb (2004), who found little change in compositional strategies after the ages of 9 to 13, perhaps due to children's competing interest in realistic depiction.

Style. Some children have recognizable drawing styles by age 5. This was demonstrated in a study in which adults judged the similarity relationships among pairs of drawings by three 5-year-old children (Hartley, Somerville, Jenson, & Eliefja, 1982). Their judgments showed that drawings by two of these children were cohesive, meaning they had a distinctive style. Judges were also able to recognize new drawings by the same two children drawn at the same time as well as 9 months later. An even stronger demonstration that children have persistent drawing styles was reported by Pufall and Pesonen (2000) who found that adults who learned to recognize the style of three 5-year-olds could identify drawings by these children done 4 years later. But Watson and Schwartz (2000) showed that only about a third of the children in their sample showed a distinctive style, with younger ones (5- to 8-year-olds) showing greater distinctiveness than older children (9- to 10-year-olds). Perhaps this decline is due to drawings in middle childhood becoming conventional, stereotyped, and less playful than those in the preschool years, as is discussed later.

Universality versus Cultural Specificity of Drawing Schemas

Many aspects of drawing development appear to be universal and to emerge independently of culture and

formal training (Alland, 1983; Anati, 1967; Belo, 1955; Dennis, 1957; Fortes, 1981; Golomb, 2004; Havighurst, Gunther, & Pratt, 1946; Jahoda, 1981; Kellogg, 1969; Kerschensteiner, 1905; McBride, 1986; Paget, 1932; Ricci, 1887; Sundberg & Ballinger, 1968; B. Wilson & Wilson, 1984). Yet, strong cultural differences in children's drawings also exist. For example, perspective is rarely found in the art of children (or adults) who are not exposed to realistic graphic representations (Golomb, 2002, chap. 4). And schemas for representing particular objects vary across cultures. For example, B. Wilson and Wilson (1981) report that many schemas in children's figure drawings common in the nineteenth century are rarely seen today, a finding which they attribute to the importance of models for children to copy. One such feature is the two-eyed profile. Ricci (1887) found that 70% of Italian children's profiles had two eyes, and half of Sully's (1895) English children's drawings were two-eyed profiles. In the Florence Goodenough "Draw a Man" collection of children's drawings amassed between 1917 to 1923 and housed at Pennsylvania State University, only about 5% were two-eyed profiles. By the 1950s, these figures were nowhere to be seen in American children's drawings. The demise of the two-eyed profile has been attributed to the decline of the profile as the culture's most characteristic pictorial view of the face and the rise of the daily comic strip with figures in every possible orientation (B. Wilson & Wilson, 1981). Wilson and Wilson note many other features that used to be found in children's drawings but are no longer: For example, ladder mouths (where the mouth looks like a horizontal ladder, with the rungs being the teeth), hands like garden rakes, and milk-bottle shaped bodies. Wilson and Wilson predict that future investigators may wonder about the origin and decline of figures with big biceps and capes flying through the air. Children's drawings, Wilson and Wilson remind us, do not emerge from some kind of innate program but instead are heavily influenced by the cultural models available to the child to copy.

The powerful effect of the pictorial culture was also demonstrated by B. Wilson and Wilson (1987) in a comparison between drawings by 12-year-olds from Egypt versus Japan. The Egyptian children were exposed to few pictures and had little arts instruction in school. Their drawings of human figures were static, figures floated in space, and there were only primitive attempts to depict depth. In contrast, the Japanese children were heavily exposed to images in Japanese comic books (and

also had a richer arts education). Their drawings of humans looked very much like the images in the comic books that they read: The drawings were dynamic (the figures were depicted in motion), complex (there were many figures), the figures were grounded, and depth was represented through occlusion and size diminution.

Winner (1989) noticed the strong influence on Chinese children's drawings of cartoonlike images published in children's magazines. Wilson (1997) made the same observation about Japanese children who now draw humans with heart-shaped faces and huge eyes, images copied from popular comic books called *Manga*. Moreover sequential graphic narratives are far more common among Japanese children (showing the influence of *Manga*) than they are among Egyptian children (B. Wilson & Wilson, 1987; for other work on cultural influences on drawing, see Andersson, 1995a, 1995b; Court, 1989; Cox, 1998; Cox, Koyasu, Hiranumu, & Perara, 2001; Martlew & Connolly, 1996; Piaget, 1932; Stratford & Au, 1988; B. Wilson & Wilson, 1977, 1984).

Does Drawing Skill Improve Linearly with Age?

While all would agree that technical drawing skills improve steadily with age, including the ability to draw realistically, researchers disagree about whether aesthetic properties of children's drawings improve linearly with age. Some aspects of drawing ability have been shown to be U-shaped, declining after the preschool years, only to return again in those children with talent and interest in drawing. Resemblances between the art of twentieth-century masters and drawings by young children (in terms of playfulness, simplicity, expressivity, and aesthetic appeal) have been noted (Arnheim, 1974; Gardner, 1980; Hagen, 1986; Schaeffer-Simmern, 1948; Winner & Gardner, 1981).

Children draw less frequently as they grow older (Cox, 1992; S. Dennis, 1991; Golomb, 2002) and drawings become conventional and lose their playfulness by age 9 or 10 (Gardner, 1980). A similar decline has been reported in the domain of metaphor (Winner & Gardner, 1981): Understanding of metaphor improves linearly with age, but the willingness to play with language and create metaphors dips in the middle school years, giving way to a desire to use words in a literally correct manner.

Support for the observation that the playful aspects of drawing decline with age during the literal stage, but emerge again in adolescence, comes from a study show-

ing that young children are more willing to violate realism than are older children (Winner, Blank, Massey, & Gardner, 1983). Children ages 6 through 12 were given copies of black-and-white line drawings by artists varying in level of realism (e.g., a realistic Picasso versus a nonrealistic Picasso) and each with a small portion of the drawing deleted. Children were asked to finish the drawings the way the artist would have done. When the drawings were representational, children were told to add the "hair" or the "arm" and were shown where the drawing was incomplete. Responses were scored by whether the level of realism in the drawing was matched in the completion. Six-year-olds performed better than both 8- and 10-year-olds and did as well as the 12-year-olds. Thus, for example, 6-year-olds completed a schematic, nonrealistic Picasso drawing with a missing arm by adding an arm with a nonrealistic, schematic hand; they completed a realistic Picasso, also with a missing hand, with a far more realistic hand. In contrast, 8- and 10-year-olds completed all works in an equally realistic way. They were preoccupied with trying to draw realistically and thus were unable or unwilling to draw nonrealistically even when this tactic was called for by the criterion of stylistic consistency. Because the 6- to 12-year-olds performed equally well and better than the 8- to 10-year-olds, the willingness to violate realism was found to be U-shaped.

J. Davis (1997) provided the strongest evidence for U-shaped development in drawing. She elicited drawings by the following groups: Those presumed to be at the high end of the U-curve in aesthetic dimensions of their drawings (5-year-olds), those presumed to be in the depths of the literal, conventional stage (8-, 11-, 14-year-olds and adults, all nonartists), and those presumed to have moved beyond the literal stage (14-year-old self-declared artists and professional adult artists). Participants were asked to make three drawings under the following instructions: Draw happy, draw sad, and draw angry. Judges blind to group scored the drawings for overall expression, overall balance, appropriate use of line as a means of expression (e.g., sharp angled lines to express anger), and appropriate use of composition as a means of expression (e.g., asymmetrical composition as more expressive of sadness than a symmetrical composition). The results were clear: Scores for the adult artists' drawings were significantly higher than scores for the works of children ages 8, 11, 14 (nonartists) and adults (nonartists), but did not differ from the scores of two other groups—the youngest children (age 5) and the

adolescents who saw themselves as artists. Thus, only the 5-year-olds' drawings were similar to those by adult and adolescent artists, revealing a U-shaped developmental curve for aesthetic dimensions of drawing. While the adult artists often depicted a mood through nonrepresentational drawings, all but one of the 5-year-olds drew representational works. Thus, artists and young children used different means to achieve equally clear expression.

Pariser and van den Berg (1997) countered that the U-shaped curve is culturally determined—a product of the Western expressionist aesthetic. They found that while Westerners judged preschool art as more aesthetic than that of older children, Chinese American judges, influenced by their own more traditional, nonmodernist artistic tradition, awarded higher scores to older than younger children's art. This finding, if replicated in other studies, shows that the U-curve is a manifestation of how we judge children's art, and could be a product a Western modernist expressionist aesthetic.

The loss of interest in drawing, and the loss of expressiveness in drawing (as perceived by Westerners) in the middle childhood years, may not be inevitable. Arts education plays a very small role in our schools. It is certainly possible (though yet untested) that if the visual arts were taught seriously throughout the school years, no decline in interest or expressiveness would be found.

MUSIC

Music is a near-constant presence in our lives, whether on the radio, TV, elevator, or concert hall, and almost all people love some kind of music. While we may not be able to talk explicitly about what it is that we hear when we listen to music, we have a great deal of implicit knowledge about music, based on certain innate sensitivities (to be discussed later) and years of exposure to the music of our culture.

Because almost all of the developmental research on music has been conducted on Western children exposed to Western tonal music, we know little about development in non-Western musical traditions. However, many musical universals exist. For example, all cultures have a systematic way of organizing pitches that repeat over octaves, and all scales have a limit of about seven pitches within an octave (Dowling & Harwood, 1986). Individuals from different musical traditions share the ability to perceive notes separated by octaves as equivalent (octave

equivalence); and there is a weaker tendency to perceive the perfect fifth as having a special status (Dowling, 1991). Almost all scales divide the octave into five to seven pitches with unequal steps between them (A to A sharp is a half step, A to B is a whole step; the Western diatonic major scale is made up of seven notes; Sloboda, 1985). This property, which leads to a sense of motion and rest or tension and resolution is not found in the regularity of chromatic scales, which have 12 equally spaced notes (and in which, therefore, every tone has equal status), and might account for why chromatic scales have never been widespread (Shepard, 1982).

Although musical universals exist (as do universals in drawing), we also know that exposure to the music of one's culture has a profound effect on musical development. Western music, whether folk, rock, classical, or songs sung to infants, consists of a fairly small set of musical relationships, which form the basis of all of our music, and from which composers often deliberately deviate to create tension and affect (Lerdahl & Jackendoff, 1983; Meyer, 1956, 1973). How we hear music is constrained by our years of exposure to these basic relationships. Adults in Western culture have internalized tonal structure and tonality organizes our perception of music (D. Bartlett, 1996; Dewar, Cuddy, & Mewhort, 1977; Frances, 1988; Krumhansl, 1979; Lipscomb, 1996). For example, the major scale is the most common structure found in Western European music, and Western listeners find it easier to recall melodies in the major scale than in any other kind of scale (Cuddy, Cohen, & Mewhort, 1981).

Evolutionary Base

Evidence of music making exists in every known human culture, from hunter-gatherers to industrial cultures (Miller, 2000). Evidence that Neanderthals had music comes from the discovery of a flute carved out of the bone of a bear and dated between 42,000 and 82,000 years ago (Wallin, Merker, & Brown, 2001). This bone had three holes, with the distance between the second and third hole twice that of the distance between the third and fourth, indicating that this flute played music based on the Western diatonic scale. We should not be too quick to conclude from this discovery that the diatonic scale is the most "natural," however, because other scales may also certainly have been used by Neanderthals or early humans.

Some have argued that music evolved for mate selection (Miller, 2000) or for group cohesion (Hagen & Bryant, 2003). Scholars may never resolve the question of whether music is a complex adaptation that occurred during evolution (Miller, 2000) or a by-product of other abilities that themselves evolved for adaptive purposes (Hauser & McDermott, 2003).

Comparative studies of musical abilities in nonhumans can help to clarify the evolutionary history of music. Here we must make a clear distinction between music production (either singing or with instruments) and music perception. No nonhuman primates sing (Hauser & McDermott, 2003), although one (Kanzi, a bonobo) showed controlled drumming on an object and bobbed his head rhythmically as he drummed (Kugler & Savage-Rumbaugh, 2002). Aside from Kanzi, the only nonhumans known to produce music are birds and bird-song is far more constrained than is human music (Hauser & McDermott, 2003).

With respect to music perception, some striking similarities have been found between human and nonhuman primate abilities. Wright, Rivera, Hulse, Shyan, and Neiworth (2000) trained rhesus monkeys to make same/different judgments of melodies and found that they treated a melody as the same when it was transposed by 1 to 2 octaves in the same key. However, if the transposition was only half or one and a half octaves from the original, the transposition (which was then in a new key) was not heard as the same as the original. This finding shows that monkeys hear two Cs as the same, even though they are separated by eight notes (octave generalization), but they hear a C and a G as different even though they are closer on the scale. Wright et al. also found that the perception of similarity between two notes an octave or two apart occurred only when the notes were part of melodies based on the diatonic scale, and not when atonal melodies were used (melodies whose notes are chosen from the 12 tones of the chromatic scale). We can conclude that nonhuman primates are sensitive to tonality and octave relationships (and we will see that human infants are as well).

Although monkeys show a humanlike sensitivity to musical structure, they do not create music. Hauser and McDermott (2003) argue that this frees us from the burden of explaining the evolutionary function of music. Human musical capacities (or at least some of them) may not have evolved as a special music faculty but instead may have drawn on auditory sensitivities that

evolved for other purposes. Domain-general auditory capacities likely evolved before humans began to make music, and at least some basic human musical capacities depend on these more general auditory capacities. The same kind of argument holds for speech perception: Chinchillas perceive some speech sounds categorically, as do human infants, and from this it has been argued that the mechanisms underlying speech perception originally evolved for auditory perception and were later co-opted for speech perception (Hauser, Chomsky, & Fitch, 2002).

Hauser and McDermott (2003) suggest that the human music faculty may also have co-opted another mechanism for music—the mechanism by which human and nonhuman animals express emotion via vocalization, and the sensitivity that young children have to the emotional message in others' voices. Sensitivity to rhythm may also have evolved for nonmusical reasons. Ramus, Hauser, Miller, Morris, and Mehler (2000) showed that human infants and cotton-top tamarin monkeys could discriminate Dutch from Japanese sentences (languages that have different rhythmic properties). Thus, the ability to perceive rhythm may initially have served purposes other than musical or linguistic ones (given that monkeys have neither music nor language).

Historical and Theoretical Approaches

After von Helmholtz published *On the Sensations of Tone as a Physiological Basis for the Theory of Music* (1877), interest in the acoustics of music was sparked. Perhaps the most influential early music psychologist in the United States was Seashore (1919, 1938). Other early music psychologists included Farnsworth (1928), Mursell (1937), Révész (1954), Stumpf (1883), Valentine (1962), and Wing (1968).

Early music psychologists conflated music perception with acoustics. They focused on the measurement of individual differences in musical aptitude, and numerous tests of musical aptitude were developed (for a review, see Shuter, 1968, chap. 2). The publication of the *Seashore Measures of Musical Talent* (Seashore, 1919) was a seminal event in the psychology of music, offering the possibility of assessing musical ability in children and adults primarily through degrees of acoustical discrimination (e.g., determining which of two tones is higher or louder, or which note in a melody has been altered). Seashore assumed musical ability to

be unaffected by training and to be adequately measured by acoustical tests, views criticized by Farnsworth (1928) and Mursell (1937).

Validity problems with the Seashore measures were noted by Mursell (1937), who found that they did not correlate highly with independent measures of musicality (defined as being in the advanced orchestra in school). This lack of validity did not surprise Mursell because he reasoned that people with good pitch discrimination skill are not necessarily musical. He criticized the atomistic approach underlying these measures. For example, it is quite possible for an individual to hear a melody as changed yet be unable to say which note was altered. Mursell also criticized the Seashore measures for focusing primarily on acoustic properties of music and on sensory capacities, ignoring important musical concepts such as the feeling of resolution when a piece ends. "Music . . . depends on the mind and not on the ear," Musell wrote (p. 57). Mursell called for the development of tests of musical aptitude that assessed judgments of rhythmic and tonal *relationships* (rather than sensory response to isolated elements) as well as affective responsiveness to music. Révész (1954) also pointed out that musical aptitude is not simply an aggregation of acoustical skills.

Since the cognitive revolution in psychology, with its focus on universal mental structures, music psychologists have turned their attention away from tests of individual differences to the search for universal principles of music perception. Psychologists of music have also begun to connect their work closely to the work of music theorists. Cook (1994) links the relationship between music theory and psychological studies of music to the work of music theorist Meyer (1956). Music theorists have developed models of musical grammar, which offer predictions for cognitive psychologists to test, with perhaps the most influential model being the grammar of music initially proposed by Lerdahl and Jackendoff (1983). For reviews of theory driven research in the cognitive psychology of music with the goal of determining the mental structures involved in the perception and interpretation of music, see Deutsch (1982) and Sloboda (1985).

Early developmental research in music consisted primarily of descriptive studies including case studies (e.g., Gesell & Ilg, 1946; Moorhead & Pond, 1978). For example, describing age norms in responses to music, Shinn (1907) reported that children show pleasure at

music at around 6 weeks, and Shirley (1933) noted that children are calmed by music between 12 to 32 weeks of age. For a review of early studies, see chapters 5 and 6 in Shuter (1968).

One of the earliest theory-driven approaches to the developmental psychology of music analyzed children's music perception in the framework of Piagetian theory (e.g., Pfleiderer, 1964; Serafine, 1980). These researchers tried to equate the perception of invariance in music with conservation and hence with concrete operations. In the past few decades, research in the developmental psychology of music has become motivated less by developmental theory than by theories in the cognitive psychology of music.

The new cognitively driven research in the psychology of music (including developmental music research) has not been immune from controversy (see Cook, 1994, and Sloboda, 1985, pp. 151–154). Some have argued that psychologists have too quickly assumed psychological reality for abstract grammars proposed by music theorists in their analysis of music. For example, Cook (1994) argues against the idea of music grammars analogous to linguistic grammars, pointing to evidence that music is more "fluid" than language, and less rule-bound.

Another controversy concerns the use of experimental materials that are short, artificial, and musically impoverished. Sloboda (1985) reminds researchers that in real pieces of music, musical events distant from one another in time may still be closely related. Just as the linguistic study of isolated sentences cannot tell us how we respond to conversations or stories, so the study of short musical fragments (e.g., an interval or a phrase) or isolated musical elements (e.g., pitches or rhythms without melody) cannot tell us about mental activity as we listen to an actual piece of music. The use of short fragments leads us to conclude that music perception is more precisely and analytically rule-governed and less fluid and holistic than it actually is (Cook, 1994). For example, short fragments that do not return to the tonic or the home key sound unfinished; but long pieces of music may well not return to the home key and yet do not sound unfinished Cook (1994). Aiello (1994) calls for more naturalistic studies of how we perceive entire pieces of music as the music unfolds, and reviews several recent studies that do just this. Developmental studies of music perception that are more naturalistic will likely be the wave of the future.

Much of the research reviewed later is subject to the criticisms that the materials on which its conclusions

are based are far from real pieces of music. Similar criticisms—that the stimuli and tasks used are too artificial—have been leveled at studies of children's drawings (Golomb, 2004, p. 40). Yet, hypothesis testing often requires the use of somewhat impoverished stimuli. The tension between those who do experimental versus naturalistic studies can be found in all areas of psychology.

Music Perception and Comprehension: Major Milestones in Development

While the ability to produce music shows wide variation, with some individuals demonstrating more talent than others, all normal humans have a considerable implicit understanding of music. And infants show an impressive perhaps inborn ability to process some (but not all) of the complexities of music.

The lullabies that adults sing to babies have universal properties across cultures, and these may influence early music perception skills. Infants show certain kinds of very early sensitivities to music. These include sensitivity to relational rather than absolute properties of melody and rhythm; sensitivity to unequal step structure in scales, a property that characterizes all scales whether Western or non-Western; sensitivity to certain prototypical structures of Western music; and preference for consonance over dissonance.

Other aspects of music perception develop only in the preschool years or later. These include sensitivity to diatonic tonal structure, sensitivity to key changes, sensitivity to the hierarchy of notes within a key, sensitivity to mode (major versus minor and the emotional connotations of each); and sensitivity to invariant structure. These later developments all involve the ability to go beyond the information given to infer a structure that is not literally present. Western children's sensitivity to these higher order properties of music very likely depends on years of exposure to Western music. Whether we are universally predisposed to acquire the structures used in Western tonal music, or whether we could as easily become acculturated to atonal music, is a question for future research.

Infant Music Perception: Sensitivity to Simple Musical Structures

In many ways, infants process music in an adultlike fashion, suggesting that the ways in which music is processed is biologically constrained and innate. These findings, reviewed here, provide support for Meyer's

(1994) view that “the central nervous system . . . predisposes us to perceive certain pitch relationships, temporal proportions, and melodic structures as well shaped and stable” (p. 289, cited in Trehub, Schellenberg, & Hill, 1997, p. 122). However, because infants are exposed to music in utero and from the 1st day they are born, experience may play a role. Even studies that examine primate musical predispositions are not immune from this possibility because primates may be exposed to music in the lab from radios (Hauser & McDermott, 2003). Only if we can demonstrate humanlike musical predispositions in primates in the wild (not exposed to music) or identical musical predispositions in infants in cultures with entirely different musical traditions can we make the strong argument that certain musical predispositions are inborn and require no musical experience for them to become manifest. This research remains to be carried out.

Music processing in infancy is analogous to speech processing in several ways: (a) Infants must process complex sound patterns with affective rather than referential meaning; (b) there are special forms of music and speech directed to infants; and (c) infants’ lack of acculturation allows them to make certain discriminations in music and speech that adults fail to make, as shown later (Trehub, Trainor, & Unyk, 1993).

Universals in Songs Sung to Infants. In all known cultures, children are exposed to music from early on, particularly in the form of songs sung to them by adults (Trehub & Schellenberg, 1995). Just as infants are exposed to child-directed-speech with certain universal properties, they are also exposed to child-directed-songs with universal properties. The types of songs infants hear are lullabies and “play songs” (Trehub & Trainor, 1998). Much like infant-directed speech, songs directed to infants in Western and non-Western cultures have certain characteristic and universal features that cut across musical traditions. These features are seen when the songs are sung by mothers, fathers, and even preschoolers.

Songs directed to infants are soothing: They are repetitive and have simple, descending contours. Unlike classical Western music or adult Western folk songs, Western nursery songs almost all remain in the same key. Dowling (1988) demonstrated this by coding 223 nursery songs, 317 folk songs, and 44 of Schubert’s songs in terms of whether they contained a key shift. Almost none of the nursery songs, almost half of the adult

folk songs, and almost all of Shubert’s songs contained a key shift. Nursery songs repeat strongly tonal patterns and thus may be particularly helpful for Western children’s learning of the Western tonal scale system (Dowling, 1988). Songs directed to infants are higher in pitch, slower in tempo, and more emotionally expressive than songs directed to older children or to adults (Bergeson & Trehub, 1999; Trainor, Clark, Huntley, & Adams, 1997; Trehub, Unyk, & Henderson, 1994; Trehub, Unyk, Kamenetsky, Trainor, Henderson, & Saraza, 1997; Trehub, Unyk, & Trainor, 1993a, 1993b). Mothers’ singing is stable, almost ritualized: When they sing the same song to their infants, the pitch level, and tempo remain practically unchanged (Bergeson & Trehub, 2002).

These aspects of infant-directed songs are perceivable by adults. Adults can distinguish lullabies from nonlullabies matched in tempo even when these come from unfamiliar cultures (Trehub, Unyk, & Trainor, 1993a). Adults can even distinguish songs *actually* sung to infants from the same songs sung by the same singers *pretending* to sing to an infant. This finding holds for musically untrained as well as foreign adults, suggesting the existence of universal features of songs sung to infants (Trehub, Unyk, Kamenetsky, et al., 1997).

The universal aspects of songs sung to babies capture babies’ attention. Infants listen longer to songs in the maternal style than to songs sung by the same singers in their usual style (Masataka, 1999; Trainor, 1996) and prefer higher to lower pitched versions of songs (Trainor & Zacharias, 1998). Infants also pay more attention to videotapes of their mothers singing than tapes of them speaking (Nakata & Trehub, 2000). These attention-getting universal aspects of songs sung to infants probably help to mold infants’ musical sensitivities.

Relational Processing of Rhythm and Melody.

Like adults, infants perceive rhythms and melodies as coherent patterns rather than sequences of unrelated sounds (Dowling, 1978; Trehub, Schellenberg, et al., 1997). For instance, 7- to 9-month-olds perceive simple rhythmic patterns differing in speed as the same rhythm—they recognize the rhythm despite the change in speed (Trehub & Thorpe, 1989). Chang and Trehub (1977b) demonstrated a similar capacity in 5-month-olds.

Relational processing also occurs for melodies. Contours—the pattern of ups and downs in a melody—are defining properties of melodies for adults (Dowling & Fugitani, 1971) and for infants (Dowling, 1999; Trehub,

2001; Trehub, Schellenberg, et al., 1997). Infants perceive two melodies as the same when one is transposed to a new octave, as long as the relations among tones (and hence the melodic contour) are maintained. For example, 6-month-olds were habituated to a 6-note melody and then exposed to a key transposition either with or without the contour maintained (Chang & Trehub, 1977a). In both cases, the transposition contained all new notes. Infants dishabituated only to the contour-altered transpositions. Because the initial and transposed tune shared contour but not notes, the infants must have "recognized" the melody. Infants are sensitive to alterations in contour, noticing them even when the task is made difficult by inserting distractor tones in between the target and comparison melody (Trehub, Bull, & Thorpe, 1984). Thus, in both rhythm and melody, infants perceive simple musical gestalts, whether these be rhythmic groupings or melodic contours.

Infants are sometimes able to recall absolute rather than relative information when it comes to pitch (Saffran, 2003; Saffran & Griepentrog, 2001). When presented with a target and comparison melody that have the same key or same initial pitch, infants react to pitch changes (Lynch, Eilers, Oller, & Urbano, 1990). For example, when they hear a melody containing a G sharp and then a comparison melody identical except that the G sharp has been replaced by G, infants note the change (Trehub, Cohen, Thorpe, & Morrongo, 1986). But such sensitivity is found only when all other pitches are unchanged. If the comparison melody is transposed, infants do not notice the change from G sharp to G and revert back to focusing on relational aspects of the melody (Cohen, Thorpe, & Trehub, 1987).

Studies claiming a dominance of absolute over relative pitch processing in infancy are based on short-term memory. When 6-month-olds listened to melodies over a period of days they could not tell when the melodies were transposed to a new key and thus recalled relative rather than absolute pitch intervals (Platinga & Trainor, 2002, cited in Trehub, 2003a, 2003b). Storing the relational information is a far more manageable feat of long-term memory than storing separate pitches.

Infants grasp other kinds of structures in music as well as rhythmic and melodic ones, as shown by their greater reaction to structure-violating changes than to structure-preserving changes. For example, when infants repeatedly heard a six-note sequence (e.g., AAAEEE, with A and E one fifth apart), and then heard the same sequence with a temporal gap, they noticed the gap only

when it occurred within (AAAE [gap] EE) but not between (AAA [gap] EEE) groups (Thorpe & Trehub, 1989; see Dowling, 1973, for this finding in adults). And infants also perceive phrases as wholes, as shown by Krumhansl and Jusczyk (1990) who reported the finding that 4- and 6-month-olds prefer to listen to Mozart when pauses are inserted *between* rather than *within* musical phrases. Parallels to speech processing are clear, because infants notice pauses within rather than between sentential clauses (Kemler Nelson, Hirsh-Paske, Jusczyk, & Wright Cassidy, 1989) and are sensitive to melodic contours of speech (Fernald, 1989).

Sensitivity to the Unequal-Step Structure of Musical Scales. As mentioned, almost all music has scales with unequal steps between pitches. Can infants distinguish between scales with unequal steps and artificial scales with equal steps? Trehub, Schellenberg, and Kamenetsky (1999) played one of three types of scales to adults and 9-month-olds: (1) the familiar (unequal step) major scale; (2) an artificial major scale with unequal steps, created by dividing the octave into 11 equal units and selecting seven tones separated either by one or two units; and (3) an artificial equal-step scale created by dividing the octave into seven equal steps. The task was to detect a note that was out of tune. Adults had no difficulty with the major scale, but performed equally poorly on the two artificial scales. Infants did as well on the familiar as the artificial major scale (both have unequal steps). These findings show that unequal step scales are easier to process than are equal step scales. The fact that infants did as well on the artificial major scale shows that their performance with the familiar major scale was not due to familiarity but rather to its unequal step property. The fact that adults performed poorly on the artificial unequal step scale suggests that their initial predispositions were overridden by years of listening to the scales of their culture.

Sensitivity to "Good" Melody Structure or "Good" Intervals. Infants show better processing for melodies that Western music theory considers well-structured. Cohen et al. (1987) showed that 7- to 11-month-olds were better able to detect a semitone change in a transposition of a melody if the transposition resulted in a well-structured melody based on the major triad (CEGEC) than if it resulted in a less well-structured melody based on the augmented triad (CEGsharp EC). Similarly, Trehub, Thorpe, and Trainor (1990) found that

7- to 10-month-olds detected a semitone change (in a transposition) only when the original melody was a “good” Western melody in which all the notes belonged to a major scale (in contrast to a “bad” Western melody with notes not in any scale or to a non-Western melody with intervals less than one semitone apart). And Trainor and Trehub (1993) showed that infants have a processing advantage for transpositions related by a perfect fifth. The most likely explanation for infants’ better performance with certain types of melodies and intervals that are privileged in Western music is that these infants have already acquired a sensitivity to Western musical structure. Yet, we cannot rule out the possibility that certain structures in Western music are intrinsically easier to process than are violations of these structures. To test this, we need to administer these same tasks to infants from a culture whose music does not follow these structures.

Preference for Consonance. Intervals separated by one semitone (e.g., a “second” such as A and B) sound dissonant; those separated by two semitones (e.g., a “third” such as A and C) sound consonant. Pythagoras showed that consonant combinations of tones have different frequency ratios than do dissonant combinations (e.g., the consonant octave has a frequency ratio of 2:1; the dissonant tritone has a frequency ratio of 45:32; Plomp & Levelt, 1965). Intervals related by simple ratios have more overtones in common than do intervals related by complex ratios. Consonant intervals such as octaves and perfect fifths have a special status in much of the world’s music (Frances, 1988; Schellenberg & Trehub, 1996; Trehub, Schellenberg, & Hill, 1997), and studies show a preference for consonance over dissonance in early infancy.

Zentner and Kagan (1996, 1998) played 4-month-olds two unfamiliar melodies in both a consonant and a dissonant version. The consonant version was played in parallel thirds (the third is the interval that adults judge as consonant); the dissonant version was played in parallel minor seconds (the interval judged by adults as most dissonant). Infants looked significantly longer at the source of the music and showed significantly less motor activity when they heard the consonant version, showing that they distinguished consonance from dissonance. Zentner and Kagan speculate that the findings also show that infants *prefer* consonance to dissonance because the dissonant version promoted more motor activity (including more fretting and turning away) and less fixation time, indicating a distressed state of arousal.

Zentner and Kagan’s (1996, 1998) research confounded consonance with pitch distance (the consonant intervals were wider), but a study by Trainor and Heinmiller (1998) kept interval size constant and again reported a preference for consonance. Six-month-olds heard consonant intervals (e.g., perfect fifths or octaves) and dissonant intervals (e.g., tritones or minor ninths). The infants controlled listening time by their looking behavior, and they looked longer to the consonant intervals. In a second experiment, 5- and 6-month-olds heard a Mozart minuet played as Mozart had composed it as well as a dissonant version of the minuet in which the Gs and Ds were changed to G flat and D flat. Again infants listened longer to the consonant versions.

Preference for consonant over dissonant intervals has been shown in even younger infants though the results were not clear-cut. As in the study by Trainor and Heinmiller (1998), Trainor, Tsang, and Cheung (2002) played consonant chords (perfect fifths and octaves) and dissonant chords (tritones and minor ninths) to 2- and 4-month-olds who could control how long the sound lasted by looking behavior. When infants heard consonant chords first, there was a near-significant tendency for them to look longer to the consonant trials. But when they heard the dissonant chords first, they did not look longer at consonant trials. Trainor, Tsang, and Cheung (2002) suggest that perhaps the dissonant chords displeased the infants so much that they did not resume interest when the consonant chords were played next (see also Trainor & Trehub, 1993; Trehub, Thorpe, & Trainor, 1990).

Numerous other studies have also shown a preference for consonant over dissonant intervals in infancy. For example, infants as young as 6 months detect quarter semitone changes in intervals when the first interval heard is an octave, a “perfect fifth,” and a perfect fourth (Schellenberg & Trehub, 1996), but they cannot detect such subtle changes when the first interval heard is a tritone, a chord considered to be unpleasing and nonharmonious. And octave intervals, the most consonant of all intervals, are clearly perceived by infants. Like adults, infants perceive octave equivalence of pitch: They can tell the difference between a pair of tones separated precisely by one octave versus a pair separated by almost an octave (Demany & Armand, 1984).

Whether perception of consonance as more pleasant than dissonance is inborn and a function of the human auditory system, as von Helmholtz (1877) believed (see

also Plomp & Levelt, 1965; Tramo, Cariani, Delgutte, & Braida, 2001), or whether such judgments are due only to the greater familiarity of consonance given its special status, could be determined by examining infants' judgments prior to any music exposure. However, because infants hear music in utero, this study would be difficult to carry out and has not been done. Instead, we must make inferences from studies of infants several months old and we cannot rule out the effects of exposure on any kind of outcome. We can also look to animal studies. One study showed that rats develop a preference for consonance over 3 weeks (Borchgrevink, 1975, reviewed in Zentner & Kagan, 1998). However, this preference emerged only after exposure and thus cannot illuminate the question of whether a preference for consonance is innate in rats, much less in humans.

Researchers should be careful not to draw the conclusion that infants' preference for consonance explains why adults have difficulty making sense of atonal music (e.g., the music of Schoenberg) in which dissonance is prominent. The kind of dissonance in atonal music is far more subtle and complex than that which is created by simply playing two adjacent notes at the same time, and the perception of dissonance in atonal music results from the context in which the interval is heard (Cazden, 1980). In addition, experience may be able to override the perception of dissonance as unpleasant: In one part of Bulgaria, singing in parallel seconds (which sounds dissonant to Western ears) is common in songs with two voices, with the lead singer remaining above the other (Sadie, 1980).

Post-Infancy: Sensitivity to Higher-Level Musical Structures

Although infants display an impressively adultlike response to simple musical structures, there are developmental changes still to occur. Whether these changes are a function of age or of years of exposure to Western music cannot be determined because we lack developmental studies of Western children's perception of music from cultures with nonwestern musical traditions.

Sensitivity to Diatonic Structure. Almost all Western tonal music (e.g., not only classical but also folk, jazz, and rock) is written within a particular key. Though Western music typically modulates from one key to another over time, at any point in time tonal music is made up primarily of the notes of a particular scale. In

the context of a given key, the notes of a scale are perceived as closely related and tones outside of this key sound less related. The relationship among the seven notes of a key is referred to as "diatonic structure."

In tonal music, the notes in a key have varying functions. The first note of the scale is called the tonic (e.g., in the key of G, the tonic is G). The tonic is heard as the most stable note in a tune and as the central tone toward which the others are drawn (Krumhansl, 1979). Melodies often end on the tonic, resulting in a feeling of stability. If the tune ends on the second note of the scale, it feels incomplete, hanging in midair and unresolved.

As a piece modulates from one key to another, the tonic or tonal center also shifts. In twentieth-century Western atonal music, there is neither key nor tonal center. Atonal music lacks the organizing framework provided by a key because the notes are not limited to one scale (Krumhansl, 1979).

The importance of tonality in organizing adults' perception of music has been demonstrated. Adults can distinguish tonal from atonal music (Dowling, 1982), and they recall tonal melodies better than atonal ones (Cuddy, Cohen, & Miller, 1979; Dewar, Cuddy, & Me- whort, 1977; Krumhansl, 1979). The ability to hear tonal structure (which is an abstraction) is critically important to understanding music, but the ability to distinguish tonal from atonal music is not present in infancy. Zenatti (1969) showed that by age 6 (but not before), children recall tonal sequences better than atonal ones. Children heard tonal and atonal melodies of three, four, and six notes followed by a comparison melody with one of the notes altered by one or two semitones. The task was to indicate which note had been changed. When the melodies had only three notes, 5-year-olds performed the same (and above chance) for both tonal and atonal melodies. By age 6, children performed better on tonal melodies, showing that they had acquired Western scale structure. By age 12, performance on atonal melodies improved and the tonal melodies did not facilitate performance. However, when the melodies were four or six notes long, the tonal framework remained easier even for adults.

Support for the claim that sensitivity to tonality is a late development (and one that is enhanced by formal training) comes from Morrongiello and Roes (1990). In their study, 5- and 9-year-olds heard brief (nine note) tonal and atonal melodies and then selected the line drawing that matched each melody's contour. Superior

performance for tonal over atonal melodies was found only for 9-year-olds. Those 9-year-olds who had formal music training (on average, 3 years) distinguished more strongly between tonal and atonal melodies than did those without formal training. Nonetheless, even those with no formal training performed better on the tonal melodies.

In a related study, Trehub et al. (1986) compared children's discrimination of pitch changes within diatonic melodies (e.g., C-E-G-E-C) versus nondiatonic melodies (e.g., C-E-Gsharp-E-C). Performance of 4- to 6-year-olds was better in the diatonic condition, but infants performed the same in both conditions. Thus, by the age of 4, familiarity with Western music has heightened children's sensitivity to tonality. Another study suggests that glimmerings of sensitivity to the Western diatonic scale may occur by 12 months of age. Lynch and Eilers (1992) tested the ability to detect changes in intervals in the same simple diatonic and nondiatonic melodies used by Trehub et al. (1986). Infants heard the melodies and their transpositions, some of which contained altered intervals. At 6 months, detection of interval changes was identical across conditions (but above chance). By 12 months, performance was better in the diatonic melodies.

Sensitivity to Key Changes. Perception of key is also late to develop. Trainor and Trehub (1992) investigated the ability to detect changes in melodies when the altered pitch was either within or outside the key of the melody. Adults found changes that violated key much easier to detect than ones that remained within key. But 8-month-olds not only performed identically in both conditions (showing a lack of sensitivity to key) but also performed *better* than adults in detecting within-key changes. Thus, years of listening to Western music impose a structure on what adults hear, such that note changes that remain in key are not heard as changes.

By age 5, children can distinguish keys that are tonally near versus far, a distinction that is independent of geographical distance, because geographically near keys (e.g., C and D) are more remote than tonally near keys (e.g., C and G). J. Bartlett and Dowling (1980, Experiment 4) played children and adults a melody followed by either a transposition or a same-contour imitation, either in a key near to the original melody (and hence sharing many pitches) or in a key far from the original melody (sharing few pitches). Adults heard

the transpositions as the same as the original melody, and the same-contour imitations as different. Five-year-olds responded in terms of key: Near key changes (whether transpositions or same-contour imitations) were heard as the same as the original melody, far key changes as different. Thus, 5-year-olds could distinguish near from far keys but could not detect interval size changes when the contour was preserved. By age 8, children were more likely to hear a far-key transposition as the same, and a near-key imitation as different, showing that, like adults, they attend both to key distance and interval changes.

Sensitivity to the Hierarchy of Notes within a Key. Children show a growing awareness of the proper structure of melodies (in Western tonal music), recognizing the importance of the tonic note for the ending of a melody. Krumhansl and Keil (1982) asked children to judge the goodness of six-note melodies that began with the tonic triad (C-E-G) and ended on a randomly chosen pitch. When adults were asked to judge the goodness of the final note, notes that are part of the tonic triad (C-E-G) were more highly rated than notes that are outside this triad (Krumhansl, 1990). However, 6- and 7-year-olds only distinguished between endings that were within key versus outside of key. Only by ages 8 to 9 did children begin to distinguish among the pitches of the key, ranking those in the tonic triad as better endings than other notes. When the task was simplified by using five- rather than six-note melodies, sensitivity to this hierarchy of notes within the scale was found by ages 6 to 7 (Cuddy & Badertscher, 1987; see also Sloboda, 1985, pp. 211–212).

The diatonic tonal scale, with its key structure and its hierarchy of notes, is specific to Western tonal music. Thus, it is not surprising that sensitivity to tonality is a late development. Acquisition of sensitivity to tonality occurs implicitly: Such acquisition depends on exposure to Western music but not on formal music instruction.

Recognizing Invariant Structure (“Music Conservation”). Intelligent musical listening requires that we hear invariant structure underneath superficial transformations (e.g., hearing a melody played in different keys, at different speeds, or with different instruments as the same melody). Such recognition of underlying structure despite surface changes has been likened to Piagetian conservation tasks (Pfleiderer,

1964). Children succeed on musical “conservation” tasks between the ages of 5 and 8 (and hence at the same age as they succeed on some Piagetian conservation tasks). Thus, children under age 5 are unable to identify a melody if its rhythm or harmonic accompaniments are altered, but by age 8 they have no difficulty with this task. The same findings hold for tasks in which children are asked to recognize meter despite a change in the duration of notes or to recognize rhythm despite a change in pitch (Pfleiderer, 1964; Serafine, 1980). But the analogy to conservation may be flawed. Children grasp conservation through logic, realizing that nothing has been added or taken away. There is no way to recognize invariance in music through logic. Instead, these studies are simply studies of perception and memory (Wolhwill, 1981).

Perceiving Aesthetic Properties of Music

Expression. More than any other art form, music has been described as the language of the emotions. According to philosopher Langer (1953), music mirrors the structure of emotional life: Music sounds the way moods feel. Music is structured in terms of tension and release, motion and rest, and fulfillment and change. These alterations mirror how our moods fluctuate.

Whether or not they are musically trained, adults agree in general on the emotions expressed by music. We hear music in the major mode as expressing positive affect—in the minor mode as expressing negative affect; we hear dissonant chords as expressing agitation, excitement, or sorrow—consonant ones as expressing happiness and calm (Crowder, 1984; Hevner, 1936).

Does the experience of the major mode as happy, and the minor mode as sad depend on learning, or might this perception be universal and unlearned, a function of the acoustics of the major and minor modes? The ability to distinguish between major and minor modes is prerequisite to the ability to hear major as happier than minor, and Costa-Gomi (1996) showed that with brief training in learning to attend to mode, 5-year-olds can hear changes in mode.

Young children agree with adults in their interpretation of musical passages of happy or sad (Dolgin & Adelson, 1990; Kratus, 1993), though there is mixed evidence about how early the ability to recognize emotion in music emerges. Cunningham and Sterling (1988) found that children aged 5 (but not 4) agreed with adults about which pieces are happy, sad, or angry. Gentile,

Pick, Flom, and Campos (1994) found that 3-year-olds agreed with adults on which pieces communicated happiness and which sadness, but only for five out of eight musical passages. Because these studies used actual segments of music, they do not allow us to determine which aspects of the music (e.g., mode, tempo, pitch, and volume) contributed to the emotion attribution.

Kastner and Crowder (1990) played 3- to 12-year-olds tunes in minor and major modes and asked them to point to the face that went with the tune (choosing among a happy, content, sad, and angry face). Even 3-year-olds matched positive faces to pieces played in the major mode (though performance improved with age). It is possible that children actually heard the major/minor distinction as a happy/sad one. But it is equally possible that children heard the major/minor distinction as a familiar/unfamiliar one, and gave positive choices when they heard something familiar. It is also possible that correct scores for the major mode were inflated by the selection of the “content” face which looked neutral (and children called it “plain”). A similar study used only a happy versus sad face, and found that 5-year-olds could not reliably match the minor melodies with the sad face and the major melodies with the happy face (Gerardi & Gerken, 1995). Thus, it may be that the perception of the minor mode as negative in affect and the major mode as positive emerges only with experience—perhaps the experience of hearing songs that pair sad lyrics or sad movies with the minor mode.

Style. A few studies have examined children’s ability to attend to the style of musical passages. Gardner (1973) asked children ages 6 to 19 to decide whether two passages from classical music came from the same piece and found that all children could succeed on this task though accuracy increased with age. When popular music was used along with classical music and children were asked to decide whether two passages came from the same piece of music, Castell (1982) found that 8-year-olds succeeded remarkably well, confirming Gardner’s findings. Both studies however showed that correct perceptual choices emerged earlier than the ability to verbalize what two passages deemed to be from the same piece had in common. Hargreaves (1982) documented the development of the ability to verbalize how two pieces are alike or different, and found that even 7- to 8-year-olds (the youngest he studied) were able to offer what he called “objective-analytic” responses describing the properties of the music.

Producing Music through Song: Major Milestones in Development

Children's first musical productions are vocal, and thus in what follows the focus is on the development of the ability to sing (both invented and standard songs). Singing is a complex task: Western rules of music dictate that songs consist of intervals sung an exact (rather than approximate) distance apart, melodies consist of diatonic notes and have a tonal center, and there is a consistent underlying metric organization. Children do not master these rules until the age of 6. Existing studies of the production of music through song are primarily descriptive rather than experimental.

Infant Song

Infants possess the rudimentary ability needed to make music: They vocalize and vary and imitate pitch. This early "singing" is much like scribbling and babbling.

Pitch Matching. Newborn cries have musical qualities and involve a wide range of pitches (Ostwald, 1973), but there is no reason to consider these cries as evidence of intentional music making. Kessen, Levine, and Wendrich (1979) provided evidence of intentional music making in infancy by showing that 3- to 6-month-olds could match isolated pitches sung to them on a pitch pipe. The ability to imitate sequences of two notes did not emerge prior to 1 year of age. See also Révész (1954) and Platt (1933) for earlier studies showing infants' ability to match pitches.

Babbled Songs. Even though 9- to 12-month-olds can imitate discrete pitches, when children this age sing they do so in continuous pitches on a single breath (sometimes called song babbling). This results in an undulating siren-like sound in which pitches are blurred. This kind of sound is rarely heard in Western adult music. Babbled songs are not based on the diatonic system and have no clear rhythmic organization (McKernon, 1979; Moog, 1976; Moorhead & Pond, 1978).

Rhythm. In striking contrast to the evidence that children can imitate pitches, there is no evidence of intentional production of rhythm in the 1st year of life (Sloboda, 1985). To count as evidence of production of rhythm, it is not enough to see a child bang something over and over. One must look for subdivision of a beat so

that there are two or more events within a regular superordinate pulse; omission of a beat with the picking up of the pulse at the correct time after a pause; imitation of a rhythmic pattern; and moving or beating in time to music (Sloboda, 1985).

Post-Infancy: Invented Songs

When it comes to language, children reach the level of the typical adult by age 5 or 6, with no explicit training; similarly, children sing at the level of the untrained adult by age 6. They have overcome three hurdles: (1) pitch has become discrete, (2) intervals have widened, and (3) their songs now have a metric and tonal organization.

Pitch Becomes Discrete. The undulating pitches of babbled song give way, at around 18 months, to an essential element of Western music—discrete pitches and discrete pitch intervals (Davidson, McKernon, & Gardner, 1981; McKernon, 1979; Werner, 1961). When children first begin to sing in discrete pitches, they do not yet use adult pitch categories—children do not yet sing in a diatonic scale (Dowling, 1988). In addition, pitches wander in and out of tune, interval sizes are not precise, and there is no tonal center (Dowling, 1984). At this age, children are not trying to imitate songs that they have heard; rather, they are inventing their own songs (Davidson et al., 1981; Moog, 1976).

Intervals Widen. The first intervals that children sing are very small, and development is characterized by a gradual expansion of interval size (Jersild & Bienstock, 1934; McKernon, 1979; Nettl, 1956a; Werner, 1961). McKernon found that major seconds were the most commonly produced intervals between 17 to 23 months. A third of the intervals sung at this age were of this type, and major seconds are among the most common intervals in songs across cultures (Nettl, 1956b). Between 1.5 to 2.5 years, the kinds of intervals increased and widened.

Children first expand their intervals and later fill them in a step-wise fashion (Davidson, 1985). Davidson refers to these early tonal structures as contour schemes—they are the stable intervals that the child possesses. These schemes are imposed on any song that a child acquires, reducing the range of a song's contour if necessary, and sometimes expanding the range to match the size of a new contour scheme just being constructed.

Melodies Gain Rhythmic and Tonal Organization. Rather than following a primarily rising or falling pattern, the contours of early songs undulate up and down (McKernon, 1979). Adult songs do this, too: Undulating contours are the most common types in adult songs across cultures (Nettl, 1956b). In this respect, as with the most common intervals produced, early songs resemble adult songs. But in their lack of either rhythmic or tonal organization, early songs are qualitatively different from adult songs (McKernon, 1979; Moorhead & Pond, 1978).

The melodic contours of children's early songs are narrow despite the fact that children can vocalize across a wide range (Fox, 1990): And almost all contours range between middle C and the B seven notes above it. Early songs consist of atonal groups of pitches: They are chromatic rather than diatonic, based on any or all of the notes in an octave rather than on the notes of a particular scale, and thus they lack the tonal center heard in Western music (McKernon, 1979; Moorhead & Pond, 1978). The lack of melodic and rhythmic structure in children's first invented songs makes these songs very different from the songs (written by adults) to which they are constantly exposed. By age 3, children are able to sing songs in a single key, though they do not do so reliably at first (McKernon, 1979).

Dowling (1984) described the invented songs his two daughters produced over a 5-year period, beginning in infancy. These children produced an average of 2.23 songs a week. The phrases of the songs had steady beats, but the beat did not always carry across phrases, consistent with findings by Moorhead and Pond (1978) and Moog (1976). Between ages 1 to 2, these two children produced songs with one repeated contour. By age 3, their songs had two to three different contours and often had a "coda," a contour that occurs only at the end of the song. The use of a coda may well have been due to having heard nursery rhymes because this form is found more often in nursery rhymes than in other kinds of songs.

Post-Infancy: Conventional Songs

Imitated Songs. At around the age of 2, children attempt to sing the songs of their culture (Davidson, 1985; Davidson et al., 1981; McKernon, 1979). These early attempts to reproduce conventional songs sound very much like spontaneous songs in their lack of a metric and tonal organization. In both spontaneous songs and early renditions of standard songs, a narrow range

of pitches and contours undulates in groups of two or three notes. The first property of a standard song imitated successfully is the lyrics—and these are simply imported into the child's spontaneous musical repertoire without their accompanying tonal and rhythmic structure (McKernon, 1979; Moog, 1976). Next to be reproduced is a song's rhythm. By 28 months, children studied by Davidson et al. (1981) could imitate the rhythmic structure of the alphabet song and fit the words appropriately into the rhythm. Last to develop is the ability to reproduce correct intervals and remain within a key. Adults pass through a similar sequence when learning a new song (Davidson et al., 1981).

By 29 months, children's spontaneous tunes have diverged in sophistication from invented tunes (McKernon, 1979). By the age of 3 or 4, children's standard songs have a clear underlying Western metric structure, even though their invented songs at this age lack this structure (McKernon, 1979). By age 5, spontaneous invented songs have declined and children become self-conscious and concerned with singing "correctly" according to the culture's norms (Gardner & Wolf, 1983; Moog, 1976).

Children are able to reproduce rhythm before pitch. Five- to 7-year-olds were followed over 3 years as they learned the song, *Row, Row, Row Your Boat* (Davidson & Scripp, 1988). Accurate rhythm production requires that a person match the number of units, keep a steady underlying pulse, capture the surface grouping, and coordinate the underlying pulse with the surface notes. Accurate pitch production requires matching the initial pitch, the melodic contour, the interval boundary (highest and lowest notes), and the key. Most (85%) of the 5-year-olds got the rhythm right, but only about half got the pitch right. The ability to reproduce pitch developed rapidly so that by age 7 the gap between rhythm and pitch had narrowed considerably.

We can conclude that musically untrained children show quite sophisticated singing abilities. By the age of 2 or 3, they can reproduce the general contour of a melody even though they cannot reproduce pitches exactly. By age 4, they can maintain intervals but cannot sing in a stable key (because they shift keys at phrase boundaries; McKernon, 1979). They are sensitive to melodic contours very early but the acquisition of a stable tonal center is not present until age 5 or 6, when they can maintain a key. Thus, in both perception and production of music, tonality is a late-developing structure.

Intentional Expression in Singing. Children as young as age 4 can intentionally vary how they sing a song to convey emotion. Adachi and Trehub (1998) asked 4- to 12-year-olds to sing a familiar song (e.g., *Twinkle, Twinkle, Little Star*) once to make a listener happy and once to make her sad. Children at all ages primarily used devices that express emotion in both speech and music—they sang faster, louder, and at a higher pitch for happy and slower, softer, and lower for sad. Devices for emotion expression that are specific to music (e.g., mode or articulation) were infrequent at all ages studied. Not surprisingly, some age trends were seen: Adults are better able to interpret the happy versus sad expression in the songs of children ages 8 to 10 than in those of children ages 6 to 7 (Adachi & Trehub, 2000).

Post-Infancy: Invented Notations

By asking children to invent ways of notating music that they hear, we can learn whether children understand that music cannot be captured by words or pictures and requires its own system of representation. This understanding emerges at least at early as age 5. In the longitudinal study mentioned earlier in which 5- to 7-year-olds without musical training heard *Row, Row, Row Your Boat*, children were asked to write down “the song” so that another person could sing it back (Davidson & Scripp, 1988a). The most common kind of notation system at age 5 was one in which abstract symbols were used to represent the notes (e.g., increasingly long lines used to represent increasingly low notes). Forty-three percent of the 5-year-olds used some kind of invented abstract system. The second most common solution at age 5 (26%) was simply to draw a representational picture that captured nothing of the musical information (e.g., a picture of a boat in water). By age 7, 56% of the children still used an invented abstract notation, though half of these combined the abstract notations with words (and almost no children used representational pictures).

The task of notating music is one that these children have probably never encountered before. What is notable is that 5-year-olds did not all rely on pictures; many invented abstract symbols. By age 5, children have learned to write letters, and also know quite a bit about pictorial representation (as shown earlier in the discussion of drawing). When asked to represent music, they invent a symbol system that is independent of both language and pictorial representation. This finding shows that young children are not only inventive when it comes to symbol-

izing but also recognize that neither words nor pictures do an adequate job of representing music, and that music needs its own form of representational system.

Does Musical Skill Improve Linearly with Age?

In two areas, development in music does not steadily improve: (1) Absolute pitch capacity may decline with age and (2) young children demonstrate a “figural” understanding of music—a kind of understanding as sophisticated as that of adult musicians.

Absolute Pitch

Absolute pitch refers to the ability to recognize pitches when heard in isolation. This skill is typically assessed by asking people to name the pitch, but naming of the pitch is only one indication that the person recognizes the pitch. Other measures that have been used include the ability to sing back a pitch and the ability to say that this was the pitch they heard before. This incidence of absolute pitch is estimated at 1/1,500 to 1/10,000 (Bachem, 1955; Miyazaki, 1988; Profita & Bidder, 1988; Takeuchi & Hulse, 1993) though it is difficult to test for absolute pitch in nonmusicians because they have not learned about the names of musical notes. Among musicians the incidence is considerably higher, estimated to be between 5/100 and 50/100 (Chouard & Sposetti, 1991; Gregersen, Kowalsky, Kohn, & Marvin, 1999). Absolute pitch cannot be trained in adults. Many experiments have attempted to teach it (Crozier, 1997; Cuddy, 1968; Takeuchi & Hulse, 1993), but all that has been shown is that people can memorize a few tones with much practice. Genuine absolute pitch is not learnable.

However, some have argued for the role of learning in early childhood because an early start to music training (before age 7) is associated with absolute pitch (Gregersen et al., 1999; Schlaug, Jäncke, Huang, & Steinmetz, 1995; Sergeant, 1969). But these data come from retrospective studies and it is possible that children with absolute pitch start music lessons earlier because their parents perceive them to be more musical. Not all musicians with absolute pitch began training early, and thus early training is not necessary for the development of absolute pitch. Moreover, only a minority of those who receive early training develop absolute pitch (Brown, Sachs, Cammuso, & Folstein, 2002).

Crozier (1997) and Takeuchi and Hulse (1993) reported greater trainability of absolute pitch in

preschoolers than at older ages. There is also evidence that the incidence of absolute pitch declines with age. Sergeant and Roche (1973) found that absolute pitch is more common in 3- than 6-year-olds. Children were taught to sing three tunes over the course of six sessions over 3 weeks. One week after the last lesson, they were asked to sing the tunes. While the older children were able to sing back the song with the correct contour and precise intervals, it was the younger children who sang back the pitches most precisely. Saffran and Griepentrog (2001) showed that when only one kind of pitch cue (absolute or relative) is available, 8-month-olds discriminate tone patterns on the basis of absolute but not relative pitch. Adults responded in opposite fashion, succeeding only on the relative pitch task. Thus, the ability to store and reproduce pitches precisely may decline with age, giving way to the ability to grasp the overall gestalt of a tune. It is possible that absolute pitch becomes “unlearned” with age as children begin to focus on the distance between tones rather than the tones themselves. Without the ability to represent relative distance, we could not grasp musical structure (but see Plantinga & Trainor, 2004).

There is some debate about whether absolute pitch (as measured by pitch memory) really does decline with age. Trehub (2003a) reports research in progress showing no age-related decline in remembering the absolute pitch level of familiar melodies. Trehub (2003b) argues that both absolute and relative pitch processing exists from infancy onward, but with age, different triggers elicit one or the other mode of processing. She suggests that absolute pitch processing is universal if we measure it by testing whether individuals can remember the precise pitch level of music (Schellenberg & Trehub, 2003). Absolute pitch is considered to be rare, she argues, because we have insisted that to count as having absolute pitch one must be able to name individual notes heard in isolation. However, some researchers feel that we should reserve the term *absolute pitch* for the ability to classify pitch according to pitch class and not extend it to heightened pitch memory (Schlaug, 2003).

Schlaug et al. (1995) have shown that adult musicians with absolute pitch have a larger than normal left-sided asymmetry in the planum temporale. The planum temporale is involved in auditory processing and is related to language (its left-sided asymmetry is considered a marker of left-hemisphere language dominance in right-handers; Geschwind & Levitzky, 1968). Whether this atypical brain structure is inborn in those with perfect pitch, or develops as a function of intensive musical

training begun at an early age, is not known. However, current longitudinal research in our lab in which children’s brains are imaged prior to and during music training may yield an answer to that question (Norton et al., 2005). If the atypical brain structure is inborn, research will need to determine whether some children with this brain structure lose absolute pitch and whether the maintenance of absolute pitch requires formal musical training and continuous exposure.

Figural Understanding

Children’s invented notations of music demonstrate that they hear music in an intuitive “figural” manner akin to how adult musicians are able to hear music. Bamberger (1991) asked a classroom of 8- and 9-year-olds to make drawings of a clapped rhythm so that someone else could clap back the rhythm. The rhythm had been invented by one of the children in the class and matched the rhythm of the familiar nursery tune, “Three, four, shut the door; five, six, pick up sticks; seven, eight, shut the gate.” Eight- and 9-year-olds invented two kinds of notations, which Bamberger refers to as figural and metric (or formal).

In the figural notation in Figure 20.12, claps 3-4-5 are shown to be alike. Clap 5 is like the two previous ones because all three form one rapidly clapped bounded figure. Figural drawings reveal that children are classifying claps in terms of gestures—the three small circles feel like they are all part of one gesture. In the formal notation in Figure 20.12, claps 5-6-7 are shown to be alike. Clap 5 is like 6 and 7, revealing that these children are classifying each clap in terms of duration from one clap to the next. To do this they must step back from the performance of clapping and compare claps.

Children who drew one kind of drawing could not understand how the other kind could be right. However,

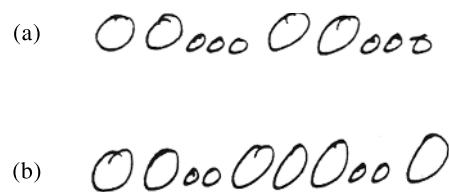

Figure 20.12 (a) Figural Notation of Rhythm. (b) Metric Notation of Rhythm. *Source:* From *The Mind behind the Musical Ear: How Children Develop Musical Intelligence* (p. 24), by J. Bamberger, 1991, Cambridge, MA: Harvard University Press. Copyright © 1991 by the President and Fellows of Harvard College. Reprinted with permission.

both can be considered right because each captures a different aspect of the rhythm (Bamberger, 1991). Metric notations capture the relative durations of claps—just what standard music notation captures. Figural notations are intuitive phrasings of what the rhythm sounds like—and they capture what musicians refer to as phrasing. For example, a musical performance of the previously mentioned rhythm might involve making claps 3, 4, and 5 louder or softer than the first two to indicate that they form a unit. Children who invented metric notations had managed to transform the continuous flow of the physical act of clapping into static and discrete symbols. These symbols are qualitatively different from the figural ones that capture the bodily flow of making music. In a further study with a large number of 7- to 12-year-olds, Upitas (1987) found that even with formal music training, children favor figural notations (though once they were shown the metric form, children with training were more able to switch to this form than were musically untrained children).

Musicians are able to perceive music both metrically and figurally: They would not be able to impose phrasing on a score without figural understanding. Musical scores often do not contain phrase markings, leaving phrasing up to the musician's interpretation. Thus, children's early and untrained understanding of rhythms as figures is an understanding that is not discarded by experts but instead is maintained. Figural drawings are too often considered less developed than metric ones. Yet, figural drawings capture what is important for musical expression—playing musically and achieving musical coherence (Bamberger, 1982). Thus, the child's earliest intuitive understanding of rhythm represents a way of knowing that remains important and ought to be retained even after more formal modes have been achieved. The challenge is for formal understanding to exist alongside figural understanding rather than have the formal replace the intuitive figural understanding.

CONCLUSIONS

A basic premise of developmental psychology holds that one can only study a developmental process of an implicitly or explicitly defined end state (Kaplan, 1967). Freud assumed the normal healthy personality; along with most cognitive-developmentalists, Piaget presupposed the full-blown logical scientific formal-operational thinker. But norms of mental health differ across

groups and cultures, and the kind of scientific thought valued by Piaget has only emerged in recent centuries.

In this chapter, by focusing on two prevalent art forms, I have viewed cognitive development through a set of different and, I hope, freshly illuminating lenses. The arts address and sometimes answer issues that are less visible in other spheres. Among these issues are why humans persist in activities with nonobvious survival value, to what extent skills develop and even flower in the absence of formal training, and in which ways development may proceed in nonlinear and even regressive directions. In addition, it is particularly in the arts that links between early and adult end states can be seen: Both child and adult artist are experimenters. Artists deliberately violate rules they have mastered; children have not yet mastered the rules and are therefore willing to be playful.

Visual arts and music are distinctly separate domains—it makes little sense to conceive of artistic development as a single entity (just as there is no single course of scientific development that encompasses the biologist and the theoretical physicist). Issues of tonal accuracy or the privileged fifth in music have little direct analogy with the emergence of the tadpole or the horizon line in children's drawings. And yet there may be certain intriguing parallels—children's inventions of their own notations may involve some of the same processes as children's attempts to master linear perspective (cf. Karmiloff-Smith, 1992). Even though the arts are universal in the way that science is not, I would not go so far as to claim that development perceived from a musical or visual artistic perspective provides the more important perspective. But I confidently assert that our understanding of development is enhanced if we can probe and synthesize findings from these various prized developmental end states.

By the age of 4, Wang Yani had produced more than 4,000 Chinese ink and brush paintings (Ho, 1989). American Michael Kearney reportedly could read before his first birthday and earned a college degree by age 10 (Winner, 1996a). Violinist Midori toured internationally starting at age 11. With no formal education, Virginia Woolf became a novelist, essayist, and literary critic with incomparable influence in her lifetime and afterwards. Apprenticed to a bookbinder at age 14, Michael Faraday educated himself by reading the books he was making, published his own scientific papers by age 25, and helped launch modern physics with his field theory (Tweney, 1989). Alexander the Great became king of Macedonia at age 20, immediately showed his

The authors would like to thank William Damon, Deanna Kuhn, and Anne Colby for their comments on earlier drafts of this chapter. With gratitude, the first author dedicates this chapter to Vera John-Steiner and the second author to William Damon.

leadership ability by quelling unrest in Greek cities, and conquered most of the civilized world by age 30. Nelson Mandela dedicated his life to the achievement of equality among the races; confined to prison for 27 years, he displayed no bitterness on release and instead effected a remarkably smooth transition from apartheid to a democratic South Africa.

What are we to make of these artists, scientists, political, and moral leaders who do surprising, unprecedented, *extraordinary* things? Through their actions, their words, and/or their works, they influence other people, organizations, bodies of knowledge, and worldviews, irreversibly changing domains, ranging from ballet to biology to business (Csikszentmihalyi, 1988; Gardner, 1993a).

On some accounts, extraordinariness is a quantitative difference, such as being more than two standard deviations from the norm for a certain criterion—for example, psychometric intelligence or running speed.

Extraordinariness is represented by outliers around a supposedly universal average. Although both tails of the normal curve might be considered extraordinary from this perspective, we do not subscribe to the global categorization of “high end” giftedness versus “low end” learning disabled. Studies of disabilities tend to use a deficit framework, focusing on diagnosing errors and how children can adapt to be more “normal.” Rarely do they consider a disabled individual’s way of thinking or acting as influential on others. In addition, there has been little research on individuals with jagged profiles of abilities and disabilities (cf. L. Miller, 1989; for summaries of the low-end literature, see Brown & Campione, 1986; Robinson, Zigler, & Gallagher, 2000).

On other accounts, extraordinariness is a qualitative difference—for example, having innate talents or unique experiences, or using cognitive processes unavailable to ordinary achievers. Extraordinariness is represented by a different cluster of skills altogether. We aim to synthesize the quantitative and qualitative views developmentally, suggesting that extraordinariness arises from repeated, cumulative deviations from a norm. These cumulative deviations eventually put a person on a qualitatively different path that may lead to acts or works influencing others to an unexpected degree.

Is extraordinariness all of a kind, or are there many varieties? Is its path set at birth or early in life, or is it emergent over the life span? How similar is its expression or development in different domains? What contributes to and constrains its development? In this chapter, we first review how extraordinariness has been studied in psychology. Then, we present a developmental-systemic framework for distinguishing end states and developmental pathways of extraordinariness in various domains. We focus on four domains—visual art, science, political leadership, and moral excellence—expounding differences as well as similarities across these domains.

HISTORY

The earliest scientific examination of extraordinariness entailed taxonomies and biographical studies of “men of genius” (Cattell, 1903; Cox, 1926; Ellis, 1926). Galton (1869) is generally regarded as the first student of individual differences, as his development of correlational and regression statistical methods made genius measurable. Arguing that abilities are hereditary and naturally lead to eminence, Galton calculated the odds of someone

in a particular generation becoming a genius based on how many eminent men were in his family tree. Yet, Galton did not distinguish the abilities or qualities critical for eminence nor did he disentangle inherited from environmental factors.

Intelligence

For most of the twentieth century, psychologists focused on intelligence as the individual quality that drives eminence. When Spearman (1904) first isolated *g*, the general intelligence factor, he conceived IQ as representing general mental energy, abstract thinking, and the ability to form and work with concepts. Other psychometricians devised hierarchical models of abilities subsidiary or additional to *g* (Thorndike, 1921; Thurstone, 1938; Vernon, 1950). Binet and Simon (1909/1976), Terman (1925), and Wechsler (1958) created simple clinical or paper-and-pencil tests to measure the “amount” of intelligence that each person had; these instruments foregrounded the linguistic, logical, and mnemonic capacities crucial for success in school. For most investigators in this tradition, which continues today, intelligence is considered an in-born trait stable across the life span and across different contexts (Eysenck, 1998; Herrnstein & Murray, 1994; Jensen, 1980; see Neisser, Boodoo, & Bouchard, 1996, for a critical discussion).

In the eyes of some, IQ, creativity, leadership, moral goodness, and eminence were expected to be of a piece. People with high IQs were likely to be the most exemplary, productive, innovative individuals in their communities (Terman, 1954). Most psychometric studies found that IQ did correlate, up to a point, with indices of creativity (Torrance, 1974), leadership (Terman, 1954), moral behavior (Thorndike, 1936), and moral reasoning (Hollingworth, 1942; Terman, 1925). Cox (1926) tried to tie IQ more directly to extraordinary achievements by estimating posthumous IQ scores for 510 eminent historical figures. She concluded that their genius could have been identified psychometrically during adolescence. However, her methods circularly calculate intellectual potential retrospectively based on achievement; she confound interests and motivation with ability; and she does not account for differences in what constituted eminence or genius across historical periods or cultural divides.

The most ambitious psychometric study of extraordinariness is Terman’s longitudinal research (Holahan, Sears, & Cronbach, 1995; Sears & Barbee, 1977; Terman, 1925, 1954; Terman & Oden, 1947). More than

90% of elementary students in California in 1921 with IQs higher than 140 agreed to provide intellectual, physical, personality, behavioral, and social data; remarkably, some have participated for more than 70 years. Far from being maladjusted bookworms, Terman's subjects were described as healthy, socially competent, and productive. Yet, if IQ is the singular most important predictor of extraordinariness, the lack of *extraordinary* achievements among these high-IQ individuals was glaring. By age 40, many subjects in the Terman sample had earned graduate degrees, worked in professional fields, and published writings (Subotnik & Arnold, 1994). But none reached a level of influence on contemporary or future generations as President Richard Nixon or scientist William Shockley—California schoolchildren of the same cohort who were not selected for the Terman sample—and few pursued the arts or other primarily creative activities like Californians Martha Graham, Yehudi Menuhin, or John Steinbeck. In addition, not all studies support the rosy life picture that Terman portrayed: Hollingworth's (1942) population of children with IQs over 180 endured neuroses, loneliness, and unhappiness as their high IQs alienated them from their less intelligent peers; Sears's studies showed that women in the Terman sample led more frustrated and less fulfilled lives than the men (Holahan et al., 1995; Sears & Barbee, 1977).

Beyond General Intelligence

The IQ approach to extraordinariness has failed to account for why some people change the course of history (see Gardner, Kornhaber, & Wake, 1996, for review). Starting in the 1950s, researchers recognized that IQ did not well predict extraordinary real-world achievement after the school years (Wallach & Kogan, 1965). In addition, complicating factors show that IQ may not be as straightforward, hereditary, or context-free as first conceptualized (Neisser, Boodoo, & Bouchard, 1996). For example, IQ scores rose steadily over the twentieth century (Flynn, 1999), but school performance and extraordinary achievement did not increase in tandem.

In addition, more recent psychometricians have construed intelligence as more than one cognitive ability—such as Cattell's (1971) difference between culturally acquired crystallized intelligence and more flexible fluid intelligence, or Sternberg's (1985) triarchic theory splitting academically oriented analytic intelligence from practical and creative intelligences. Intelligence also has been construed as a measure of metacognitive

control rather than the cognitive abilities themselves (Alexander, Carr, & Schwanenflugel, 1995; Sternberg, 1985), beliefs about one's own competence and its malleability (Dweck, 2000), and properties of the brain, from processing speed (Ceci, 1991) to dopamine system functioning (Fried, Wilson, Morrow, Cameron, Behnke, Ackerson, & Maidment, 2001; Previc, 1999).

Gardner's (1983, 1999) multiple intelligences theory synthesized findings from previously disparate research traditions, including the study of: cultural symbol systems, isolation of neurological functions, the highly skewed abilities of prodigies and/or savants, as well as experimental and psychometric findings. He concluded that each individual possesses a profile of linguistic, logical-mathematical, spatial, bodily kinesthetic, musical, interpersonal, intrapersonal, naturalistic, and possibly existential intelligences that can develop or stagnate based on experience with different cultural domains of performance.

All individuals possess this spectrum of intelligences, but in light of hereditary and experiential considerations, individuals differ from one another in their respective intellectual profiles at any given time. Highlighting this distinction, Gardner distinguishes between *intelligences* as computational capacities and *domains* as socially valued activities in which individuals can participate and eventually excel (Connell, Sheridan, & Gardner, 2003). The domains present in a society, the training resources available, and the individual's own computing powers and motivations combine to determine how, and to what extent, various intelligences are expressed (Gardner, 1983, 1999).

Specific intelligences are linked to different forms of extraordinariness. Spatial intelligence plays a role in visual art, logical-mathematical and sometimes spatial intelligences in science, interpersonal and linguistic intelligences in political leadership, and the personal and existential intelligences in moral excellence. Still, such generalizations should be tempered; case studies suggest that, in regards to career trajectories and contributions, an *unusual* profile of intelligences may be as important as sheer intellectual power. The asynchrony of Freud's enormous linguistic and personal capacities, in the context of unremarkable mathematical and poor spatial skills, may have contributed to his innovative approach to science.

Expertise

Other researchers, including Gestalt and cognitive psychologists, stressed not mental ability per se but the

strategic use of such abilities (Davidson & Sternberg, 1984; Perkins, 1981). How does a person interact with constraints of a problem (Wertheimer, 1954), use information simultaneously or sequentially to organize actions (Luria, 1976), or change mental representations to build more complex understandings of phenomena (Piaget, 1972)? Differences in these processes lead toward more or less expertise, which is defined as the highest level of performance in a specific domain (Bereiter & Scardamalia, 1993). In contrast to novices, experts not only have more knowledge but also use qualitatively different strategies. They think ahead further, chunk knowledge more flexibly, use resources more strategically, are more efficient, and base decisions on the deep rather than surface features of the problem (Bereiter & Scardamalia, 1993; Chi, Glaser, & Rees, 1982; DeGroot, 1965; Ericsson, 1998; Newell & Simon, 1972). This line of research emphasized experience over genetic endowment. For example, mastery of a domain requires 10 years of deliberate practice (Ericsson, 1998) and includes sensitivity to environmental conditions and affordances (Perkins, Tishman, Ritchhart, Donis, & Andrade, 2000). Crucially, however, the expertise approach does not distinguish between individuals who achieve competence and those who come to stand out in some way from other expert peers.

Creativity

Since the 1950s, creativity has been studied psychometrically as a trait separate from IQ; the two traits do not correlate above an IQ of 120 (Getzels & Jackson, 1962). Guilford (1950, 1967) developed paper-and-pencil tests to measure ideational fluency, flexibility, and elaboration, and Mednick and Mednick (1967) devised a test to assess associational power. Guilford differentiated between convergent and divergent thinking traits. Experts and high-IQ individuals excelled at converging to one best answer for well-structured problems, whereas creative people diverged along multiple lines of thinking for relatively ill-defined problems. Getzels and Csikszentmihalyi (1976) went a step further, suggesting creativity involved problem formulation itself. Torrance (1963, 1974) determined that creative potential could be measured even in children; but in the American educational system, creative students were much less valued than high IQ students (Getzels & Jackson, 1962; Torrance, 1963). Follow-up studies of Torrance's students showed that those who scored high on creativity tests

did not necessarily achieve extraordinary ends as adults, although a few demonstrated more modest accomplishments (Millar, 2002; Plucker, 1999).

Building on influential earlier work on complex problem solving (Wallas, 1926; Wertheimer, 1954), theorists in the 1980s and 1990s emphasized how creativity can emerge from ordinary information processing (Finke, Ward, & Smith, 1992; Mumford, Baughman, Supinski, & Maher, 1996; Mumford, Baughman, Threlfall, Supinski, & Costanza, 1996; Mumford, Baughman, Maher, Costanza, & Supinski, 1997; Mumford, Supinski, Baughman, Costanza, & Threlfall, 1997; Perkins, 1981) and systemic interaction of emotional, cognitive, conative, and social factors (Csikszentmihalyi, 1988; Gruber, 1989). Researchers in artificial intelligence designed computer programs that recreated historically creative acts such as Kepler's discovery of the laws of motion (Boden, 1990; Hofstadter, 1995; Langley, Simon, Bradshaw, & Zytkow, 1987). Although these computer models have been criticized for programming in far too much already organized data, the models suggest how ordinary information processing can bring about extraordinary results. Dynamic computer models of creativity emphasize rate of change and interaction of abilities rather than a singular ability (Eckstein, 2000; Goertzel, 1997; Martindale, 1995).

As with intelligence, there has been a shift from investigating general creativity to processes of creativity as they unfold in specific domains and under specific conditions (Amabile, 1996; Csikszentmihalyi, 1996; Gardner, 1993a; Simonton, 1994). Idiographic case studies (Bloom, 1985; Feldman, 1986; Gardner, 1993a; John-Steiner, 2000; Wallace & Gruber, 1989) provide a way to understand how the affordances of the domain and individual characteristics interact over time to yield creative outcomes. Researchers are building a cumulative database that can serve to establish general principles of creativity (Policastro & Gardner, 1999; Simonton, 1994).

Leadership and Morality

Leadership and morality have been studied separately from intelligence and creativity for most of the twentieth century, yet their study has followed a similar path—first conceived as a stable trait, later more as a process. Early, hereditary “great man” theories (Ellis, 1926; Galton, 1869) gave way to stable personality and motivational trait approaches (Cox, 1926; McClelland, 1967) then to interactionist theories involving cognitive

“transactions of minds” (Gardner, 1995) and social-cognitive systems of leaders, followers, and situations (Burns, 1978; Gergen, 2000; Hunt, 1999; Jacobsen & House, 2001). Although high-IQ individuals often displayed leadership qualities (Terman, 1954), Thorndike (1921) suggested independence between social and academic intelligence. Extraordinary leaders tended to have above average rather than exceptionally high IQs (Cox, 1926; Thorndike, 1950), and too high an IQ could prove detrimental to leadership (Mann, 1959). In the same vein, social and moral thought became differentiated from behavior. Making perceptive moral judgments, knowing when to act appropriately, and acting morally did not always coincide (Jarecky, 1959; Walker, 2003).

Morality was first conceived psychologically as a set of character traits (Hartshorne & May, 1928–1930) acquired from society through membership in a collectivity (Durkheim, 1961), internalization (Freud, 1923/1961b, 1930/1961a), or reinforcement (Skinner, 1971). These theoretical foundations reverberated through the 1960s in psychoanalytically tinged studies relating child-rearing practices to defense mechanisms (Sears, Maccoby, & Levin, 1957) and social learning theory’s research on reinforcement’s contribution to guilt and internalization of norms (Bandura & Walters, 1963). Still, scholars and laymen noticed individual differences in moral maturity, which were attributed variously to heredity (Galton, 1869), gender (Freud, 1930/1961a), or stable intelligence (Terman, 1954; Thorndike, 1936). Piaget (1932) focused on the development of judgments about social relationships and documented how, with experience, these judgments become more complex, abstract, and flexible. Morality was constructed, not imposed. Kohlberg (1984) further developed Piaget’s ideas, incorporating extraordinariness in his highest stages of moral reasoning.

Personality

In contrast to the psychometric and cognitive traditions, researchers at IPAR, the Institute for Personality Assessment and Research (e.g., Barron, 1972; Helson, 1996; MacKinnon, 1975; see also Cattell & Drevdahl, 1955; Cross, Cattell, & Butcher, 1967), construed personality traits as key contributors to extraordinariness. These researchers found that creative individuals in various domains shared several personality characteristics: independence, unconventionality, openness, flexibility, and risk taking. Csikszentmihalyi (1996) synthesized these findings through his concept of complexity, with

creative individuals demonstrating integration of seemingly opposite traits such as being both energetic *and* quiet, or childlike *and* serious.

Another personality-oriented line of research continued the nineteenth-century fascination with the genius-insanity connection. The path to extraordinary achievement may be psychologically treacherous, as argued in Freud’s (1910/1957) case study of Leonardo da Vinci, Erikson’s (1958) case study of Martin Luther, Geschwind and Galaburda’s (1987) studies of left-brain deficits and immune disorders in gifted children, and other studies of eminent creators, especially artists and poets (Andreason, 1987; Gedo, 1996; Jamison, 1989). However, Rothenberg (1990) suggests that productivity only occurs during times when the mental illness is under control. Furthermore, Storr (1988) argues that a craving for solitude or other putatively antisocial behaviors associated with extraordinariness need not stem from psychopathology.

Our survey of the literature reveals that the study of extraordinariness originally was rooted in the study of intelligence as a measurable quantity of competence leading to expertise. This competence, at first, was believed to be global in application. However, it increasingly came to be seen as domain-specific, context-dependent, and differentiated from creativity, leadership, morality, and personality factors. Interest has shifted from an all-encompassing IQ number as a predictor of extraordinariness *per se* to the properties, conditions, and interactions of person and setting that bring about or thwart extraordinary results.

CURRENT ISSUES

The issues involved in the study of extraordinariness revolve around four foci:

1. *Definitional*: What is extraordinariness?
2. *Developmental*: How does extraordinariness arise?
3. *Domain specific*: What are the characteristics of various forms of extraordinariness?
4. *Methodological*: How can extraordinariness be studied?

Definitional Issues

End-state extraordinariness includes expertise, creativity, leadership, and moral excellence. Researchers often intermingle these different forms of extraordinariness. Are these forms on the same continuum, or are they

qualitatively different? Expertise comprises the highest performance in a domain without changing the domain. Examples include chess masters who can play better than anyone else but do not come up with innovative moves or new rules (De Groot, 1965) and map readers who understand the curvature of the Earth in two dimensions but do not conceive of a better representation (Anderson & Leinhardt, 2002). Expertise has been shown to extend beyond *more* knowledge to include qualitative differences in the complexity of interconnections among chunks of knowledge and in the strategies used to deploy those chunks. Expertise emerges as the most common form of end-state extraordinariness—the artists who can draw realistically, scientists who can reason rigorously, leaders who can garner a small group of followers, and everyday moral heroes.

Transformative end states, alternatively, only emerge for a handful of people per domain per century. Compared to experts, these end states of creativity, leadership, and moral excellence lead to novel configurations of symbolic resources, social organizations, or cultural values. They influence others' minds sufficiently to change the domain.

Creators engage in “conversations” with their materials or media—mathematical symbols, scientific theories, paint and canvas, and so on—that ultimately redirect or change the structure of a domain (Gardner, 1993a). Einstein reconceived Newton’s mechanical universe in relativistic terms. Thomas Edison ushered in the twentieth-century, electronics-dominated, modern lifestyle. Creators influence others indirectly through their products. For example, other artists or patrons thought differently after seeing Cubist paintings by Picasso and Braque. Depending on the number, intensity, and timing of people influenced, creators’ achievements can range from everyday, little-c creativity to historical, big-C creativity. We emphasize individuals whose innovations are historically important. For example, Newton and Leibnitz invented calculus in the late seventeenth century; it is now standard fare for high school and college students.

In contrast, leadership is a more direct form of influence, customarily achieved through person-to-person contacts or organizationally role-mediated interaction (Gardner, 1995). Leaders affect members of a society directly through their words or actions. They also attempt to influence through the power bases of organizations—such as legislatures, funding organizations, and regulatory agencies—that garner and dispense important

resources. Like creativity, leadership forms a continuum, from little-l forms such as a child taking initiative to organize a playground game or a parent who organizes a bake sale, to middle-l forms such as local politicians or small-business presidents, to big-L forms such as revolutionaries, key national political figures, and executives of multinational organizations. The less ambitious forms of leadership tend to involve basic exchange processes to satisfy current needs, whereas the higher forms are transformative, impacting future, foreseen (and perhaps also unforeseen) needs (Burns, 1978).

Like the political and corporate forms of leadership, moral influence typically proceeds in a direct manner, through language, imagery, and social interaction. But in contrast, moral excellence dwells in the realm of values and is as much a conversation with oneself as with others. The outcomes can be far-reaching and symbolic; like the most impressive forms of creativity, moral excellence can change the value structure of a domain or society (Gardner, 1993a, 1997; Gardner, Csikszentmihalyi, & Damon, 2001). For example, like other leaders, Gandhi conveyed his message of India home rule through speeches, writings, and peaceful demonstrations. But his philosophical principles of *satyagraha* (a composite of the Hindu words for “truth” and “holding firmly”), which featured nonviolent resistance to injustice, continues to affect religious and legal/political domains around the world (Erikson, 1969; Gardner, 1993a). Moral excellence also forms a continuum, from little-m such as individual altruistic or heroic acts, to middle-m such as leading others in a moral way, to big-M which mobilizes groups to build a more socially just society.

At the start of the twenty-first century, the growing complexity and variety of forms of extraordinariness call for an integration of individual differences research with developmental research. *Genius* no longer suffices as an all-encompassing term. Extraordinariness can vary by form (expertise, creativity, leadership, moral leadership), degree (everyday acts as contrasted with transformative movements), interaction (direct and social as in leadership versus indirect and symbolic as in creativity and morality), and scope (influence within a domain versus crossing domain or national boundaries).

Developmental Issues

Although extraordinariness is viewed increasingly as a life-span phenomenon, developmental research has focused primarily on children. Extraordinariness at early

ages includes giftedness, talent, and prodigiousness. Compared to adult end-state forms of extraordinariness that emphasize achievement, developmental forms aim to identify children with potential; often, efforts are undertaken to accelerate or enrich the early experiences of select youngsters. *Giftedness* generally reflects an unusually high capacity for, proclivity toward, or faster rate of learning in a domain, mostly in scholastic domains such as language and logic or mathematics (Lubinski & Benbow, 2000; Winner, 1996a). *Talent* is used to designate high capacity or faster development in non-scholastic domains such as the arts, athletics, or social graces (Winner, 1996b). Although intelligence is still mostly conceived of and measured as a singular, global, abstract, problem-solving ability, trends suggest a construal of intelligence as a complex profile of domain-specific, biopsychological potentials. The issue changes from a determination of whether a person *is* gifted to an identification of domains in which a person *displays* gifts. Identification is based usually on comparative performance evaluations by teachers and coaches. *Giftedness* or *talent* is no longer “being smarter”; rather, these terms can be invoked to describe people of all ages and profiles who master a domain or situation with unusual facility.

Prodigiousness represents an interesting cross between an end-state and a developmental form of extraordinariness. The term describes adult, expert-level performance in a domain by a child younger than 10—for example, performing complicated pieces, calculating quickly, vying with chess masters, and drawing realistically or with personal style (Feldman, 1986; Winner, 1996b). Found most often in domains that have clear performance standards, such as mathematics, chess, and music, and less often in more ill-defined or integrative fields, such as politics, business or morality, these *Wunderkinder* reach the pinnacle of the culture’s current standard at a phenomenal rate. They demonstrate an uncanny affinity for and agile skill in a particular domain’s tasks and requirements, and they are well supported by parents, teachers, and structured practice (Bloom, 1985). Although prodigies might seem more likely to become adult extraordinary achievers, prodigiousness actually can constitute an obstacle. Young people may become stuck in the expert position, having received such acclaim for their early performances that they do not develop the independence or rebelliousness entailed in the most impressive, transformative achievements (Gardner, 1997).

Accordingly, developmental researchers have distinguished between potential and achievement, with potential an early precursor or capacity that influences and supports, but is not sufficient to determine, later work outcomes (Bloom, 1985; Gardner, 1993b; Helson & Pais, 2000). Many studies have examined antecedents of extraordinariness, such as birth order, family environment, and apprenticeships (Bloom, 1985; Goertzel & Goertzel, 1962, 1978; Simonton, 1994; Sulloway, 1996). Researchers who study extraordinariness through its products (Martindale, 1990; Simonton, 2000) or its most powerful exemplars (Gardner, 1993a; Wallace & Gruber, 1989) emphasize the interaction of individual differences and expected developmental trajectories (Gardner, 1993a; Helson & Pais, 2000).

Domain Issues

Extraordinariness has become viewed increasingly as a domain-specific phenomenon. Domains were invisible to earlier researchers (Piaget, 1937/1995, 1955/1995; Terman, 1925). The discovery of Vygotsky’s work (1935/1994, 1934/1962, 1978) called attention to media and tools as mediators of performance. Several perspectives—cognitive science (Fodor, 1983), artificial intelligence (Boden, 1990; Hofstadter, 1995; Langley et al., 1987), and developmental psychology (Feldman, 1986; Gardner, 1983, 1988; John-Steiner, 1985)—have directed attention to the importance of the particular sphere in which an individual works. To understand extraordinariness, one must understand its contexts—the socially valued activities and corresponding symbol systems that afford extraordinary performance. As a result, researchers have called for ecologically valid studies of people working in situ (Dunbar, 1996; Gardner, 1993a; Hutchins, 1996; John-Steiner, 2000). Context, in turn, entails two aspects: (1) the symbolic and (2) the social.

The symbolic context involves the domain itself as a body of knowledge, symbol systems, and notations associated with a certain type of work or activity (Csikszentmihalyi 1996; Gardner, Phelps, & Wolf, 1990). For example, in the United States, the Constitution, federal and local laws, and legal terminology are all aspects of the law domain. Domains exist in individuals’ minds and in artifacts produced by individuals, such as books, files, artworks, and inventions. No one individual “holds” all of a domain in his or her mind; rather, a domain is parceled out differentially among minds and media (Hutchins, 1996; Mieg, 2001).

This dispersion in any domain creates an important tension that stimulates extraordinary efforts. To be sure, much of an established domain is agreed on by people who have mastered it through schooling or a formal or informal apprenticeship; that is what makes it a domain. But surrounding this agreed-on core are idiosyncratic perspectives—old conceptions, misunderstandings, or yet-to-be-accepted, potentially innovative approaches (Merton, 1949/1967; Moran & John-Steiner, 2003; Vygotsky, 1934/1962). As such idiosyncratic perspectives are explored and found promising, what is initially unique or idiosyncratic ultimately becomes domainwide, culturewide, and possibly even universal (Feldman, 1994; Martindale, 1990). In addition, domains can change in their importance to the wider society and culture; some, such as science and business, have become increasingly more central in America, whereas arts, crafts, and civil debate to some extent have been marginalized (Bourdieu, 1993; Feldman, 1994; Gardner, 2001; Sorokin, 1947/1969).

The social context involves the field, a social organization for controlling practices in the domain. For example, law schools, the Bar, and the court system comprise institutions in the law field. Individuals who know something of the domain may be inside (professionals) or outside the field (amateurs or eccentrics). Based on abilities, interests, and opportunities, individuals take on roles defined by the field, such as trial lawyer, law school professor, or paralegal aide. With respect to extraordinary achievement, the function of the field is to determine which individual contributions are worthy to incorporate into the domain and preserve for future generations. Usually this judgment is based on the criteria of “novel and appropriate” (Amabile, 1996). Even in domains in which individuals seem to work in solitude, such as painting or writing, social institutions enable, disseminate, and give value to their contributions—consider the roles of teachers and mentors, materials suppliers, developers of technical improvements, critics, preservers (such as libraries and museums), and audiences (Becker, 1982; Bourdieu, 1993; Gardner, 1973).

The first societal activities to be researched from a domain-specific perspective were art and science: Bamberger’s (1982) studies in music, Gardner’s (1982) and Winner’s (1982) studies in the visual and literary arts, and studies in math and science by Gruber (1981), Helson and Crutchfield (1970), Roe (1946, 1952), and Zuckerman (1977). In contrast to other spheres of activi-

ty, such as business or law, art and science tend to be more isolated from quotidian interactions and to require more specific, focused skills and dispositions, which we might call “laserlike” intelligences (Gardner, 2006). Artists and scientists keep to themselves, and their work depends less on consumers other than fellow artists and scientists (Bourdieu, 1993; Martindale, 1990).

Other domains, including leadership and morality, are murkier to formulate. Although leadership is found in many occupational domains, from business to sports, it also constitutes a form of expertise in itself. Similarly, any domain—art, science, politics, medicine, and so on— involves moral dimensions, but morality is also a domain organized, studied, and reproduced in its own right. Forms of extraordinariness that cross traditional domain boundaries emphasize “searchlight” intelligences that integrate information and skills from a variety of sources and that allow for communication to an audience much broader than one’s fellow practitioners (Gardner, 2006).

Methodological Issues

The end-state and developmental forms of extraordinariness typically have been studied by different methods. Experimental or observational studies with children or savants compare potential in abilities and dispositions (Milbraith, 1998; Selfe, 1995; Siegler, 1978). Experimental and microgenetic problem-solving designs examine differences between strong and weak performers’ cognitive processing mechanisms and environmental constraints (Chi et al., 1982; Ericsson, 1998; D. Kuhn, Garcia-Mila, Zohar, & Andersen, 1995). Antecedents and concomitants of extraordinary achievement are ascertained through case studies (Colby & Damon, 1994; Gardner, 1993a; Gergen, 2000; Wallace & Gruber, 1989), interview studies (Csikszentmihalyi, 1996; John-Steiner, 1985), document analyses (Gruber, 1974; Holmes, 1989; A. Miller, 1989; Tweney, 1989), and historiometric surveys (Cox, 1926; Murray, 2003; Simonton, 1994).

Solid developmental or longitudinal evidence is in short supply. Most studies have been correlational and cross-sectional, documenting numerous differences between novices and experts, experts and creators, creators and leaders, followers and leaders, and children with low or high potential. Less is known about how a novice becomes an expert or creator. Retrospective and historiometric studies start with individuals known to

be extraordinary; but often a collection of their childhood work or experiences is lacking. Longitudinal studies provide a richer base of developmental material, but there is no guarantee that childhood potential will develop into adult extraordinariness. More recent microgenetic studies have illuminated the detailed processes of thinking, discovery, or creation at a small scale but often do not connect these thinking patterns with real-life, domain-transforming events. The few longitudinal and case studies show that extraordinariness takes decades to develop. Its particular form is epigenetically determined as genetic endowment and environment change affect each other in different ways over the life span (Lykken, McGue, Tellegen, & Bouchard, 1992; Spinath, Ronald, Harlaar, Price, & Plomin, 2003).

A common criticism of the extraordinariness literature is its overreliance of samples of White, middle-class males (e.g., Murray, 2003). A few researchers, however, have looked at how gender, race, and culture affect interaction, performance, and assessment (Jensen, 1980; Simonton, 1998). For example, women's paths to extraordinary achievements seem to be more complex, less integrated, and less culturally supported than men's (Benbow & Stanley, 1983; Helson, 1999; Holahan et al., 1995; Sears & Barbee, 1977). Similarly, studies in non-middle-class or non-Western cultures suggest a disjunct between real-life and scholastic performance: Brazilian street children can run a business and Kenyan students can do sophisticated mathematical manipulations at home, but they do not perform well on SAT or IQ tests (Ceci, 1996; Sternberg et al., 2001). In addition, cultural and historical contexts affect which qualities are deemed desirable and which work is innovative—consider the different criteria obtained from China in the Ming dynasty, Florence in the Renaissance, or Silicon Valley circa 1990 (Csikszentmihalyi, 1996; Gardner, 1989; Schneider, 1999; Simonton, 1994).

A DEVELOPMENTAL-SYSTEMIC FRAMEWORK

To capture the contemporary pull toward a multidimensional, interactive, developmental perspective, we expand a model originally developed for creativity (Csikszentmihalyi, 1988, 1996). Extraordinariness emerges in a three-component system composed of *individuals* working in a particular *domain* that is under partial control by the

field. The role of the individual is to generate variation in the domain—to come up with new ideas, procedures, arrangements, or products that may stimulate domain growth or newly position the domain relative to other domains (Simonton, 1999). The role of the domain is to provide a fount of past knowledge and practices against which to judge new contributions, cross-generational storage of past contributions, and symbolic materials on which future extraordinary contributions draw (Feldman, 1994; T. Kuhn, 1962; Martindale, 1990). For example, researchers in genetics must learn what is already known from past researchers, methods that are currently acceptable scientific practice, and scientific discourses (e.g., publication formats, conference formats). The role of the field is to allocate resources and determine which variations are worthy to incorporate into the domain and preserve for future generations. For example, researchers in genetics must work in one or another institution where research is carried out, such as universities, hospitals, or for-profit companies; submit papers to journal editors, who will determine whether they merit publication; and abide by regulations relating to conflicts-of-interest. Extraordinariness requires all three components. Without individual variation, the domain stagnates. Without the domain, there is only social interaction with no collective memory. Without the field, there is no informed way to evaluate new contributions.

This systems model freshly illuminates extraordinariness. It shifts extraordinariness from being a property of an individual—be it IQ score or personality trait—to being a property of a constantly evolving and interacting set of components. Experts are individuals (typically with laserlike intelligence) who understand the domain well and hold established positions of power in the field. Prodigies are similar except they rarely hold positions of power. Thus, experts stabilize both the domain and the field, and serve as the primary gatekeepers of distribution channels—be they artistic galleries or scientific journals—to which an individual's contribution must be submitted to garner field support. Expertise represents a relatively unproblematic alignment among individual, domain, and field.

Creators also command the domain but often stand in significant misalignment to the standardized concepts presented by the field (i.e., the concepts as presented in textbooks). Creators may also exhibit laserlike intelligence, but the laser pinpoints different, less well-known aspects of the domain. Whereas experts seem to fall into a career based on fit between the

person and the environment, creators select a domain with an eye toward making an original contribution (Gardner, 1993a; Gardner & Nemirovsky, 1991; Rank, 1932; Shekerjian, 1990). Creators may, but need not, work their way up the career ladder of a field. Innovative contributions may be accepted by a field early or late in one's career (Galenson, 2001; Lehman, 1953; Simonton, 1994; Zuckerman, 1977). Creativity stems from a fruitful misalignment within or among individual, domain, and field, at least during key stages of career development.

Like ordinary leaders, who tend to function similar to experts and are often termed "managers," extraordinary leaders need to understand relevant domains. Thus, J. Robert Oppenheimer was knowledgeable about physics; Alfred Sloan mastered the automobile industry (Gardner, 1995). To effect significant change, however, leaders need a big-picture, generalist knowledge base and searchlight intelligence (Gardner, 2004a; Gergen, 2000). Unlike the scholastically gifted, leaders rarely are recognized in childhood; they need to spend significant time in real-world interactions. Leaders tend to emerge from the ranks—CEOs have held lower-management jobs, presidents held local political positions, generals were once privates or sergeants. Initially, leadership arises from a power alignment between individual and field—others follow the leader. But a transformative leader demonstrates his or her skill by navigating a misalignment between the current field composition and the ideal resolution of the situation or aspirations of the followers.

By changing values, moral extraordinariness can result in dramatic transformation of all parts of the system. For example, both indirectly, through his writings and speeches, and directly, through his nonviolent protests, Martin Luther King Jr. changed the status of the African-American community in America in the 1960s. His influence continues to be felt today. In its most extraordinary form, moral excellence takes the longest, faces the most resistance from current domain and field forces, and is the most difficult to accomplish. Moral excellence results from a misalignment of assumptions and values among individual, domain, and field. For example, Gandhi overcame the entrenched imperial notions of the British nation (Gardner, 1993a), while French economist Jean Monnet overcame nationalistic and jingoistic predispositions to lay the foundation for the European Union (Gardner, 1997).

The systems model also alters the construal of how extraordinariness develops. Extraordinariness is no longer an unfolding of inborn talents nor the consequence of well-timed environmental supports or challenges. It is manifested differently at different ages, can be impacted differentially by the same experience depending on age or circumstance, and it must respond to the continuing evolution of the domain and field (e.g., Feldman, 1986; Gardner, 1993a; Lykken et al., 1992; Sawyer, 1999). For example, with age, individual genetic contribution goes up (Plomin, DeFries, McClearn, & McGuffin, 2001) but general intelligence's contribution goes down (Ceci, 1996) in relation to cognitive performance. Adults may be better able to choose and tailor their environments—both social and symbolic—to their inborn sensitivities and dispositions (Changeux & Ricoeur, 2000; Granott & Gardner, 1994; Moran & John-Steiner, 2003).

Several new tensions arise in this framework. For example, experts work to maintain the status quo or make only controllable, small, incremental, quantitative changes to the system, whereas transformers work to effect riskier, qualitative leaps. Should creators and leaders succeed in transforming the system, they render the experts' expertise less valuable and experts' power less palpable. For example, the Impressionists and the Cubists made the works of nineteenth-century Academicians look staid and less collectable. Yet, experts hold the strings to the primary resources and outlets for these innovators' efforts and often are the mentors of future transformers. So creators and leaders must change the minds of enough experts to secure social support needed to make a difference.

Issues of timing are also crucial for the aspiring transformer. If someone else publishes a breakthrough scientific finding or artistic technique first—as Einstein and Woolf did—a person working along the same lines is thwarted from earning the label of "creative" and citation in future textbooks (Kasof, 1995; Merton, 1957; Simonton, 1994). This timing is partially under the power of current experts in the field regarding to whom they pay attention and provide support. Therefore, individuals in different field roles battle for influence over the domain, thereby facilitating or thwarting development for themselves, contemporaries, and successors.

A second tension involves the differential influence of domain and field across an individual's life-span development. Domains and fields come to the fore and oc-

cup specific niches at different periods of a person's life. Children first learn about many domains—such as science, drawing, music, and storytelling—through play or informal social interaction. Most people (except prodigies) do not encounter the field until adolescence, when they come to realize and experiment with the social manifestations—roles, positions, institutions—associated with different domains. For example, a child scribbles as a preschooler, learns drawing conventions in school, and starts to pursue a career in art after winning the high school art prize. Established requirements of roles, jobs, and social propriety can eclipse opportunities for more direct interaction with the domain through play or leisure. It may be easier for people who hold marginal positions in the field to make transformative breakthroughs—consider Einstein as a patent office clerk in Bern or Gandhi as a young expatriate Indian lawyer in South Africa. Such outliers have the time and space to play in the domain and explore its latent opportunities without the responsibilities and the obligations of field roles. For these individuals, field influences came into play chiefly after they had developed key ideas and practices.

Third is the interdependence of the individual and domain (Moran & John-Steiner, 2003). We focus on individual development, but it is important to note that cultural domains develop as well (Freud, 1930/1961a; Vygotsky, 1960/1997). As individuals create, their variations slowly change the norm for their domains (Martindale, 1990). Individual development proceeds at a much faster pace than domain development, but the two dialectically affect each other. For example, artists first work with domain elements in accordance with socially accepted standards and aesthetic tastes of their times (Getzels & Csikszentmihalyi, 1976; Simonton, 1994; Vygotsky, 1965/1971). Certain innovations cannot occur until the supporting tools are available—whether those tools be new graphic, perceptual, or conceptual instruments (John-Steiner, 1995; Vygotsky, 1935/1994). The power structures of the field can limit or enable the person's awareness of and access to these domain elements (Bourdieu, 1993).

Furthermore, the current state of a domain determines whether a particular individual's contribution will have a ripple effect. Domains follow a trajectory similar to individuals: from amorphous and general forms through increasing differentiation and integration to more complex forms. A new, relatively undifferenti-

ated domain, such as computer software in the 1980s or Internet journalism recently, can be a fertile ground for new ideas to grow as there are few social or symbolic constraints. However, the primitive state of the domain makes it difficult to separate the good ideas from the bad. A well-developed, cohesive domain, such as mathematics, makes it easier to notice useful novelties because a broader base of knowledge for judgment exists, assessment criteria are clearer, and a hierarchical field structure is in place.

A fragmented domain, such as visual art, may prove especially conducive to the development of individual creative potential (Simonton, 1975). Such a domain provides a complex environment to stimulate individual development toward transformative ends. As a "horizontal" environment, it is less restrictive than traditional "vertical" domains with more stable career paths (Keinanen & Gardner, 2004; Li, 1997). Such fragmentation and complexity at the societal level also may enhance individual potential. For example, splintered politics, cultures that interact via trade or immigration, and rebellion against oppression can increase the likelihood of extraordinary achievements from individuals in these milieus (Simonton, 1975; Sorokin, 1947/1969; Wolfe, 2001). One need only think of Florence in the Renaissance or Vienna in 1900 (Csikszentmihalyi 1996; Schorske, 1979).

We now turn to an analysis of these developmental processes and trajectories in four domain systems: (1) visual art, (2) biological and physical sciences, (3) political leadership, and (4) moral excellence. We organize findings from the literature to show how each domain presents a particular end state, developmental trajectory, and individual-domain interaction pattern for ordinary (usually deemed universal) and extraordinary achievements. The ordinary development trajectory, at its extreme, leads to expertise. The treatment of extraordinary development highlights key developmental points or processes culminating in domain or field transformation.

ART

Art involves giving symbolic form to individual or collective thoughts, emotions, or ideas (Arnheim, 1966; Gardner, 1973; Goodman, 1976; Langer, 1957). The most valued artworks often play in surprising ways with the cultural or social expectations of the artist and/or audience (Bruner, 1962; Meyer, 1956). Extraordinary

artists must master the techniques of the domain through independent work and/or working with masters from the field; they also feel free to reconfigure the media. In some historical periods, the art field has been more supportive of technical mastery—as with the portraitists in the seventeenth and eighteenth centuries; at other times, the field has been more oriented toward innovation—as in the twentieth century. Therefore, the time in which an artist enters the field greatly influences the expected developmental end state. Unlike other fields, where the expert is the expected end state, the expected end state for artistic development currently is the creator, although most artists only become technically proficient professionals. The expert designation in the field tends to be relegated to the supporting roles of art historian, critic, or curator—people who know a lot *about* art but do not necessarily produce it (Becker, 1982; Gardner, 1973).

We have chosen to focus our analysis largely, though not exclusively, on the role of the visual artist. Drawing and painting are accessible to children at a very young age, and children's visual artistry has been studied extensively (see Winner, Chapter 20, this *Handbook*, this volume). Art production is a nearly universal practice of young children as they scribble on paper, associate those marks with objects in the world, and increasingly portray those objects realistically. Yet, few children become professional artists as adults—much less artists who change the way people see and represent the world. Longitudinal studies show no more than one-third of young artists continue their artistry past college, and very few achieve lasting influence (Getzels & Csikszentmihalyi, 1976; Milbraith, 1998).

Ordinary Development

Children tend to be conservative in their initial artistic efforts, using a circle to represent many different objects, or changing peripheral but not core features (Arnheim, 1974; Goodnow, 1977). Over time, young scribblers learn to differentiate, coordinate, and vary the shape, size, quantity, and position of pictorial elements into an integrated whole (Goodnow, 1977; Karmiloff-Smith, 1990). Children go through a less expressive, so-called “literal period” in middle childhood, when they accept realistic cultural norms, such as those found in comic books. Many never develop their artistic skills beyond this stage of stereotypical representation (Winner, 1982).

In adolescence, those who continue in art become more sensitive to expressive and aesthetic qualities of pictures. They experiment with subject matter, media properties, and cultural conventions in accordance with their budding artistic purposes (Gardner, 1980; Winner, 1996b). Depending on their individual values and available social opportunities, some start to orient more toward fine art and others toward applied art, such as advertising or design (Getzels & Csikszentmihalyi, 1976). Those who identify themselves as artists, find appropriate social outlets for expressing their talents, and manage to eke out a living may go on to become adult artists (Csikszentmihalyi, Rathunde, & Whalen, 1993).

As adults, artists attempt to become recognized in the field. Because the art field is more loosely organized than many others (Becker, 1982; Csikszentmihalyi, 1996), the developmental trajectory for an art vocation is not so age—or stage—graded. Many, including extraordinary achievers like Van Gogh, try other careers first (Brower, 2000; Sloane & Sosniak, 1985). Artists do not need institutionalized credentials; they can create art, sell their works, and earn awards without a formal field position, although such a position can help secure resources and opportunities (McCall, 1978). Most artists' productivity peaks in their 40s, a later age than that characterizing most other fields (Lindauer, 1993; Simonton, 1994). Moreover, as long as they remain healthy, artists can produce well into old age—Picasso and Titian being two well-known examples.

Markers of Extraordinariness

When young, extraordinary achievers' works may not stray far from the ordinary. Knowledgeable contemporary judges could not distinguish the childhood drawings of Klee, Toulouse-Lautrec, Calder, Miro, Munch, O'Keeffe, and Wyeth from those of schoolchildren (Rostan, Pariser, & Gruber 2002). Though later extraordinary artists may stand out by learning more quickly, they apparently did not go through different stages that distinguished them from many other children (Gardner, 1980; Milbraith, 1998; Pariser, 1995; Winner, 1982).

Nonetheless, the literature documents five facets relevant to extraordinariness: (1) innate talent, (2) precocity, (3) conceptual versus perceptual orientation, (4) realistic versus stylistic goals, and (5) identification with the field. These approaches roughly coincide with developmental ages through the samples used to study

them—precocity and orientation with young children, realism and style in early adolescence, and identification with late adolescence and adulthood—but they should not be considered strictly age-graded. Studies of younger children focus more on individual attributes, the domain becomes a factor in middle childhood, and the field becomes increasingly important thereafter.

Talent

More than other domains, art seems to call for special talent. Even though everyone draws as a child, not everyone draws well. Many who do draw well seem to learn it on their own with little coaching or coaxing. Even the earliest drawings of talented children stand out—portraying a scene from an unusual angle or with remarkably more detail (Winner, 1996b). Historically, artistic ability seemed to run in families: Picasso's father was a painter; Marcel Duchamp had three siblings who were also artists; and the Wyeth family name has long been associated with visual artistry. Talented artists often show a pattern of strengths and weaknesses characteristic of dominance of the brain's right hemisphere: tendencies toward left-handedness; strong pattern recognition, mental rotation, and visual memory abilities; language deficits such as dyslexia; simultaneous/spatial rather than sequential/categorical information processing strategies; detail orientation; and heightened emotionality (Geschwind, 1984; Winner, 1996b). Striking evidence for innate talent comes from artistic savants, who may be found in both visual art and music (L. Miller, 1989; Sacks, 1995). Selfe (1977, 1995) documented the artworks of Nadia, an autistic child with severely curtailed linguistic and social abilities who, without instruction, could draw with photographic realism and conventional perspective when but 4 or 5 years old.

The talent approach suggests that those who achieve extraordinary ends are unusual from the beginning. With mere exposure to the domain, they easily and enjoyably learn by themselves the skills to draw realistically, an achievement that presumably creates momentum. Although such ease in learning might suggest a role for general intelligence, artistically inclined individuals tend to score poorly on traditional, scholastic-oriented IQ tests (Getzels & Jackson, 1962; Hudson, 1966). Artistic talent coincides more with a jagged profile of intelligences. Extraordinary drawing ability often coincides with weak intelligences—perhaps, interpersonal or scholastic—as well as expectedly strong spatial and

bodily kinesthetic intelligences. For example, Picasso had difficulty learning to read, write, add, and subtract (Gardner, 1993a), as did several other precocious children artists (Milbraith, 1995). Alternatively—at least in our era—it may be that children who are both artistically and academically gifted are less likely to become artists because they have available careers that are more valued, such as science or business. Artistic extraordinariness in today's economic and cultural conditions may *require* a jagged profile, which narrows vocational choice.

No one intelligence is artistic in and of itself; all can be mobilized for aesthetic purposes (Gardner, 1983). However, exceptional spatial intelligence, in particular, can help the visual artist with observation, orientation and perspective taking, sensitivity to form, and fine motor control (Golomb, 1995). Still, spatial intelligence need not be focal for an artist; other intellectual strengths such as the geometric facet of mathematical intelligence or the sensual movement of bodily kinesthetic intelligence may also catalyze breakthrough artworks. For example, Maurits Escher's optical artistry reflects keen mathematical skills, and Jackson Pollock's action paintings were as much created by his whole-body movement with the paint as by his eyes or his hands. Such diversity challenges a neat formulation of artistic talent. The biopsychological potential to render one's experience graphically may be less important than the aesthetic (or nonaesthetic) ends to which that potential is mobilized (Goodman, 1976; Winner, 1996b).

Precocity

Studies that focus on young children emphasize differences in the timing of milestones. Extraordinariness stems not from a different path or skipping stages but rather from an easier and speedier journey—for example, drawing recognizable shapes and increasing one's repertoire of forms, details, orientations, and strategies 1 to 2 years ahead of others (Golomb, 1995; Milbraith, 1998; Winner, 1996b). Picasso, whom many consider to have been a prodigy, could draw with near adult skill at age 9 (Gardner, 1993a). Klee and Toulouse-Lautrec also tackled the common childhood drawing problems well ahead of their age-mates (Pariser, 1987).

In a landmark comparative study, Milbraith (1998) observed that more talented children, as nominated by teachers, draw recognizable shapes at age 2 rather than the expected ages 3 to 4. Precocious artists start pictures in unusual places (such as with the ear instead of

the head); present noncanonical views of a subject (such as from the back or side rather than the full frontal view); and may pick up geometric perspective without instruction. Overall they are more confident and less likely to erase lines. Their strategies and products are unusually varied. The more talented tend to show less stable, nonlinear trajectories, whereas the less talented exhibit steady, linear growth. Still, the less talented rarely catch up to the skill level of the more talented. Although models of art might be available, the more talented have been playing in the domain largely on their own and developing idiosyncratic strategies for dealing with common art problems.

Early excellence does not always translate into later artistic extraordinariness. For example, Eitan, who first drew at age 2 and could depict with perspective around age 3½, as a young adult considered architecture or automobile design rather than fine art as a career (Golomb, 1995). One reason for the disjunct may be a chasm that needs to be leapt in middle childhood or adolescence. The precocious child must reconcile idiosyncratically derived, motor-based strategies with the culturally derived strategies favored in academic settings—a battle between individual and field-approved approaches to the domain. Bamberger (1982) described such a “midlife crisis” for early achievers in music as the bridge from figural to formal musical knowledge structuring. Milbraith (1995) extended this argument to the visual arts: later representation strategies that use linear perspective may prove hard to assimilate for precocious artists who somehow contrived their own ways to render depth.

Conceptual versus Perceptual Orientation

By age 3, most children categorize an entity as a chair, an apple, or an elephant. They draw on these general schemas and have no reason to inspect the object further (Arnheim, 1974; Gombrich, 1960; Goodnow, 1977). Milbraith’s (1998) comparative study found this conceptual predominance among the less talented. This overreliance on standardized knowledge impoverishes these children’s visual sensitivity, limiting what they can later draw.

In contrast, the more talented children approach their subject matter with a different kind of mental eye. They tend to draw what they see, even if it counters the conventional models. These students draw categorically only briefly before switching to visually oriented rendering. More sensitive to visual discrepancies and patterns, their drawings include more elaboration. Talented

young artists may not necessarily need to *know* how to draw in perspective; their drawings may simulate perspective simply because the children can see that certain lines of an object approximate a particular diagonal angle. A strong perceptual faculty also may inoculate these children during the literal stage of artistic development. Rather than taking cultural norms as given, they construe them as one more variable to manipulate in their drawings; they trust what they personally observe, in the process developing their own visual vocabularies (Radford, 1990).

Observations of autistic youth support the argument of differences in orientation. Alex exhibited low conceptual abilities but high spatial abilities. He could draw “in perspective” at age 6. In the absence of input from the field via schooling, he was dominated by the properties of the domain. But as he developed more field-influenced conceptual knowledge by age 8, his drawings became less realistic and more like those of his age-mates (Milbraith, 1998). Similarly, as Nadia grew older and developed a few more language skills, she began drawing in the more canonical, conceptual way of young children (Selfe, 1995).

An overreliance on perception can harbor its own problems. For instance, young Picasso wanted to treat numbers as visual patterns not quantity symbols, a proclivity that held him back in school (Gardner, 1993a). Milbraith (1998) concludes that neither conception nor perception is intrinsically better. Rather, the integration of the two perspectives leads to advanced artistic skill by providing children with flexible control for experimenting with subjects and medium properties. Extraordinariness seems to arise from the individual’s purposeful manipulation and integration of both more field-influenced conventions and more idiosyncratic understandings of the domain.

Realistic versus Stylistic Goals

Most studies of childhood drawing assume an end state of realism. However, at least since the invention of photography, which undermined the mission of preserving experience graphically, a newer end state of expressiveness has emerged—the domain and its attendant field expectations changed. The capacity to produce expressive works may prove crucial in determining whether an artist becomes creative and not just proficient and professional. Whereas a child may be heralded as a prodigy for nearly photographic reproduction, an adult artist is expected to create a deeper stratum of feeling, under-

standing, or meaning (Gardner, 1980). Creativity extends beyond technical proficiency to the emergence of a distinctive style. Despite impressive achievements, savants rarely go beyond photographic realism to improvise and, therefore, their products are rarely considered creative (Gardner, 1982). As a result, researchers who study artistic development in adolescence or adulthood now emphasize the emergence of style and expression (Csikszentmihalyi et al., 1993; Hudson, 1966; Radford, 1990).

Although individual differences in style can appear as early as age 7, they do not fully blossom until adolescence (Winner, 1996b). Children first imitate others' styles. Even eminent artists at first studied and appropriated the styles of historical masters or contemporary artists in their quest for opportunities inherent in their artistic media (Brower, 2000; Gardner, 1973, 1993a; Pariser, 1987; Vendler, 2003). Superceding standard technical expectations, some eventually develop a personal aesthetic that guides their decision making (Kay, 2000). Klee's whimsical sketches as a child, for example, seemed to support his later mature style, and Toulouse-Lautrec's intense concentration on the emotional impact of certain graphic approaches led to his highly stylized posters and other works (Pariser, 1987, 1995).

Some researchers suggest that style does not develop linearly but follows a U-shaped trajectory, at least in Western culture. Preschool children's drawings have personal style, which tends to decrease during elementary school when stereotypes predominate. Style reemerges in adolescence for a few, who now have gained more control over their graphic repertoire (Davis, 1997; Gardner & Wolf, 1988; Rosenblatt & Winner, 1988). Perhaps those who emerge on the upward swing of the U-curve—who survive the literal period—are those who establish a trust in their own viewpoint at a very young age, thus achieving a resilience that others lack. Young children can produce (but not perceive in others' artworks) stylistic elements without knowing why they are important, whereas adolescents and adults—more metacognitively aware—can perceive and produce stylistic elements intentionally (Carothers & Gardner, 1979). Their ability to manipulate the artistic medium subtly becomes focal to their artistry.

Precocious young artists may develop their first style as young as age 10; they do so by increasing details or providing variations on canonical themes or methods (Gardner, 1980; Winner, 1996b). Golomb and Haas's

(1995) longitudinal case study of Varda from age 2 to her adult vocation as a sculptor shows such a shift. Early styles rarely are innovative. Even Picasso's Blue and Rose periods in his 20s stray little from the realistic norms of Western art at the time.

Vendler (2003) conducted a detailed study of four major English-language poets "coming into their own." She documented how each, with increasing intention, played aesthetically with the affordances of language: Milton with mystical imagery, Keats with the sonnet form, T. S. Eliot with middle-class mores, and Plath with the constraints of domesticity and family relations. Brower (2000) conducted a similar study of Van Gogh. After years of experimenting with lighting, drawing, painting, multiple media, and Japanese techniques, Van Gogh matured his own style of pulsating lines, thickly applied paint, and vibrant coloring. These artists learn to manipulate, manage, and integrate many aspects of their ideas, media, and practices until they become able purposefully to vary cultural or domain conventions. Once field norms have been internalized but no longer dominate one's thinking, style emerges from the ongoing interaction of individual interests and domain properties.

Identity as an Artist

A final approach to extraordinariness in art, typically focused on late adolescence and early adulthood, emphasizes the social dimension: how a person identifies as an artist, is accepted by others as an artist, and finds a congenial position in the art field. Construing the determination of creativity as a social process, some researchers analyze how a person navigates interactions with other people, groups, and institutions, thereby garnering psychological and economic resources (Becker, 1982; Bourdieu, 1993; Csikszentmihalyi & Robinson, 1988). In part, this process depends on the state of the field. For example, the current modern art field demands innovation, whereas the pre-nineteenth-century Western academy-dominated field and the traditional Chinese painting field preferred works that were imitative of great masters (Li, 1997).

As adults, artists go through the same challenges of identity as others (Erikson, 1959; Marcia, 1966), but art plays a pivotal role in helping them define their unique contribution to the world, build relations with and receive praise (and criticism) from peers and family, and explore less popular vocational options (Getzels & Csikszentmihalyi, 1976; Rank, 1932; Sloane &

Sosniak, 1985). Despite their compulsions to draw as children, individuals do not necessarily experience a calling to an art career (Wrzesniewski, McCauley, Rozin, & Schwartz, 1997). Instead, their choice to become an artist evolves through accumulated and interacting decisions and happenstances with field elements—for example, attending art school, finding a mentor, envisioning a career, and becoming acculturated to art historical and critical stances (Getzels & Csikszentmihalyi, 1976).

Those who become eminent, such as Pablo Picasso or Andrew Wyeth, may benefit from a parent already in the field, so they have earlier exposure to authentic—as opposed to standardized or generic—role models, current controversies, emotional support, and exacting professional-level standards (Bloom, 1985; Gardner, 1993a). For most, however, parents and teachers either provide minimal direction or steer children away from risky artistic careers (Getzels & Csikszentmihalyi, 1976; Ochse, 1991; Sloane & Sosniak, 1985). Social obstacles or challenges also may play a role in defining one's place in the field; they may prove even more important than support in taking on a creative position that challenges the field's status quo (Gardner & Wolf, 1988).

Despite the Romantic notion of the artist as independent and free-spirited—a portrayal often perpetuated by artists themselves (Rank, 1932)—artists must develop social skills to gain attention from others (Gardner, 1993a; Getzels & Csikszentmihalyi, 1976; Kasof, 1995). Sometimes these contradictory notions of marginality and connectedness can come together when artists—such as Warhol, Toulouse-Lautrec, and Picasso—intentionally cultivate an image as an eccentric talent. Still, the artist's social interactions are often complex and sometimes antagonistic to those in powerful positions, who may themselves have been the innovators the generation before (Bloom, 1997; Bourdieu, 1993).

With no singular, culturally accepted end state for art beyond the realism of middle childhood, artists develop “against” what has come before—Impressionists reacted against academic painting, Abstract Expressionism against Cubism. So artists must learn to deal with anxiety and rejection, as well as to watch their artworks take on lives of their own in the world of art criticism and history (Jaques, 1990). It also may take considerable time for their work to be recognized. For example, concept-driven artists tend to be recognized as innovative at a younger age and their earlier paintings are worth more in the field, whereas experimental artists tend to be rec-

ognized and their work worth more later in their careers (Galenson, 2001).

Summary

In the opening years of life, extraordinariness involves innate talent announcing itself in first drawings. The individual is preeminent. In preschool and elementary school, extraordinariness involves precocity in reaching the milestones of recognizable shapes, realism, and perspective, as well as better integration, flexibility, and control of conceptual and perceptual abilities. The individual and domain gradually begin to be affected by the field. In adolescence and adulthood, extraordinariness involves going beyond realism to develop a distinct style and finding one's place in the art field. Both constitute interactions of individual and field, somewhat paradoxically: the first in overcoming field conventions of the domain and the second in settling into (or perhaps helping to reformulate) the field's power structure. Although most of us rarely develop artistically beyond the production of stereotypical images appropriated from our culture, those who become extraordinary seem to “march to their own drummer”—trust their own vision, develop their own style, make their own mark(s) on the art world (Winner, 1996b).

SCIENCE

Science involves the cumulative process of theorizing, testing ideas, and interpreting evidence to explain and predict how the world works. Despite science's usual steady march of small steps toward more sophisticated understanding, occasionally conditions in the domain occur in which a particular step, move, or reorientation produces an extraordinary leap in understanding (T. Kuhn, 1962). Familiar examples include Copernicus and the heliocentric solar system, Newton and his mechanical universe, and Darwin and evolution.

As with art, the most memorable or extraordinary discoveries reorient cultural or social understanding of a phenomenon. But unlike contemporary art, science includes both experts and creators as important end states. Experts deepen and extend our current understanding of a phenomenon through replication studies, use of current methodologies, and support of current theories. Creators reformulate understandings of a phenomenon through innovative methodologies, unexpected findings, or new theoretical frameworks. Because of the trajectory of science, in which ideas build on one another, once a creator's idea or discovery becomes accepted by the field

and transforms the domain, he or she tends to hold an expert position in the transformed field. Very few scientists make more than one large-scale, transformative discovery. They spend their later years solidifying their breakthrough idea and training those who, they hope, will perpetuate and deepen it but who may ultimately overthrow it (Gardner, 1993a; Nakamura & Csikszentmihalyi, 2003).

This linear trajectory also creates differences across domains. Although the initial appearance in children of scientific thinking remains a subject of controversy (cf. Carruthers, 2002; Gopnik & Meltzoff, 1997), researchers agree that scientists *must* spend at least 10 years in school or apprenticeships mastering domain knowledge, such as molecular biology or theoretical physics (Ericsson, 1998). One cannot contribute new knowledge to a scientific domain one has not fully mastered. As these domains become increasingly complex and specialized (Leach, 1999), the young scientist may choose or even need to spend additional years in postdoctoral positions. Groundbreaking discoveries rarely occur without such intense years of training and collaboration.

Ordinary Development

Ordinary development in science has been a staple of cognitive development and educational research (see D. Kuhn & Franklin, Chapter 22, this *Handbook*, this volume). Most studies emphasize problem solving and use either a Piagetian (1937/1995, 1955/1995) or a think-aloud (Chi et al., 1982; Newell & Simon, 1972) approach to illuminate how novices or younger children differ in their thought processes compared to experts or older children. Despite studies that challenge particular Piagetian claims (Fischer & Pipp, 1984; Gardner, 1973), Piaget's general approach underpins most work on the development of skills and concepts in mathematics and science (Fischer, Kenny, & Pipp, 1990; D. Kuhn, Garcia-Mila, Zohar, & Andersen, 1995; Tytler & Peterson, 2004). Recent work has turned attention to how analogies (Goswami, 1996), metacognitive processes (D. Kuhn, Katz, & Dean, 2004), and biases (Klahr, 2000) affect children's scientific reasoning.

Less work has been done on the development of scientific thinking beyond the school years. Newer lines of research have examined scientific thinking as a social discourse by studying scientists at work (Dunbar, 1996) or science as a form of argument or persuasion (Kelly & Bazerman, 2003; D. Kuhn, 1993). Adolescents and

young adults who continue scientific pursuits come to understand that science is not simply a collection of facts but rather a process of recursively testing hypotheses and devising explanations (D. Kuhn et al., 2004; Leach, 1999; Schable, 1996; Smith, Maclin, Houghton, & Hennessey, 2000). Without explicit instruction and practice, most people never go beyond considering science as the accumulation of absolute, incontrovertible facts. Indeed, they become increasingly entrenched in their biases, confirming what they already believe, and stumbling when they encounter the norms of inquiry and exploration underlying the scientific domain (Gardner, 2000; Greenhoot, Sembe, Columbo, & Schreiber, 2004; Klaczynski & Robinson, 2000).

Markers of Extraordinariness

Some possible early flags of extraordinariness include: (a) innate, domain-relevant abilities evident as early as age 2, (b) unusual and independent curiosity in early childhood that is maintained over decades, (c) stronger skills for approaching problems encountered during training, and (d) social connections and circumstances that catalyze extreme productivity in one's adult career. As with art, these markers roughly follow an age profile, starting first with individual characteristics and expanding to include the domain and field.

Innate Ability

Science is often associated with computational ability, high IQ, and analogical thinking, which may have biological roots. Computational ability often (Feist & Gorman, 1998) but not always (Radford, 1990) arises early in life, perhaps even in infancy (Gopnik & Meltzoff, 1997; cf. Carruthers, 2002). Unusual abilities can be demonstrated well before formal instruction (Bloom, 1985). Prodigies, such as Blaise Pascal, Carl Friedrich Gauss, and Norbert Wiener (Radford, 1990), as well as savants (Sacks, 1985), demonstrate near-miraculous abilities to add large numbers in their heads, determine the day of the week for a particular historical date, and recall complicated numerical series such as timetables or financial columns. Mathematical ability, at least below the genius level, runs in families, as with the Bernoulli brothers and Pascal and his father. Higher correlation in monozygotic twins points to a heritable component (Feist & Gorman, 1998). However, as Einstein's story attests, computational ability is not a prerequisite for extraordinary achievement in science, and extraordinary scientists can emerge in ordinary settings.

IQ is another supposedly innate ability that is proposed to underpin scientific achievement. Many well-known scientists are believed to have high IQs (Cox, 1926). Children with high IQs are quicker and more flexible in problem solving (Radford, 1990), pass through Piaget's stages of scientific reasoning more rapidly (Carter & Ormrod, 1982), and benefit from accelerated and enriched school activities (Lubinski & Benbow, 2000). IQ correlates more with scientific achievement, at least while in school, than with artistic achievement (Lubinski & Benbow, 2000), presumably because logical and mathematical skills are foregrounded in these measures (Gardner, 1983). However, as in art, prodigious behavior in science does not necessarily predict adult professional contributions. Lubinski and Benbow (2000) reported that only 25% of gifted young scientists persevere into a scientific vocation, a statistic that still does not implicate creativity or extraordinary achievement.

Standard IQ scores denote a child's overall ability to solve problems, whereas most children show uneven ability between the math and verbal sections of IQ, SAT, or other aptitude tests (Hudson 1966; Radford, 1990; Winner, 2000). The higher the IQ, the more jagged the intelligence profile is likely to be (Detterman & Daniel, 1989). In addition, correlations among verbal, mathematical and spatial abilities tests prove to be somewhat discipline specific. In Roe's (1952) studies, theoretical physicists scored the best on all tests, and psychologists tended to do relatively well across the board. But anthropologists scored well only on verbal sections, and applied physicists scored well on spatial but not verbal tests. Logical-mathematical intelligence is not the only intelligence on which scientific breakthroughs draw (Cox, 1926; Gardner, 1983). Spatial intelligence also seems to play a leading role in scientific breakthroughs, at least in physics and biology (Gardner, 1993a; Root-Bernstein, Bernstein, & Garnier, 1995). Darwin, Feynman, Faraday, Einstein, as well as Watson and Crick, all relied on images, diagrams, or other spatial tools to help them construct and organize their thoughts (Anderson & Leinhardt, 2002; Gooding, 1996; A. Miller, 1989; Watson, 1968).

Analogical thinking—the ability to effect connections among disparate things—is believed to underpin scientific achievement (Goswami, 1996). Such reasoning by analogy may be present from infancy as babies try to make sense of their world. Later deductive reasoning might be undermined by these early connections

because it is often difficult for people to set aside the "truth value" of a premise based on their own experience and adopt a premise as an abstracted given. Consequently, analogical thinking may be both a support and a challenge to scientific achievement—extraordinary scientists often rely on analogy to create fruitful frames for problem solving (Gruber, 1989) but they also must overcome the biases that such analogies might entail (Klahr, 2000).

Curiosity

When asked what set them apart as children, eminent scientists and their parents and teachers most often mention unusual curiosity—an emotional and intellectual resonance between individual and domain (Feist & Gorman, 1998; Gustin, 1985; Sosniak, 1985). Pascal was fascinated with making charcoal drawings of perfect circles or equilateral triangles, Pierre Curie with ponds. In a post hoc analysis of 100 of Cox's (1926) sample of eminent achievers, Terman (1954) found a predictive childhood interest in half the cases. He also found significant differences in the childhood interests of his subjects who eventually became natural scientists, social scientists, and nonscientists (Terman, 1955). Lubinski and Benbow (2000) reported that interests are both differentiated and stable by age 12; moreover, with age, interests surpass ability as a predictor for a scientific career.

Future mathematicians or scientists love to learn, count, and make logical connections for their own sake—science is intellectual play for them (John-Steiner, 1985; Radford, 1990; Roe, 1952). They develop precise or sophisticated ways to arrange their toys; they enjoy jigsaw puzzles, model-building, and other manipulables (Bloom, 1985; Sosniak, 1985). Although some may have trouble learning to read (Gardner, 1993a; Gustin, 1985), once they master the skill, they devour texts to expand their scope of knowledge and solidify their interests in the domain (John-Steiner, 1985; Walters & Gardner, 1986).

Like artists, future eminent scientists tend to be loners (Roe, 1952; Storr, 1988). Rather than joining existing groups as most children do, they develop independent projects (Gustin, 1985; Sosniak, 1985). Einstein conducted thought experiments during his youth (Gardner, 1993a), and the biologist E. O. Wilson preferred designing his own Boy Scout projects (Csikszentmihalyi, 1996). Future mathematicians and scientists tend to see other people as something to study (e.g., social scienc-

tists) or ignore (e.g., natural scientists) rather than relate to, help, or dominate (Gardner, 1993a, 2004b; Gustin, 1985; Hudson, 1966; Roe, 1952).

Such isolation may catalyze flexibility in classification skills by distancing nascent scientists from the normal categories of their culture (Gardner, 1983; Radford, 1990). It helps them overcome the obstacles of bias, confusion between theory and evidence, and lack of counterargument typically found with ordinary development (Gardner, 1991; Greenhoot et al., 2004; Klaczynski & Robinson, 2000; Klahr, 2000; D. Kuhn et al., 2004). Einstein spoke of the scientist's need to be "rendered independent of the customs, opinions and prejudices of others" (Gardner, 1983, p. 131). Time to develop one's own ideas and personality also may prepare future scientists for a life of scientific challenge, argument, and criticism (Feist, 1993; John-Steiner, 1985; Watson, 1968). Independent projects may keep students, who otherwise are bored in school, interested in scientific pursuits. One reason adolescents may not continue in the sciences is that schoolwork is too didactic and not sufficiently investigative to pique their interest (Feist, 1991; Lubinski & Benbow, 2000; Subotnik & Arnold, 1994). Most who do pursue scientific careers do not remember their school years favorably (Gustin, 1985; Shekerjian 1990; Sosniak, 1985). Without the early blossoming of interest, field constraints and prescribed educational paths may support technical mastery of existing knowledge while inhibiting the exploratory behavior that can lead to new knowledge creation (Amabile, 1996; Berlyne, 1950).

Approaches to Problems

In adolescence and adulthood, what one knows becomes less important than how one knows. Process supercedes memory as a marker of extraordinariness. Most studies of problem-solving strategies compare responses to current field standards (e.g., Chi et al., 1982); accordingly, these investigations do not account for qualitative differences in solutions or approaches that attempt to change what the "right" response is. These studies do not differentiate creators from experts but rather provide additional support for how creators in science must first become experts and for what differentiates experts from novices. Beyond expertise, though, extraordinary scientists have a knack for finding good problems to work on, which often are not yet recognized by the field as important. They may even risk their entire career on one potentially fertile but still risky problem (Bereiter

& Scardamalia, 1993; Gruber, 1974). Whereas most people don't notice anomalies or explain them away (Chinn & Brewer, 1993), extraordinary scientists are drawn toward, rather than ignorant of or afraid of, anomalies (Csikszentmihalyi, 1996; Gardner, 2004b; Gardner & Nemirovsky, 1991). Those who do better in science—first as experts, then as creators for a select few—display several salient characteristics. They keep an open mind, persevere to make nuanced distinctions, create fruitful problem representations, coordinate theory and evidence, and are relentlessly meta-cognitive.

First, rather than favoring perceptual or conceptual information, experts stay open to both (Gooding, 1996; Langley et al., 1987). In contrast, novices rely excessively on their early perceptions, biases, or concepts learned didactically (Grotzer & Bell, 1999; Klahr, 2000; Perkins & Simmons, 1988); this reliance limits their ability to complexify their problem representations (Anderson & Leinhardt, 2002). Creative scientists go a step further to develop highly tuned observational mechanisms to perceive what others blinded by conventional conceptions fail to notice (Langley et al., 1987); moreover, to guard against their own conceptual inertias, they often work on more than one problem or project (Gruber, 1989). Individuals who believe that knowledge is mutable and uncertain, and who have faith that their curiosity and investigative efforts will be fruitful, are more likely to engage in scientific and other knowledge creation pursuits (De Corte, Op't Eynde, & Verschaffel, 2002; Dweck, 2002; Klaczynski & Robinson, 2000).

Second, whereas novices jump quickly to formulating solutions that coincide with their current beliefs, experts spend more time and attention setting up and revising problem representations (Klahr, 2000; D. Kuhn et al., 1995; Rostan, 1994; Schaffner, 1994; Smith et al., 2000). If children or novices learn scientific concepts by rote, they may become technicians without understanding clearly the opportunities lurking in the deeper structure of problems (Perkins & Simmons, 1988; Zuckerman & Cole, 1994). These individuals also do not learn how to separate and coordinate theory and evidence, nor do they come to appreciate the extent to which knowledge is uncertain, provisional, and constructed by a scientific field (Kuhn, Cheney, & Weinstock, 2000; Leach, 1999). Once a focus on anomalies or assumptions arises, it is not necessarily used consistently; many adults continue to exhibit confirmation bias and snap judgments that inhibit their creativity (Graanhout et al., 2004; Klahr, 2000; D. Kuhn, 1989).

Creators are more tenacious than experts about going beyond the “right” answer currently accepted in the field. Notebooks of famous scientists show multiple problem representations based on imagery or analogy (Dunbar, 1996; A. Miller, 1989; Tweney, 1996). These representations help scientists to break free of conventional conceptions (Gardner, 1993a; Gruber, 1974), develop new methods and theories (Rostan, 1994), and maintain mental openness (Holmes, 1996). Whereas most people argue what they know, breakthrough thinkers focus on what they don’t know (Qian & Pan, 2002). They orient to the gaps, anomalies, and counterfactuals of a situation. Yet, even acclaimed scientists acknowledge the difficulty in facing contradictions and maintaining a skeptical yet open-minded perspective (Wertheimer, 1945/1959; Zuckerman & Cole, 1994).

Third, whereas novices have less conscious control over their mental processing, experts are more metacognitive and metastrategic. High-IQ children show consistently better awareness of their knowledge and mental activities. Better science students exert more control over their strategy use in problem solving and thus become more conscious of not only *what* they learn but *how* (Alexander et al., 1995; Radford, 1990). Their coordination of theory and evidence, the transformation of their mental models with new information, and their understanding of the scientific process improves (Kuhn et al., 2004; Schauble, 1996; Sinatra & Pintrich, 2003; Tytler & Robinson, 2004; Zimmerman, 2000). Skilled scientists pay more attention to cues in the problem space (Klahr, 2000; Newell & Simon, 1972) as well as the aesthetic qualities of possible solutions (A. Miller, 1989; Polya, 1973; Radford, 1990). Experts tend to control their cognition based on correctness, creating a feedback loop to reduce variation. Creators control their cognition based on novelty, creating a feedback loop to enhance variation (Gruber & Davis, 1988).

The Scientific Career

Although studies of scientific process often focus on cognition and problem solving, much interest has arisen in the social aspects of scientific achievement (Latour, 1987). Focus has shifted from problem solving to argumentation (D. Kuhn, 1993). Science is viewed as a discourse in which people try to persuade each other to accept one concept or theory over a rival account (Bell & Linn, 2002; Leach, 1999). People must understand the general discourse of science before they can make sense of scientific methods and findings (Lehrer, Schauble, &

Petrosino, 2001). Scholarly journals are a market or battlefield for dominance by those who are most persuasive (Kelly & Bazerman, 2003). From this perspective, a scientific career entails not only knowledge creation but also political and communicational savvy amidst a field of other scientists.

This discourse “game” has time constraints—scientists’ work must connect with the flow of the field. If he or she is too early, eccentricity results; too late, ordinary science results. The timing must be right for a contribution to be considered creative. The normative scientific career trajectory peaks early and tends to follow an inverted-U arc over one’s lifetime (Lehman, 1953; Simonton, 1988). One’s first valuable contribution usually occurs in one’s 20s, the biggest breakthrough in one’s late 30s or 40s, and a final, important contribution in one’s 50s (Simonton, 1991a). Mathematics and physics tend to show earlier peaks—in terms of seminal contributions—than biology or earth sciences (Gardner, 1983; Simonton, 1988, 1991a; Zuckerman, 1977).

Nowadays, these age trends are likely to have later peaks, given increasing complexity in scientific domains and fields that lead to longer training periods and delayed launching of one’s official career—and possibly also better health in later life (Gardner et al., 2001; Simonton, 1991a). Although the field has long played a background role, budding scientists only become part of the field proper in college or graduate school. They start working alongside other scientists on problems that lack known solutions (P. Davis & Hersh, 1980; Gustin, 1985; Sosniak, 1985) and must learn to communicate in a scientific community (Kelly & Bazerman, 2003; Leach, 1999).

Despite the lengthy apprenticeship period, many extraordinary scientific breakthroughs have been made early in careers. The examples of Einstein, Newton, and Krebs are well known (Gardner, 1993a; Holmes, 1989). Although transformative scientists independently have studied the domain and are familiar with the field, often having been mentored by a more advanced scientist, at the time of their breakthroughs, they are often marginal to the field. They do not hold traditional expert positions of power that may inundate them with administrative work and reduce the time available for creative work (Nakamura & Csikszentmihalyi, 2003; Perry-Smith & Shalley, 2003).

Still, social support heralds a higher likelihood of making a breakthrough contribution, as it aids the ac-

quisition of scientific cultural capital (Bourdieu, 1993). Even though science has often been viewed as solitary thinking (Gruber, 1989), collaboration skills are extremely important (Gardner, 1999; John-Steiner, 2000). More likely to continue and excel in science are those students who participate in talent searches and science fairs (Lubinski & Benbow, 2000), work in another scientist's lab at a young age (Fischman, Solomon, Greenspan, & Gardner, 2004; Gardner, 1993a; John-Steiner, 1985), and find (or are found by) influential and supportive mentors (Gardner, 2004b; John-Steiner, 1985, 2000; Noble, Subotnik, & Arnold, 1996; Zuckerman, 1977).

Furthermore, collaborations with other strong thinkers often continue throughout a scientific career. Einstein and his mathematician friend Marcel Grossman, physicists Richard Feynman and Freeman Dyson, and Marie and Pierre Curie, for example, established long-lived, joint productivity based on complementarity of skills and perspectives (John-Steiner, 2000). The Human Genome Project, the culmination of a century of work in biology, resulted from the cross-historical and contemporary collaborative efforts of hundreds of scientists (Keller, 2000). However, women scientists' careers tend to follow a more complex pattern, with fewer supports, different kinds of mentors, and less recognition. They produce fewer publications that tend to be longer, more discursive, and more synthetic (Holton, 1973). This scientific pattern of required credentialing, long training arcs, institutional affiliation, and collaboration differs from that found in less "vertical" domains (Li, 1997).

The most striking marker of extraordinariness as an adult is prolific productivity. A few scientists produce the most publications. Nobel laureates average more than three papers a year, whereas *American Men and Women of Science* scientists average only about 1.5, and most ordinary scientists publish only once or twice in a lifetime (Simonton, 1988). Mathematicians considered most creative by colleagues published three times more papers than the less creative (Helson & Crutchfield, 1970). Early productivity predicts later productivity, creating a cumulative advantage in both publication and citation rates (Merton, 1968; Zuckerman, 1977).

By middle age, the odds of making a transformative contribution diminish (Simonton, 1988). Even for those who become domain-transformers, their role in the field often changes afterward (Csikszentmihalyi, 1996; Nakamura & Csikszentmihalyi, 2003). Most likely, sci-

entists focus on integrating their own work (Gardner, 1993a), synthesizing others' work in the field (Csikszentmihalyi, 1996), institutionalizing their work in labs or writings (Holmes, 1996), becoming administrators or gatekeepers of field resources (Gardner, 1993a; Holmes, 1996), or philosophizing and critiquing the field and domain (Csikszentmihalyi, 1996; Gardner, 1993a). The attention garnered from a creative breakthrough may make it difficult for the scientist to devote the time and effort, or evince the risk taking needed for another breakthrough (Holmes, 1996).

Summary

Extraordinariness in science comprises a fruitful "co-incidence" (Feldman, 1986) of ability, curiosity, training, opportunity, and support. Some, but not all, groundbreaking scientists display natural ability, either high IQs or more specific computational, logical, or spatial intelligences. Many exhibit a strong drive to learn the domain even before school starts. Through independent projects, schooling, and practice, budding scientists develop strategies, mechanisms, and epistemological beliefs to help them build, and navigate in, anomalous yet promising problems. Once launched on a scientific career, they develop networks of intellectual projects, social relations, and scientific discourse skills to garner resources, stimulate productivity, and continually feed their minds. Although many people acquire the basics of observing, hypothesizing, examining evidence, and drawing conclusions, those who become extraordinary in science also learn the importance of framing questions from a perspective independent of the field's conventional wisdom and/or their own biases; they persist systematically despite the uncertainty of scientific pursuits, and combine both collaborative and competitive aspects of breakthrough thinking. The field plays a major role, often as an antagonistic force in early schooling that focuses on more canonical methods and knowledge, but later as a supportive force in providing resources and opportunities for one's career.

POLITICAL LEADERSHIP

Leadership consists of the role assumed by one person (or a small group) who garners resources and power to guide and align the beliefs and actions of others toward a goal, vision, or mission (Burns, 1978; Gardner, 1995, 2004a; J. Gardner, 1984; Simonton, 1991b). At one time

based on presumed divine magic power, leadership evolved into an inherited right of royalty, a paternalistic autocracy of rulers and owners, or most recently the group most expert in a field. Now, in treating leadership, researchers de-emphasize the command-and-control aspects while stressing the importance of getting often antagonistic constituents to work together (Heifetz, 1994; Zander & Zander, 2000). Leadership occurs across domains; the domain of leadership—including general techniques and strategies—has been studied in itself (see Kellerman & Webster, 2001 for review). However, leadership is also situated in more traditional domains, such as art, science, law, and business. Leadership has been most studied in the business and political domains. In these realms, searchlight intelligences are more prevalent in field and domain dynamics than in arts and sciences, where expertise, creativity, and laserlike intelligences are foregrounded. Leadership does arise in the arts and sciences. Picasso was a leader of Cubist painters and Oppenheimer led scientists in the Manhattan Project. But their power stemmed more from their expertise than from the field-oriented, social skills and qualities we emphasize.

In business and politics, the creation of a social organization with purposeful momentum is often the main point, not just a side effect of one's primary expertise. Whereas in art and science, the medium of transformation is usually symbolic—through images, words, or mathematical formulae—in business and politics, the field structure with its current power relations is the medium to be transformed. The transformation is social. We focus chiefly on political leaders because they influence a wide circle of diverse people and have been most studied.

Ordinary Development

As is true for the other domains surveyed, rudimentary sociopolitical activity can be observed even in young children. Except for individuals with severe disorders, everyone develops social skills for understanding, communicating with, and influencing others. The foundation for leadership—social dominance, or the variance in ability to compete for resources with, from, or through others—starts in preschool (Hawley, 1999). In early pretend play, children can symbolize the self and others, enact different roles, understand that people have different perspectives, and learn the consequences of different stances and actions (Gardner, 1983; Harris,

2000; Vygotsky, 1978). As with art and science, one's first encounter with leadership is through play with the domain—in this case, role playing. However, as the play medium is social interaction itself, such play is rarely unmediated by field forces; from their first years, children learn “good behavior” and tactics of influence just by operating in the family.

By kindergarten, some children display exceptional abilities to coerce, persuade, help, cooperate with, and command their peers to get their needs met; youngsters may also display a preference for either coercive/instrumental or prosocial/empathic strategies (Hawley, 1999). During elementary school, children's understandings of roles become more complex, starting with definitions based on specific actions, then incorporating motivations and intentions, and finally coordinating multiple roles and perspectives across situations (Fischer, Hand, Watson, Van Parys, & Tucker, 1984; Flavell, Botkin, & Fry, 1968; Selman, 1980).

In American society, adolescents take on institutionalized leadership roles such as student council representative, cheerleader, band drum major, or babysitter. Typically, they first become amateurs in the leadership domain, occupying “pretend” or “shadow” versions of generic roles that occur in many fields. Such early experiences can help form the values—such as left- or right-wing political activism—that may continue into adult leadership (Braumgart & Braumgart, 1990; Flacks, 1990). Those elected to leadership positions also learn to value and exhibit dependability (Mason, 1952), integrity, and knowledge (Morris, 1991), even as they explore potential vocations (Govindarajan, 1964). Traditionally, Scouts organizations, churches, the European *grands-écoles*, the American armed services and their academies, and scholarship programs offer ladders that train youth in leadership skills. Evaluations of these and other programs rarely take a developmental perspective or separate leadership qualities from the demands of stipulated roles (Furr & Lutz, 1987; Hohmann, Hawker, & Hohmann, 1982; Kielsmeier, 1982).

As adults, most people are followers. Instead of taking initiative or responsibility for others, they work for others in an already established organization geared toward someone else's vision (Berg, 1998). Those oriented toward leadership typically are managers, rising up their organizations' hierarchies, taking on roles with increasing responsibility, maintaining efficient operations, but for the most part, still contributing to another person's or institution's vision (Kotter, 1990). As was

the case in comparing experts and creators, leadership studies that use managers as subjects may not be useful—or even germane—for understanding the development of extraordinary leadership (Hunt, 1999; Lowe & Gardner, 2001). Moreover, exceptional leaders may arise from outside normal institutions, and such individuals may use their newly acquired authority for ends that are benign (e.g., Martin Luther King Jr. or Mahatma Gandhi) or malevolent (e.g., Adolf Hitler or Joseph Stalin; see Bullock, 1998). Compared to adolescents, adults tend to define leadership more by sense of purpose rather than by activities (Morris, 1991); yet, most forms in which adults engage tend to be transactional, based on exchange of resources for mutual benefit, rather than transformational toward a new, higher purpose (Burns, 1978).

Markers of Extraordinariness

Goertzel et al.'s (1978) sample of eminent politicians, including Robert Kennedy, Lyndon Johnson, Cesar Chavez, and Adolf Hitler, depict a fairly normal childhood. The most effective leaders seem to have not the *extremes* of certain psychological abilities, such as a super high IQ or the most charismatic personality, but a better *balance* or relatively flatter profile of intelligences or traits. As a result, the individual can adapt to various situations; even though the person may not necessarily stand out from the crowd on any one attribute, he or she may well rise above others as the leader. Although neither necessary nor sufficient for leadership to arise, several identified features correspond with later eminence in leadership: (a) "high enough" general intelligence, (b) skills in connecting to others, (c) unusual drive, and (d) adversity in early life that is somehow addressed, plus (e) an opportunity to perform on a wide stage in adulthood—granted or seized—correspond with later eminence in leadership (Burns, 1978; Gardner, 1995; Simonton 1994; Wills, 1994).

Intelligence

Compared to students with average IQs, students with high psychometric intelligence tend to show leadership potential (Terman, 1954). But too high an IQ can create difficulties in relating to others (Fischer, Hand, Watson, Van Parys, & Tucker, 1984; Hollingworth, 1942). IQ studies of historical leaders give mixed results, sometimes and sometimes not correlating with the measure of

leadership (Cox, 1926; Simonton, 1976, 1981, 1986, 1991b). The most eminent leaders tend to have above average—but not too high—intelligence and a moderate level of schooling (Cox, 1926; Mann, 1959; Simonton, 1976; Thorndike, 1950).

Unlike creators, leaders tend to be well rounded and versatile (Simonton, 1976). Most exhibit strengths in linguistic and possibly bodily kinesthetic intelligences for communication and embodiment of one's ideals and in the personal intelligences related to self-mastery and social competence (Gardner, 1983, 1995, 1999). This generalist, body-conscious (often including impressive stature), social-oriented intelligence profile helps leaders be good problem solvers, adapt to changing circumstances, and communicate with people of diverse abilities and interests (Connell et al., 2003). With this searchlight intelligence profile, such individuals can see the big picture—the gestalt of the situation—before others can, and they do not become distracted by the accumulation of details as might scientists, artists, or other specialists with more laserlike intelligence (J. Gardner, 1990).

Connecting to Others

Although most management models adhere to a rational decision-making model emphasizing technical and administrative tasks, extraordinary leaders tap into the emotional energy of their followers (Burns, 1978; Goleman, 2002; Jacobsen & House, 2001). Some may effect this emotional connection simply to have and wield the power; others to use the power instrumentally to achieve a goal that can be constructive or destructive (McClelland, 1967). The most eminent seem to be able to blend the dual purposes of potency and instrumentalism, as Huey Long did (Williams, 1981). Therefore, interpersonal intelligence—the potential for empathy, perspective taking, and distinguishing crucial aspects of personality—underpins leadership effectiveness (Gardner, 1983, 1995). Such social facility has been shown to be independent of general IQ as well as prosocial behavior (Abroms & Gollin, 1980; Walker & Foley, 1973). Interpersonal giftedness can become apparent as early as kindergarten. In enacting the roles of friend, negotiator, and leader (Hatch, 1997), some young children are more flexible and theatrical in their performance (Fischer & Pipp, 1984), pick up more quickly on the key aspects of different roles (Bruchkowsky, 1992), and better coordinate potentially competing social values such as honesty and kindness (Lamborn, Fischer, & Pipp, 1994).

Several psychoanalytically based studies suggest that leaders reduce followers' anxiety in uncertain situations (Jaques, 1955), primarily through the leader's clear vision and personal example (Gardner, 1995). Followers, in turn, contribute their resources to the leader's cause (Berg, 1998; Jacobsen & House, 2001; Lawrence, 1998). Over time, the leader's vision and exemplary behaviors can become routinized, institutionalized, and depersonalized (Jacobsen & House, 2001; Weber, 1947), creating a "long shadow" on which others can stand (Gergen, 2000). Change cannot be too jolting, so leaders must stay one step ahead—not three or four. Such sensitivities to anxiety and timing seem to arise by adolescence. Compared to nonleaders, adolescent leaders exhibit superior emotional stability, coping mechanisms, and temporal perspective (Morris, 1991).

According to recent analyses, leaders typically articulate their vision through dramatic stories that stir the hearts and minds of others (Gardner, 1995, 2004a; Gergen, 2000; Hirschhorn, 1998). Franklin Roosevelt's story featured renewed economic stability through strategic government intervention; Reagan's and Thatcher's was prosperity based on individual initiative, a story that deliberately countered the entrenched narrative of Rooseveltian governmental hegemony (Gardner, 1995; Gergen, 2000). The ability to create such compelling stories commences around age 4, when children tell single, action-oriented episodes. During middle childhood, children add and integrate plot twists and internal motivations (Bruchkowsky, 1992; McKeough, 1992). Better storytellers exhibit more detail, flexibility, and expression in their stories (Faulkner, 1996; Porath, 1996); the most successful leaders tell stories that give meaning to the lives of their followers and embody those stories in their own daily actions.

Drive

In contrast to the less eminent and the less successful, extraordinary leaders start and stick with their chosen missions (Bennis & Thomas, 2002; Bogardus, 1934). Besides intelligence, initiative emerged as the key predictor of leadership quality among 48 political leaders (Simonton, 1991b) and successful outcomes among generals in battle (Simonton, 1980). Years of experience predict presidential eminence (Simonton, 1981) and the perceived competence and trustworthiness of U.S. presidents as assessed by historians (Simonton, 1986). Although normal development of leadership focuses on taking already established roles, extraordinary leaders

often do not wait for a role to make their presence felt (Burns, 1978). With unusual confidence in themselves, such leaders—even as children—present themselves as equals to others in leadership roles, challenge authority, negotiate or take power, and organize groups from scratch, manipulating and persuading others to join their team (Gardner, 1995; Goertzels et al., 1978; Kotter, 1990; Winter, 1987).

Early Adversity

Facing a steep challenge, tapping into one's personal strengths to feel useful, and dealing with frustration in one's early years may prepare future leaders for the ups and downs of life in the limelight (Goertzels et al., 1978; Kotter, 1990; McClelland, 1967). Early adversity—such as sickness or poverty, the loss of or intense conflict with one's father, or early failure—can create tension and dissatisfaction that spur the future leader to act more independently (Bennis & Thomas, 2002; Bullock, 1998; Gergen, 2000; McClelland, 1967). Early career challenges—such as the sinking of John F. Kennedy's PT boat or the failure of Winston Churchill's plans at Gallipoli—can also create "awakening moments" that disembed the person from the conventional view of a situation and sow the seeds of personal, and perhaps later social or political, transformation (Burns, 1978; Kotter, 1990; Lukacs, 2002). To test their mettle, many future leaders intentionally choose difficult, risky assignments (Bennis & Thomas, 2002). If leaders have the most of any one quality, it is perhaps a robust temperament or the ability to bounce back from failures and try again despite the odds (Schwartz, Wright, Shin, Kagan, & Rauch, 2003). Such resilience makes it possible to be responsive to events in a timely fashion—a pattern that contrasts with that exhibited by scientists, artists, and moral leaders who dwell in longer mental time frames.

Opportunity to Act

Once working in their fields as adults, leaders require a situation or issue conducive to their abilities and preparation to manifest their greatness. It is misleading to name leaders in isolation. It is not just Franklin D. Roosevelt but FDR and the Depression that made him extraordinary; not Lee Iacocca but Iacocca and the turnaround of Chrysler during a time when American automobile manufacturers were under assault from East Asian and European competition.

This need for opportunity may help explain why there are fewer women than men leaders in the history

books. Except for hereditary power, social structure has precluded women from powerful roles or even being present in situations that presented leadership opportunities (such as battle, political voting bodies, or the boardroom). As in the sciences, where roles and opportunities are highly field-controlled, leadership roles have tended to be given to or taken by men. This situation, however, has changed in recent decades as women—and increasingly non-White populations—start companies, gain board seats, win elected positions, and voice their political views in mainstream venues. As a result, exemplary women leaders such as Indira Gandhi, Margaret Thatcher, Golda Meir, and Sandra Day O'Connor are emerging.

Whereas creativity is assessed in relation to a certain structure of the domain at a given time, leadership is assessed in relation to a certain structure of the field. Perhaps that is why some studies suggest situational factors, rather than personal qualities, predict leader accomplishments (Simonton, 1976, 1984). War, assassination, scandal—regardless of whether the leader had any control over them—can tend to increase one's historic memorability (Simonton, 1984; Winter, 1987). Whereas the medium for art is the canvas or marble, and for science is the experiment or hypothesis, the medium for leadership is the issue or social situation that calls for vision, organization, and action.

The world in which leaders grow up also influences their values and actions. For example, young “geek” leaders of the current technological age—who grew up in the 1980s of economic abundance, distrust in institutions, blended families, and globalization—prefer a leadership style of collaboration and experimentation. The older “geezer” generation—who grew up during the uncertainty and fear of the Depression and World War II—alternatively, prefers to lead in stable, structured organizations (Bennis & Thomas, 2002). Still, what places someone in a leadership position may be different than what makes others later perceive him or her as outstanding. People tend to vote for individuals with motivations similar to their own, but the presidents ranked the greatest—Washington, Lincoln, Theodore Roosevelt—tended to have motivations at odds with (and typically ahead of) the current *Zeitgeist* of their time (Winter, 1987).

When a situation presents itself, extraordinary leaders are ready to rise to the occasion. What others might consider a stressful problem, they view as an opportunity to make a difference. They are better able to act in

the moment—whether on the battlefield or in a televised debate or in a tense cabinet meeting. They are more prepared to take on such high stakes performances (Gardner, 1993a, 1997) with less notice, perhaps because almost every problem is learned from and integrated into their later repertoire of experiences and skills. Possibly stemming from their searchlight intellect, they can simultaneously be fully present in the moment yet also be able to stand back mentally, see themselves as others see them, and place the moment in social and historical context (Gardner, 1995, 2004a; Klein, Gabelnick, & Herr, 1998).

Summary

In contrast to the domain-specific, targeted extraordinariness typical of the arts and sciences, leadership features extraordinariness as horizontal and integrative (Connell et al., 2003). The development of a leader stems from a convergence of multiple developing capacities that interact in nonlinear fashion. The field's social forces play a strong role from the beginning, more indirectly in childhood through parenting and schooling, then more directly in adolescence and adulthood through training and opportunities to act. A person's innate potentials foreshadow a versatile generalist profile. During childhood and throughout life, the future extraordinary leader learns to handle social adversity without losing equilibrium; develops self-control and social competence; and becomes able to tap into unconscious sources of energy and affect, tell compelling stories, and embody one's ideals in one's person. The leader takes initiative when opportunities arise or in making one's own opportunities, and stays the course. These actions, in turn, develop a disposition to behave in leaderly ways, tapping into the power of others toward transformational change in world view, organization, or action.

MORALITY

Traditional philosophers and religious leaders pondered the nature of a virtuous life. This classical concern with moral excellence has reappeared in recent years. One impetus emanates from the disastrous bloodshed and genocidal episodes of the twentieth century. Scholarly direction has come from important philosophical tracts (e.g., Rawls, 1971) and empirical studies in developmental psychology. Included are pathbreaking works on

moral judgment by Piaget (1932) and Kohlberg (1984); cross-cultural studies by Shweder, Mahapatra, and Miller (1987), and studies of particular moral traits like empathy, altruism, a sense of justice, or willingness to act on principle.

In contrast to social rules and roles that consist of manners, conventions, or other interpersonal routines, morality involves human relations governed specifically by deeply felt principles of right and wrong. The honorific term *moral* is usually reserved for individuals who behave in prosocial, honest, and fair ways that benefit more than themselves (and may at times be inimical or even dangerous to themselves). The psychological study of morality encompasses understanding how children and adults construe often ill-defined situations, formulate arguments, reach decisions, and take action in circumstances where issues of good-bad or right-wrong are salient (Damon, 1988). Such circumstances might include individuals with respect to their own standards (i.e., Freud's superego) as well as individuals' relationships with one another, with institutions, with one's professional domain, or with the wider society (Fischman et al., 2004).

The purview of morality has changed over history, becoming less divinely mandated and entailing choice among competing perspectives (Wolfe, 2001). Moral issues arise across domains. However, some domains, such as law, religion, psychotherapy, medicine, and politics, are rife with moral dilemmas. Other domains, such as art, science, and much of commerce, are less morally inflected. In psychology, morality has been mostly studied as its own domain—analogous to memory, personality, or leadership. With respect to the moral compass of the individual, the influence of the field derives from peers, colleagues, constituents, and competitors who expect one to live up to—or to violate—one's own or the community's moral standards.

We distinguish three varieties of moral excellence, roughly yoked to the three nodes of the system's model:

1. Individual acts of caring, courage, or heroism (whether or not lives are at risk). Included here are the actions of individuals who hid Jews and others during World War II as well as individuals who devote a significant part of their lives to helping the less fortunate.
2. Leadership in the moral sphere. Examples are individuals like Martin Luther King Jr. or Nelson Mandela, who assume direct leadership of a moral

crusade and confirm or alter long-standing values of a domain.

3. The creation of an organization dedicated to a moral issue. Our focus is directed to individuals who alter the field by launching or nurturing an institution that is dedicated to moral ends.

After describing the general markers of moral extraordinariness, we show which developmental features and combinations of features most clearly distinguish these three forms of moral excellence.

Ordinary Development

The lines of ordinary moral development have been extensively documented (see Eisenberg, Chapter 11, this *Handbook*, Volume 3; Turiel, Chapter 13, this *Handbook*, Volume 3). Infants exhibit biological predispositions to be fearful of, curious about, or aggressive toward stimuli (Kagan, 1989; Schwartz et al., 2003); to understand emotional facial expressions; and to make movements and noises that draw others to help them (Trevarthen & Logohtet, 1989). Through play and social interaction, infants and toddlers—unless they are autistic—quickly develop capacities to differentiate themselves from others (Piaget, 1932), understand intentions (Tomasello, 1999), appreciate how others see the world differently (Astington, 1993), empathize with others' distress (Hoffman, 2000; Zahn-Waxler, Radke-Yarrow, Wagner, & Chapman, 1992), share resources and take turns (Damon, 1988; Hay, Castle, Stimson, & Davies, 1995), distinguish universally applicable moral rules from context-specific social rules (Glassman & Zan, 1995; Turiel, 1983), perceive deviations from standards (Kagan, 1989), and learn to regulate their own behavior (Freud, 1930/1961a; Kagan, 1989).

Preschool is a period when children increase aggressive behaviors (Dunn, 1987) but also evolve from an egocentric to a more sympathetic form of empathy, becoming able to take on various perspectives and roles (Hoffman, 2000). They can separate their own distress from that of others—an important constituent of prosocial behavior (Astington, 1993; Miller, Eisenberg, Fabes, & Shell, 1996). Still, children's understandings of moral situations link to self-interest, obedience, and avoiding punishment (Kohlberg, 1984). Although children of kindergarten age can share their toys and help others, they base their decisions primarily on their own wants (Damon, 1988; Eisenberg & Fabes, 1992).

During the school years, children still judge moral situations based on authority, but apply the rules more flexibly and autonomously, with less need for external reinforcements (Piaget, 1932). By age 10, intentions, rather than consequences or rules, come to ground moral judgments (Helwig, 1995). At this time, children can better direct their attention and delay gratification (Metcalfe & Mischel, 1999), take initiative to comfort or get help (Zahn-Waxler et al., 1992a), consider cultural good-bad stereotypes (Eisenberg & Fabes, 1992), and empathize beyond specific situations to wider general life conditions (Hoffman, 2000). Sharing is based increasingly on fairness in elementary school and on merit in middle school (Damon, 1988).

Although adolescents share on the basis of who has the greatest need (Damon, 1988), self-centeredness may also increase temporarily at this time (Eisenberg & Fabes, 1992). As they become more aware of cultural conventions, adolescents tend to make moral judgments based on maintaining social order through cooperation or abiding by established rules (Eisenberg & Fabes, 1992; Kohlberg, 1984). They start to think ideologically, can envision utopias and dystopias, and consider social interaction apart from its current manifestations (Fischman et al., 2004; Michaelson, 2001). Adolescents often can make clear decisions in the abstract—be “for” free speech—but have difficulty coordinating the details of the case to take an unequivocal position regarding specifics—such as the Ku Klux Klan holding meetings at a community center (Helwig, 1995).

In adulthood, most people peak at the conventional rules-and-roles stages of moral judgment. A few adults reach postconventional stages where decisions are made based on contracts, justice, and rights (Kohlberg, 1984), and those who do reach these higher stages almost always are college educated (Shweder, Mahapatra, & Miller, 1987; Simpson, 1973). However, in a consideration crucial for the study of moral extraordinariness, judgment level does not correlate strongly with moral behavior (Damon, 1988; Hart & Fegley, 1995). Professional moral exemplar is not a recognized ambition, there are no credentials required, and anybody from any walk of life may rise to the occasion to become an exemplary figure.

Markers of Extraordinariness

Although some have speculated about signs of early moral excellence, as manifest in the selection of the

Dalai Lama, moral prodigies or savants have yet to be found (Hart, Yates, Fegley, & Wilson, 1995). Still, precursors to exceptional morality may occur in childhood: marked helpfulness, compassion, generosity, responsibility, and, with age, participation and leadership toward humanitarian ends. The most studied qualities associated with moral extraordinariness are: (a) precocity in moral judgment, (b) emotional sensitivity in childhood, (c) self-knowledge, (d) integrity, and (e) a disposition to act in adolescence and adulthood. Certain of these markers may be particularly associated with specific varieties of moral excellence.

Precocity in Judgment

Early psychology studies tied moral extraordinariness to intelligence. Psychometric researchers found that intelligence was positively correlated with European royalty’s moral behaviors (Thorndike, 1936) and the moral reasoning of children (Hollingworth, 1942; Terman, 1925). Such children tend to score higher than their age-mates on Kohlberg’s stages of moral judgment (Howard-Hamilton, 1994; Simmons & Zumpf, 1986). But precocious use of abstract reasoning may not be conducive to precocious moral behavior. Average-IQ students tend to base their thinking on emotion-laden humanitarian ideals; high-IQ children may inhibit their empathic feelings for the sake of logical coherence in their moral arguments, with a resulting detachment from action (Andreani & Pagnin, 1993; Dentici & Pagnin, 1997). Additionally, high-IQ, logic-oriented children often feel compelled to follow a chain of reasoning to its bitter end, whereas those with less imposing IQs take a more nuanced position (Erikson, 1959).

Individuals who display extraordinary caring or heroism are not distinguished by high levels of moral reasoning or educational accomplishment. In contrast, of the 14 men who approved the “final solution” at the January 1942 Wannsee Conference, eight had doctorates from Central European universities. Nonetheless, we believe that the most impressive moral leaders are marked by the high—and sometimes, the highest—levels of moral judgment (e.g., Kohlberg, 1974).

Unusual Sensitivity

From a very young age, some children display an instinctive knack for understanding themselves and reaching out to others in a caring way (Eisenberg & Fabes, 1992; Greenacre, 1956; Hoffman, 2000; Kagan, 1989). For

example, as a child, Gandhi was keenly interested in the notions of right and wrong, tended to play peacemaker in schoolyard games, and felt extreme guilt at his transgressions of his own moral standards (Gardner, 1993a). Twin studies suggest that perhaps as much as half of a person's abilities for empathy, nurturance, and altruism may be heritable (Davis, Luce, & Kraus, 1994; Zahn-Waxler et al., 1992b). Strong relationships further cultivate this innate sense (Aitken & Trevarthen, 1997), providing the support and sometimes motivation for moral action in adolescence and adulthood (Fischman et al., 2001; Michaelson, 2001; Youniss & Yates, 1999).

Sensitive children seem more easily to internalize moral expectations (Kagan, 1989), understand the role of intentions (Fischer & Pipp, 1984; Goldberg-Reitman, 1992), have a longer-term outlook in coordinating group moral efforts (Hart et al., 1995; Silverman, 1994), and act in a moral way (Arsenio & Lover, 1995). But there may be costs to hypersensitivity. Such young persons may become emotionally distraught at too much stimulation (Dabrowski, 1979/1994; Silverman, 1994), have trouble making straightforward decisions or become destabilized because they can see the exceptions and subtleties of situations (Lovecky, 1997), worry over potential consequences invisible to others (Silverman, 1994), and tend to question the rules (Erikson, 1958; Gross, 1993).

Self-Awareness and Control

Self-awareness and self-control are important components of a moral orientation. Self-regulation is required if one is not to become inhibited (Kagan, 1989), overwhelmed (Silverman, 1994), or isolated (Getzels & Jackson, 1962). Moral exemplars are marked by strong intrapersonal intelligence as well as keen abilities to distinguish their own feelings and intentions, interpret their mental and physical states, draw on a vivid imagination, and/or express their inner states (Gardner, 1983; Parks, 1986). These emerging strengths aid them in imaginatively empathizing with people different from themselves (Zahn-Waxler et al., 1992a), determining their personal goals in a clear and comprehensive manner (Colby & Damon, 1994; Walker & Pitts, 1998), regulating their own needs (Colby & Damon, 1994; Eisenberg & Fabes, 1992), and having faith in their pursuits (Colby & Damon, 1994; J. Freedman, 1996; Parks, 1986).

Understanding options and consciously choosing one's personal values may provide the strongest moral

foundation (Perry, 1968/1999; Wolfe, 2001). Youths who become more reflective about their field and its moral stances are in a better position to stand apart from the status quo and aspire to deeper understanding of moral dimensions. Adolescent inner-city social activists, for example, do a better job than their peers in forming a coherent set of beliefs about themselves that not only situates them socially in relation to others but also temporally in relation to their past and future selves (Hart et al., 1995). Strong intrapersonal intelligence helps individuals to know who they are, yet pursue goals that transcend themselves and affect a wider sphere (Colby & Damon, 1994). Such self-awareness and control is particularly important for those who seek to lead a moral enterprise (Erikson, 1958).

Self-awareness may be catalyzed in early life by a crystallizing experience, such as the death of a loved one or a special mentoring partnership, that challenges values previously absorbed from family and culture (Colby & Damon, 1994; Fischman et al., 2001, 2003; Gardner, 1993a; Walters & Gardner, 1986). Such experiences may shift an individual from a general leadership or entrepreneurship orientation toward a particular focus on morally tinged missions.

Integration

Moral extraordinariness results from an unusual integration of the domain and the person's identity—morality becomes the foundation of who the person is (Colby & Damon, 1994; Gardner, 1993a; Walker, 2003). For Martin Luther, nailing the 95 *Theses* on the church door in Wittenberg was the culminating act of his identifying with personal, direct faith in opposition to absolute, institutional dogma (Erikson, 1958). Moral extraordinariness incorporates both thoughts and feelings (Haste, 1990), justice and care principles (Colby & Damon, 1994; Walker, 2003), a complex level of thinking regarding good and evil (Parks, 1986), a sensitivity to others' specific perspectives as well as more global issues (Dabrowski, 1979/1994), immediate and future consequences (Hart et al., 1995), faith in self and something greater (Colby & Damon, 1994; Walker, 2003), and principles and practices (Gardner et al., 2001). Integration, however, does not necessarily mean "the most of." As with leadership, too much of one facet—hyper-rationality, caring to the point of self-sacrifice, blinding honesty—can be detrimental (Dentici & Pagnin, 1997; Lamborn, Fischer, & Pipp, 1994; Walker, 2003). Although a sense of integration is important for all in the

moral sphere, it is particularly salient for those who would devote their lifetimes to moral pursuits, less crucial for those who commit singular acts of courage.

Disposition to Act

Moral exemplars act on their feelings and beliefs (Colby & Damon, 1994; Michaelson, 2001). Such agency begins young as children learn that their requests and demands influence adult behavior (Kagan, 1989). The more initiatives the person takes, the more habitual helping others becomes (Colby & Damon, 1994); over time, the person may develop an altruistic personality (Krebs & Van Hesteren, 1992). Compared to people who merely planned to go on Freedom Rides in the 1960s, those who actually went defined themselves as activists and needed tangible confirmation of that identity (McAdams, 1988).

This disposition can collectivize into professional codes of ethics that regulate how whole groups of people behave, in effect institutionalizing the preferred actions into professional or societal "shoulds." A doctor or therapist should do no harm and should intervene whenever a need arises. A scientist or journalist should seek the truth. These professional codes stabilize the foundational principles—utilitarianism, duty, virtue—as well as the moral conflicts, motives, intentions, and standards that arise in a particular professional domain (Beabout & Wenneman, 1994; B. Freedman, 1983; Tirri & Pehkonen, 2002). These codes also can draw people who resonate to certain values toward particular occupations, such as a sensitivity for fairness toward law, health toward medicine, or safety toward firefighting (Gardner et al., 2001). When the individual, field, and domain elements are in alignment working toward positive values, ethical judgments and behavior are less problematic; in contrast, when misalignments occur, more of the responsibility falls on the individual to decipher and decide what would lead to good work (Gardner et al., 2001; Gardner, 2005). Moral exemplars are at a particular premium when fields or cultures are in transition, and normative values have broken down or become so rigid that people are alienated from them (Gardner et al., 2001; Merton, 1957).

Summary

Most of us do our best to do what is right, to be individually moral. But few of us risk creature comforts or personal safety to come to another's aid or change others' minds about what is good—to address morality at the

field or domain level. Although individuals are rarely considered exemplary in the moral domain before adulthood, individual differences at various ages correspond to different emphases for extraordinariness: unusual sensitivity in young children, precocity in making moral arguments in school-age children, notable self-knowledge and initiative in adolescence, and self-defining altruism or social activism in adulthood. Learning when young how to cope constructively with difficult situations is an important marker as well. When these abilities, skills, experiences, and dispositions interweave and meet an opportunity to act courageously, moral extraordinariness may emerge.

Varieties of Extraordinariness

A person can show moral extraordinariness in three ways: individual acts of caring, courage, and heroism; moral leadership; or the creation of an organization dedicated to a moral issue. All three types highlight an initial moral orientation, but leadership and institution building entail additional features. In most cases, an individual will emerge as outstanding in one of these respects. Only rarely does an individual—like Mahatma Gandhi—stand out as a person of courage, a leader, and the architect of a social organization.

We note that individuals may put their gifts to immoral or amoral ends. Individuals who are personally courageous may carry out terrorist acts; leaders who see themselves as moral agents (like Lenin) may condone immoral acts; and gifted organizational leaders may create crime syndicates. Judgments about moral excellence must be rendered by a field of knowledgeable observers. In the case of morality, the criteria for judgment include a coherent set of principles about human relations and justice; action based on these principles, even when one's own self-interest is sacrificed; and respect for the interests and sanctity of other human beings (Colby & Damon, 1994; Fischman et al., 2001; Gardner et al., 2001; Lawrence-Lightfoot, 1999; Oliner & Oliner, 1988).

Individual Acts of Caring or Heroism

Every year, a number of individuals are recognized for acts of unusual caring or courage. In general, these acts are carried out without any expectation of reward or recognition. Sometimes these acts are one-time occurrences, as when a passerby jumps into a river or rushes into a burning house to rescue a stranger. The decisions

are made instantaneously. At other times, these acts are recurring, as when a person without considerable resources regularly takes in foster children. Occasionally, individuals risk themselves and their families, as when individuals shielded Jews from the Nazis by allowing them to live in their homes.

Contrary to what might have been predicted, these individual moral agents rarely have high levels of education, let alone special training in morality. They do not perform at high levels on measures of moral judgment. They are more accurately described as seemingly quite ordinary individuals who, when faced with a morally tinged decision, act directly, in a forthright matter, and without obsession. Found in the same situation, such individuals typically expect that others would do likewise.

Three recent lines of research have enriched our understanding of moral commitment at the individual level. Oliner and Oliner (1988; see also Oliner, 2003) carried out extensive studies of individuals who hid Jews during World War II. In contrast with those who were mere bystanders, the rescuers stand out in terms of their benevolent view of their parents, the strong religious and personal values that they absorbed at home, their sense of personal agency, and especially, their inclusive and generous view of other human beings. During the rescuers' childhoods, parents exhibited caring, avoided physical punishment, offered explanations for preferred courses of action, and modeled high standards of conduct toward others. The rescuers did not see how one can simply segment human beings into two exclusive groups, let alone consider one group nonhuman, subhuman, or inhuman. In addition, norms of the surrounding culture and features of the physical environment (i.e., areas where Jews could be hidden) also were factors in determining whether an individual became a rescuer or a bystander.

Colby and Damon (1994) studied a small group of individuals who devoted their lives to aiding others. Many of these individuals were highly religious. They had a sustained commitment to high ideals, the capacity to act in terms of these ideals, a positive and optimistic orientation, and a willingness to suspend self-interest in favor of the needs of others. Once again, these individuals did not view themselves as special, even though their accomplishments would have seemed heroic to most others. Colby and Damon view this caring orientation as the outcome of a lengthy developmental process. Once the requisite behaviors and attitudes had coalesced, the individuals came to speak and behave instinctively in prosocial ways (cf. Youniss & Yates, 1997).

Fischman et al. (2001) studied Schweitzer Fellows, a group of young medical workers who devote themselves to treating underserved populations. Frequently these young persons drew their motivation from the combination of a traumatic personal loss early in life—such as the loss of a parent to AIDS—and a strong religious faith. Rather than becoming depressed or bitter at their loss, they selected a profession in which they could alleviate the disease or social pathology that occasioned their early trauma (see also Kidder, 2003). Learning to deal with adversity early helped them take in stride later obstacles—or “boulders” as they called them. The Fellows trace their choice of calling to a desire to prevent such tragedies in the future.

Moral Leadership

Earlier in this chapter, we identified the principal features of leaders in business and politics: the capacity for creating compelling narratives, the ability to embody these narratives, the tenacity to remain committed to one's mission despite inevitable setbacks, and the capacity to recognize an opportunity and to make the most of it. These features also characterize individuals who provide leadership with a moral dimension.

Accordingly the question arises: Are there special characteristics of individuals who employ their leadership skills to promote missions deemed moral? Case studies of the lives of individuals who go on to become moral leaders—Martin Luther King Jr., Nelson Mandela, and Mahatma Gandhi—reveal many of the early markers found in highly caring individuals as well as certain distinctive patterns (Gardner, 1993, 1997, 2004a). In a number of cases, these individuals come from families that are personally secure but that represent a marginal or at least a nonmajority part of the population. The young individual feels both a part of the broader society but also—because of unusual demographic characteristics—alienated from that mainstream. At critical points in their young lives, such individuals witness examples of injustice. Either they themselves elect—or those around them encourage them—to protest this injustice. Such protest can, of course, lead to disaster or to null results. The future moral leader, however, discovers that he or she is able to influence other people and, in the happiest case, the course of events. Thus, in a way similar to, but broader than, the prototypical caring individual, the person is launched on a pathway of moral leadership. Skills of leadership sharpen and combine with personal courage. The moral leader realizes that, at any time, he may be

assassinated by enemies or—as in the case of Gandhi and Israeli Prime Minister Yitzhak Rabin—by members of his own group who feel that the moral leader has been insufficiently faithful to his own core beliefs.

Gardner, Csikszentmihalyi, and Damon (2001) studied individuals whom they term *good workers*—professionals who are both excellent in a technical sense and who seek to act in ways that are socially responsible. Although their subjects did not reach the level of a Mother Teresa or Abraham Lincoln, many of them would qualify as moral leaders. These extraordinary individuals tend to come from homes where there are strong values and principles, often of a religious nature. These foundational values endure, even when the religious origins diminish in importance. Future good workers are inspired by mentors, peers, and paragons who are themselves oriented to good work. These inspirational colleagues do not emerge by chance; rather, the workers search for morally oriented colleagues who, in turn, are also seeking individuals with a moral orientation. Importantly, good workers do not select their occupations for strictly instrumental purposes. They reach out to do good work in their professions and they gain pleasure from that work. When purely financial or utilitarian considerations threaten to override the core of a profession, the good worker speaks out about and acts on her beliefs. And in the ultimate case, good workers are prepared to leave their organizations and to join in the creation of new institutions that more faithfully capture their moral values (Hirschman, 1970).

Building Organizations with a Moral Mission

In recent years, an additional form of moral extraordinariness has been recognized. The social entrepreneur is an individual or group who recognizes and tackles a significant problem in the community, region, or even the world at large (Barendsen, 2004; Barendsen & Gardner, 2004; Bornstein, 2004; Drucker, 1992). Examples include Ashoka Fellows and Schwab Fellows—individuals from developing countries who devote their energies to the improvement of health, the reduction of poverty, the creation of new sources of energy, and other imperatives. On the American scene, exemplars range from Wendy Kopp, who began Teach for America immediately after graduating from college, to the social architect John Gardner, who launched a series of organizations including Common Cause, Independent Sector, the White House Fellows, and The Urban Coalition. Perhaps the most remarkable example, in a *Handbook of Child Psychology*, is the 12-year-old Canadian youth,

Craig Kielburger. Learning from the media about deplorable child labor practices in southern Asia, Kielburger launched Free the Children which soon grew into an internationally known organization with 100,000 organizers in 30 countries.

Such social entrepreneurs frequently exhibit leadership traits: they may be articulate and charismatic. But they stand out in two other respects. First, they have a strong moral orientation, typically a deeply felt concern about one or more vexing issues in their community or region. Second, they have an entrepreneurial bent, and they develop the skills requisite for building up an effective organization. Unlike designated moral leaders, they are prepared to remain in the background and give primary credit to their associates. The concatenation of these capacities is the distinguishing feature of a social entrepreneur. Without a caring mission, these individuals would simply be individual entrepreneurs. Without the entrepreneurial skill, these individuals could provide care only on a local, person-to-person scale.

In a study of 15 outstanding social entrepreneurs in their teen years, Michaelson (2001) found that the young persons were precociously sensitive to examples of suffering or injustice. Intriguingly, several of the subjects were raised by highly engaged single mothers who themselves were social activists. Examining social entrepreneurs in their 20s and 30s, Barendsen (2004) discerned early tragedies that had given a sense of mission to these individuals. What separated these subjects from individual caregivers or moral leaders was their interest in and capacity for building an organization. The social entrepreneurs thought more broadly about the problem, marshaled human and financial resources, inspired others to join them, and derived pleasure from steering the organization's growth. Indeed, once the organization had coalesced, these founders sometimes moved on to new challenges. Though often competing for limited resources, they nonetheless made common cause with other young social entrepreneurs. They have been recognized in the media and by organizations like the World Economic Forum as a distinctive moral agent for our time (Bornstein, 2004).

Summary

Three distinct types of moral extraordinariness can be distinguished: (1) caring individuals, (2) moral leaders, and (3) social entrepreneurs. From their early years, all exhibit concern with issues of fairness, social justice, human rights, and social relations. Often they come from religious and ethically oriented families and have

had to deal personally with traumatic events. Caring individuals stand out as adults in light of their virtually instinctive capacity to aid others. Moral leaders are distinguished by their capacity to mobilize members with often heterogeneous backgrounds to pursue an ethical agenda. Often content to remain in the background, social entrepreneurs have the capacity and inclination to build an organization that pursues a positive moral agenda.

Extraordinariness in the moral sphere does not yet occupy as well-delineated a place in the research literature or the popular consciousness as does artistic excellence, scientific excellence, or excellence in political or business leadership. Its dimensions are more controversial; its judgments are less secure. Indeed, Colby and Damon report that some experts refused to nominate moral exemplars, citing their dubiety about the very existence of the category (personal communication, August, 2004). We do not yet know at what point, or in what manner, moral precocity trifurcates into the varieties of caring, leadership, and entrepreneurship. Although moral judgment has been extensively studied, much less is known about capacities of integration and dispositions to act that mark the three principal varieties of moral excellence. We submit, however, that it is foolhardy to ignore the importance of moral excellence, particularly at a time when the very survival of our species and our planet may be in jeopardy. If we can understand better the origins of a caring orientation, of moral leadership, and of social entrepreneurship, our science may make a contribution to the society that supports our research.

CONCLUSION

Extraordinary achievements demonstrate that people are makers of their destinies—both personal and, through their ultimate impact on others, historical. However, a long road—often unpaved and full of obstacles and sharp turns—extends from potential to realization of creativity in art or science, leadership in politics, or moral excellence. Furthermore, the end state of extraordinariness is a moving target because an extraordinary achievement by one person changes the playing field for everyone in the domain. Virginia Woolf made nonlinear, psychological novels with female protagonists a viable option for contemporary and later authors. Pierre Omidyar, founder of E-bay, created a viable, na-

tionwide market without middlemen. Such changes are not always for the better, as Hitler's, Napoleon's, or Osama bin Laden's extraordinary performances attest. Still, extraordinary achievements show that progress can happen. Individuals, fields, and domains are changed by their occurrence, often irreversibly. Table 21.1 summarizes our analysis of the four domains of art, science, political leadership, and morality in terms of their differences and commonalities.

Domain Differences

Extraordinariness exhibits different features across domains. First, the relative importance of different forms of extraordinariness varies by domain. Creativity is most associated with art, science, or invention; leadership in politics and business; and moral excellence in religion, law, politics, and clinically, educationally, or public-service oriented professions. Some might say leadership and moral excellence are relatively marginal forms of extraordinariness in art. Perhaps Alfred Barr, founding director of the Museum of Modern Art, or Peggy Guggenheim, who helped launch the careers of mid-twentieth-century American artists, might be considered individuals who transformed the art institutions of New York. Likewise, creativity is often not wanted in many professions, such as accounting or engineering, and might even be considered immoral in light of these fields' ethical codes. Nonetheless, leaders (e.g., opinion leader collectors or gallery owners) and experts (e.g., art critics and historians) do exist in art, and doctors and lawyers have been known to devise innovative techniques to save their patients or clients.

Second, domains build on different intelligences. People with the most jagged profiles—an extreme strength in one or two intelligences and weaknesses in the others—are most often found in creative domains like art and science. Artists may use a variety of intelligences, depending on whether their media are canvas or clay (where spatial intelligence may be strong) to sound (where musical intelligence predominates) to their own hands and torso (where bodily kinesthetic intelligence comes to the fore). Science tends to build on logical-mathematical and spatial intelligence. Leadership-oriented domains prefer generalist profiles, with moderate ability across intelligences. Leadership particularly draws on linguistic and interpersonal intelligences, and moral excellence also tends to reward those with intrapersonal or existential strengths. However,

TABLE 21.1 Summary of Domain Similarities and Differences

Domain	Art	Science	Political Leadership	Moral Excellence
<i>Between-Domain Differences</i>				
Examples	Pablo Picasso Igor Stravinsky Virginia Woolf	Charles Darwin Marie Curie Albert Einstein	Franklin Roosevelt Margaret Thatcher Charles de Gaulle	Mahatma Gandhi M. L. King, Jr. Rescuers
Forms of extraordinariness	Mostly creator	Expert or creator	Transformative leader Cross-domain generalist rather than domain expert	Caring individual Moral leader Social entrepreneur
Intelligences	Jagged Profile/Laserlike Any intelligence used aesthetically Spatial Musical Bodily-kinesthetic		Flat Profile/Searchlight Logical-mathematical Spatial Linguistic Interpersonal Intrapersonal Intrapersonal Existential	
Principal entities	Objects/media People affected through work	Objects	People Organizations	People Principles Organizations
Personal qualities	Risk work but not self May have an advocate/spokesperson		Risk self Resilience Charisma Caring	
Career arcs	Gradual Peak early or late	Peak early and decline	Peak in middle or later life	Peak late
Early markers	Talent Perceptual orientation Personal style Identification as artist Immersion in one's own emotional life	Computational ability Curiosity Deeper problem structuring Problem finding Early productivity	Social graces Drive/initiative Early adversity Leadership opportunities and mentoring	Judgment precocity Emotional sensitivity Self-awareness and reflectivity Action orientation Constructive reaction to trauma
Turning point	Distinctive personal style	Breakthrough discovery	Position of power + problematic situation	Personal action in problematic situation of wide scope
Influential researchers	Arnheim Milbraith Winner	Gruber Roe Zuckerman	Burns Simonton	Colby and Damon Kohlberg Oliner and Oliner
<i>Cross-Domain Similarities</i>				
Ordinary to expert to extraordinary/transformation continuum of influence 10-year rule of domain mastery Developmental sensitive periods Integration of individual, field, and domain at highest levels Confidence, perseverance, and risk taking				

those saints who lead in moral ways should not be considered more interpersonally intelligent than those knaves who are bent on power or destructiveness; rather, these individuals are using their interpersonal (and other) intelligences in the service of different values (Gardner, 2005).

Third, domains emphasize different objects of interest (Gardner, 1993a; Prediger, 1976). Idea-oriented do-

mains manipulate symbolic objects and are more domain-sensitive; people-oriented domains manipulate people and are more field-sensitive. In our analysis, science is the domain most oriented toward ideas or objects, as scientists focus on stars, cells, corn, and so on and often ignore the personal dimensions or consequences of their work. Art also orients toward ideas and objects; it tends to affect people's emotions indirectly

through crafted objects. Politics and morality are more people oriented, with politics the most people oriented, directly influencing others through communication and embodiment of goals. Moral leadership and social entrepreneurship tend to be principle based, whereas moral caring necessarily entails person-to-person interaction.

Fourth, domains differ in the motivations and qualities required of members in the field. Some domains that emphasize creativity are less time-pressured and reward laserlike intelligence, solitude, and time-on-task (Ericsson, 1996; Galenson, 2001; Storr, 1988). In leaping into the unknowns of their domains, such innovators risk their ideas and products, but their selves remain in the background. Other domains that emphasize leadership reward searchlight intelligence, versatility, in-the-moment thinking, resiliency, and charisma to respond to social changes in a timely way (Burns, 1978; Simonton, 1984). As their extraordinary products *are* their personal actions and embodiments, they risk themselves as well as their ideas when going beyond what is currently accepted. Even more subtle differences exist. For example, some sciences, such as genetics, are becoming less solitary, collaborative, and more influenced by quotidian market forces (Gardner et al., 2001). Similarly, moral leaders and social entrepreneurs navigate in longer time frames than political leaders; and their reasons for controlling events and effecting social change demonstrate a “universal intent” of personal ideals (Polanyi, 1958) as opposed to a “seize the day” mentality that characterizes most politicians today.

Fifth, domains present different career arcs. Some peak early, whereas others offer a slow, steady climb. Extraordinariness is most likely in math and physics to come early, in one’s 20s and 30s, but can come later in biology or natural history (Simonton, 1988). The apex often depends on the versatility or specialization of the scientist (Sulloway, 1996). Artists can either peak early with more conceptual art or have their work recognized later with more experimental efforts (Galenson, 2001). The longest career arcs are shown by political leaders and moral exemplars, perhaps because they require less task-specific and more situational competence (Connell et al., 2003) and, therefore, more real-world experience. These individuals may seem rather undirected and drifting early in their careers before they find a group of people, institution, or situation that draws on their capacities and values. However, eminence may accrue not only to those with the longest lives and careers but also to those who have been stopped dramatically in their

prime—a pattern associated with Alexander the Great, Abraham Lincoln, and the Kennedy brothers (Simonton, 1994).

Domain Similarities

Common ground in extraordinariness also can be found across domains. These similarities seem to be both developmental and systemic. Despite differences in end state and career arc steepness, the general path for most domains extends from novice to experts, who often are considered the pinnacle of normal development, to transformers (e.g., creators, leaders, and moral exemplars), who change the symbolic meanings, social structures, or values of their domains. Experts and more ordinary performers tend to have a more balanced ensemble of activities across several domains (i.e., have relatively separate work, leisure, and family lives), aim to satisfy requirements or standards, and depend on existing institutions to provide both a foundation and direction for their careers. They accept the field as currently constituted. Creators and leaders, alternatively, show a more integrated (though not a more balanced) identity stemming from an internally driven compulsion to master a specific domain, push its institutional boundaries, often with little institutional support, in a manner that encompasses almost all aspects of their lives. Their mates, friends, and hobbies tend to tie into their work. At the time of their breakthroughs, these individuals identify principally with the core mission of the domain and only marginally with the field. They continue to learn and reach beyond standards, maintain a lingering sense of dissatisfaction and incompleteness in all they do, and utilize the elements of the domain (i.e., symbol systems, task properties, or ideas) rather than field institutions as a foundation for their careers (Gardner, 1997).

Extraordinariness arises epigenetically, usually requiring at least 10 years of cultivation to show itself (Ericsson, 1998; Shekerjian, 1990). It may be thought of like a swinging pendulum that picks up speed based on its own momentum. It starts with individuals who engage in extraordinariness on the littlest (little-c, little-l, little-m) scale—for creativity, attempting slight modifications of conventional ways of doing things; for leadership, attempting to organize small groups of friends or events; for morality, eking out individual acts of courage and noting their consequences. Over time, some of these individuals continue on to midscale extraordinariness,

which influences some people but not enough of a critical mass to transform the domain in a noticeable way. Examples include showing one's artwork in a regional show or running for local office or starting a nonprofit organization. This midlevel is often an important point for garnering recognition or more field resources, such as the MacArthur "Genius" Prize (Shekerjian, 1990), that can catalyze the continued transformation of one's potential into extraordinary performance—and hence one's personal development into domain development. Finally, a few jump to historically important creativity, leadership, or morality with corresponding far-reaching influence and implications.

Although these scales form a continuum of influence, the psychological factors contributing to them seem to involve nonlinearity. There is a jump in kind, not just in degree, from ordinariness, which mostly involves being a consumer of culture, to expertise, which involves being a reproducer of culture, to extraordinariness, which involves being a producer of culture (Bourdieu, 1993). Extraordinariness breaks free of the constraints of what already exists, using cultural heritage as a tool rather than a limit, and focuses on possibility—what could be.

Because extraordinariness arises from the particulars of a person's history in interaction with a domain and field, it is possible that certain moments in development present sensitive periods (Rostan, 1998; Winner, 2000). Society often posits expertise, which reproduces culture as is, as the main end state in development. Perhaps one reason is that expertise is safer, more common, more understood, or easier to achieve. But what if extraordinariness were the end goal of a career? Then the question becomes: Why, except in the most remarkable historical epochs, do so few people make transformations? There may be critical points when many people seem to slip off the path toward extraordinariness: when they do not demonstrate biological dispositions or talents in the earliest years of life (Winner, 1996a); when they fail to gain access to a domain, such as living in a culturally isolated location or coming from a family without resources that allow cultural exposure (Gardner, 1993a); when the enforcement of domain conventions in middle childhood may hinder children's independent exploration of the domain or fail to be integrated with their idiosyncratic styles (Bamberger, 1982); when adolescents find no appropriate or rewarded societal outlet for their efforts (Csikszentmihalyi et al., 1993); when young adults encounter the constraining forces of the field during their first jobs (Allmendinger, Hackman, &

Lehman, 1996; Gardner et al., 2001); when the work of young adults fails to be accepted by the field and they seek more regular forms of work to pay the bills (Stohs, 1991); or when would-be innovators become successful—for example, acclaimed prodigies—and may slip into a "formula" that works in the field but inhibits the development of a rebellious and robust personality (Gardner, 1993a; Rank, 1932).

The earlier childhood sensitive periods stem more from individual-domain interactions, whereas the later adolescence and adulthood sensitive periods involve more individual-field interactions. Individuals who become the most extraordinary appear ultimately to integrate in a personal manner all three nodes—individual, domain, and field. Although, historically, extraordinariness has been studied as an individual trait, the developmental-systemic perspective highlights the fact that rarely do extraordinary achievers go it alone. For those who reach the highest echelons and have the most influence, involving others and being mentored by others is crucial (Gardner, 1993a, 1995; John-Steiner, 1985, 2000). Future great leaders are often taken under the wing of current leaders. Mentorships provide field-supported stepping stones that include both emotional and career-building support—from a romantic view of the domain via early nurturing mentors, to a skill-oriented view of the domain via later technical mentors, to an integrated and innovative view of the domain as individuals move beyond mentors' direct influence to create their own approach (Bloom, 1985).

In a sense, the domain and field operate behind the scenes even before the individual is born. The *Zeitgeist* (e.g., individualistic versus collectivistic, progress versus tradition oriented), the state of the domain (e.g., organized versus chaotic, central versus marginal to the culture's values), and the state of the field (e.g., harmonious versus fragmented, resourceful versus poor) while the child grows up and into which she is socialized determines whether a developmental trajectory toward extraordinariness is even relevant. It is surely no accident that Athens in the fifth century A.D., or the T'ang Dynasty in China at the end of the first millennium A.D., produced a disproportionate number of extraordinary individuals and contributions (Csikszentmihalyi, 1996; Sorokin, 1947/1969). Such periods may have enjoyed a particularly fruitful combination of alignments and misalignments that led to an unusual blossoming of creativity and influence. If the culture is overly conservative, or the domain and field are toxically misaligned or

disorganized, extraordinariness is less likely even if the individual leaps all of the above developmental hurdles. Extraordinariness does arise from tension and asynchronies among system elements, but too much tension may thwart even the most talented, resilient, ambitious individual.

Further Research

Extraordinary achievements are never guaranteed by following a formula, including a stair-step, “universal” developmental path. Too many factors regarding individual, field, and domain characteristics must coincide for them to arise. Therefore, uncertainty underpins extraordinariness; it is probabilistic not deterministic.

How does this situation affect the outlook for extraordinariness research? In our view, researchers need to move conceptually beyond traits, categories, and linear prediction to models of interactions and emergence; and from direct, cross-sectional cause-effect toward recursive, reciprocal causal models with an explicit temporal dimension that allow for new end states and domain configurations to be formed. In addition to the general or universal mechanisms classically favored by developmentalists, we must look more closely at domain-specific contributions to extraordinariness and at domains not considered in this survey. And we must further integrate the cognitive with motivational, social, and historical factors, including their interactions at critical developmental junctures.

Methodologically, extraordinariness shows the limits of a laserlike or reductionist science isolated from other perspectives. This phenomenon calls for collaboration among social scientific and humanistic approaches. So few truly extraordinary individuals come along that it is difficult—and perhaps inappropriate—to apply traditional psychological research designs (Gardner, 1988; Simonton, 1999; Wallace & Gruber, 1989). Many methods have been used to explore different forms and factors of extraordinariness, from statistical analyses of large databases in an effort to ferret out general laws to in-depth, qualitative analyses of particular individuals that illuminate the life-span contours of an extraordinary life. A developmental-systemic approach calls for more longitudinal research. Given what we know now, if we could redo Terman’s 70-plus-year study, what would we examine? Possibilities include using domain-specific sample selection criteria, such as curiosity in science, rather than a universal measure like IQ score; incorporating descriptions or assessments of the state of various

domains and fields, which define supports and constraints that operate on the individual; securing data on commitment (Moran, 2004) and other motivational-cognitive interactions; incorporating information about neural structure and functioning as well as genetic profile; tracking the individuals’ relationships with and positioning in their respective domains and fields over time—perhaps via computer modeling—to see how intelligences become competences, performances, expertise, and perhaps move “beyond the given” (Bruner, 1962); and focusing our data collection points on the sensitive periods described earlier, when individual, domain, and field critically interact. Such a complex design may make us wish for the simpler days of searching for a test or gene for extraordinariness.

Finally, we need to expand the forms of extraordinariness about which we draw our conclusions. What are the extraordinary forms of parenting, social networking, and caring for the environment—just to name a few pursuits—that may have made a crucial difference but were ignored by researchers in the grip of a *Britannica* view of extraordinariness (cf. Murray, 2003)? What do the different forms of extraordinariness look like, and how do they develop among the working class, women, other ethnic groups, or third-world cultures (cf. Helson, 1999; Nisbett, 2003; Richie, Fassinger, Linn, Johnson, Prosser, & Robinson, 1997; Simonton, 1998)? This analysis could be expanded to include historical time period: As Fish (1999) and Bourdieu (1993) argued, the conceptions of “merit”—of which extraordinariness is a form—change over time as different ideas and people come to power. Therefore, what extraordinariness looks like now in early-twenty-first-century America differs from twentieth-century China, fourteenth-century Florence, or a twenty-fourth-century Star Trek-type scenario. As study of extraordinariness examines the borders of human possibility, it has a special obligation to encompass the widest definition of “human.”

WHY STUDY OLDER CHILDREN?

A look at the table of contents of this volume reveals three chapters devoted exclusively to the period of infancy. Inclusion of the present chapter yields a total of four chapters that address specific periods in the life cycle. Human development texts typically adopt either a topical or an age-level organization, with the topical approach generally considered preferable for higher-level, research-based treatments. Why, then, does this volume include these chapters that are exceptions? Justification

for chapters dedicated to infancy is perhaps clearer. It is critical to identify and examine as closely as possible the earliest origins of cognitive achievements, with the goal of better understanding the process of evolution into their later, more complex forms. But why the present chapter? Aren't the remaining chapters exhaustive in elucidating the spectrum of developmental phenomena, from brain growth, perception, and action to information processing, learning, and thinking?

It happens that these chapters focus largely on the early years of the life cycle—a majority on the very early years,

well before a child is of school age. The life-span perspective of Moran and Gardner's chapter is a notable exception. This focus should perhaps not be surprising in topic-based chapters. Again, to best understand how a capability emerges and further evolves, current thinking suggests, one should seek to identify and examine it in its earliest, most rudimentary forms. Since one set of research studies typically gives rise to others on the same topic, it is easy for such trends to assume a life of their own. In this light, statistics from the 2003 meeting of the Society for Research in Child Development become less surprising. Of 3,483 submissions to the meeting, only 222 fell under the primary topic heading of adolescence, and only 14 to 26 of these (depending on inclusion of topics such as moral reasoning and school achievement) were concerned with adolescents' cognition (Moshman, personal communication).

Are these numbers a cause for concern? A possible answer is no. If the authors of the topic-based chapters in this volume have done a good job of elucidating the patterns and processes that characterize development of the dimensions they address, this knowledge should be sufficient to explain any development that continues to occur in the years beyond early childhood. The argument is a reasonable one. If we understand the fundamentals of children's perception, information processing, learning, or memory in their early years, can we not assume that these processes continue to operate in much the same way as children develop through childhood and adolescence and into adulthood? This is exactly the question we address in the present chapter. Does any evidence exist for changes in the nature of children's cognitive functioning as they progress beyond the early childhood years and through later childhood and adolescence, into adulthood?

It is instructive to look at how textbooks answer this question. Developmental texts organized by age level typically include at least one chapter devoted to adolescence (and, if the text covers the life span, one or more chapters devoted to the adult years). The section on adolescent cognition invariably centers on the claim that adolescent cognition has important new features absent in children's cognition. The reader is left with the impression that these changes are a matter of established fact, far more than they in truth are.

But don't all textbooks smooth over controversies and present what is known as more certain than it actually is? Our examination of textbook chapters on adolescent cognition highlights two differences worth noting. First, they have undergone little change in the past several decades, in contrast to chapters on just about every other

topic. Just about the same things are being said about adolescent cognition in early twenty-first century texts as were said in texts from the 1970s or 1980s. Second, the gap between what is presented in current texts and what is being claimed in current research literature appears greater in the case of adolescent cognition than in the case of other topics. In a word, the emergence of Piaget's stage of formal operations at adolescence remains the centerpiece of textbook chapters, often with accompanying portrayals of adolescent thought as more abstract and less egocentric than childhood thought, perhaps followed by a section on the adolescent personality (Elkind, 1994; Inhelder & Piaget, 1958). In stark contrast, in current scholarly literature the idea of thought developing toward greater abstraction has been largely dismissed as either incoherent or wrong (Keil, 1998), and no contemporary scholarly reviewer of research evidence endorses the emergence of a discrete new cognitive structure at adolescence that closely resembles Inhelder and Piaget's description of formal operations (Keating, 2004; Klaczynski, 2004; Kuhn, 1999a, 1999b; Moshman, 1998, 2005).

This striking divergence suggests the need for a chapter like the present one. The research literature on cognitive development in the years beginning in middle childhood, and extending through adolescence and into adulthood, is not huge, compared to research devoted to the early years of life. But it is substantial enough to have begun yielding some converging evidence, some tentative conclusions, and some coherent directions in which to proceed. This chapter hopefully will contribute toward reducing the significant gap between what we know in this area and what textbooks tell readers we know. In addition, we reflect on the topic itself, suggesting why it is worthwhile to look beyond early childhood, at least well into the 2nd decade of life, in seeking to achieve a fuller understanding of the developmental process itself.

RECOGNIZING COMPLEXITY AND THE VALUE OF DEVELOPMENTAL ANALYSIS

Why Is Younger Children's Thinking Easier to Study Than Older Children's Thinking?

One explanation for cognitive development researchers' focus on young children's cognition, we have suggested, is their desire to examine the earliest origins of later forms. If we can understand how something simple de-

velops, we are arguably in the best position to understand the later development of its more complex instances. There may be another reason, however, and that is that cognition in older children and adolescents is more complex and problematic to study than is the cognition of young children. This is true in a practical respect—it is generally easier to gain access for research purposes to preschoolers than to high school students—but also in a theoretical respect. The cognition itself is more complex, having been longer in developing and subject to many more kinds of influences. A large number of researchers study adult cognition, but if one's interest lies in development, a focus on early origins seems a prudent choice.

Beyond the complexity of the cognition itself, there is another source of complexity that makes the study of older children's and adolescents' cognition challenging. The skills and understanding that develop during the early childhood years develop in more or less all children of the appropriate age level who fall within the broadly defined range of normal development. Researchers seek to understand the patterns and perhaps the mechanisms involved. The developmental phenomena themselves, in any case, are fairly regular and predictable.

By middle childhood, in contrast, researchers commonly encounter cognitive achievements that may or may not develop, depending on a child's experience. Indeed, many of the cognitive achievements we consider in this chapter are ones that are not universal. Some children will have attained them by the time they reach early adolescence; others will never do so throughout their adult lives. These attainments range from highly specific ones that appear only under particular conditions to those that develop given sufficient general experience of any of a wide variety of types. The result is enormous variability in cognitive functioning among normal adolescents, with some performing no better than third graders on many reasoning tasks and others performing as well or better than most adults. We probe in this chapter the factors that contribute to this great variability, among them not just environmental diversity but the greater role that older children and adolescents play in choosing what they will do, hence assuming a role as producers of their own development (Lerner, 2002).

But none of this variability implies that developmental analysis ceases to be useful. Wherever attainments lie on the individual/universal spectrum, it is useful to see them as building on a foundation of what has come

before and proceeding along paths and toward endpoints that can be identified and examined, with the mechanisms of this progress amenable to investigation. It is not that developmental analysis becomes any less useful, only that it becomes more complex. In part reflecting this complexity, the distinctions between development, learning, and acquisition of expertise become less clear. Also, the concerns of the developmentalist and the educator converge to a greater extent than they do during earlier periods of the life cycle. If many of the important cognitive skills we examine here do not inevitably develop, the educator becomes concerned with identifying the conditions that will increase likelihood of attainment. Yet, it remains the developmentalist who stands to contribute essential knowledge about the paths, patterns, and mechanisms of development.

Yet another element of complexity is introduced by the fact that developmentalists studying older children and adolescents must compare them to younger children in two respects, not one. First, what new capabilities or understandings have they acquired? Second, are the mechanisms of acquisition different from those in operation during the earlier period? Researchers studying young children, in contrast, assess their abilities and may seek to identify mechanisms of acquisition, but they do not concern themselves with the possibility that the mechanisms themselves may undergo change. In this chapter, we are as interested in developmental changes in mechanisms of acquisition as we are in new acquisitions themselves.

If the response to all of this complexity is not to abandon developmental analysis but to recognize and appreciate the developmental complexity of the phenomena we examine, the first step, we suggest, is to recognize the need to reject simple answers. We begin, then, with that as our initial task.

What Develops? Abandoning the Singular Answer

Widespread interest in adolescent cognition as having unique characteristics absent in children's thinking began in the context of Piaget's stage theory. Inhelder and Piaget (1958) proposed a final stage of formal operations as supported by a unique logical structure emerging at adolescence and manifesting itself in a number of different capabilities, most notably systematic combination and isolation of variables. What is important about formal operations from the perspective of Piagetian stage theory is that they are taken as reflections of the

emergence of an underlying stage structure, which Piaget identified as composed of operations on operations. With the attainment of this stage, according to Piaget, thought becomes able to take itself as its own object—adolescents become able to think about their own thinking, hence the term “operations on operations,” or, more precisely, mental operations on the elementary operations of classification and relation characteristic of the preceding stage of concrete operations. The formal operational thinker becomes able, for example, not only to categorize animals according to physical characteristics and according to habitats but also to operate on these categorizations, that is, to put them into categories and on this basis to draw inferences regarding relations that hold among animals’ physical characteristics and habitats. The formal operational thinker is thus said to reason at the level of *propositions* that specify relations between one category (or relation) and another. As aspects of this second-order operatory structure, according to the theory, there emerge the other reasoning capabilities noted above—systematic combination and isolation of variables—and several others such as proportional and correlational reasoning, also thought to involve second-order operations.

Subsequent cross-sectional research generally upheld Inhelder and Piaget’s (1958) claim that adolescents on average do better than children in tasks purported to assess these competencies (Keating, 1980, 2004; Neimark, 1975). Piaget, however, hypothesized these capabilities to appear in early adolescence as a tightly linked, integrated whole, a manifestation of the emergence of the formal operational thought structure. In this respect, subsequent research has been less supportive, yielding little evidence for a singular or abrupt transition from a childhood stage of concrete operations to an adolescent stage of formal operations.

Three kinds of variability contribute to this conclusion. One is inter-individual variability in the age of emergence of the different alleged behavioral manifestations of the formal operational structure, for example, combinatorial and isolation-of-variables reasoning. A second is intra-individual variability in the emergence of formal operations skills. There is little evidence to support the claim that these skills emerge synchronously within a single individual. Third, and most serious, is task variability. As is the case with respect to virtually all reasoning skills, whether an individual is judged to possess or not possess the skill is very much a function of the manner in which it is assessed, in particular the amount of contextual support provided (Fischer &

Bidell, 1991). Indeed, task variance is so pronounced that we confront in this chapter the phenomenon we shall call the paradox of early competence and later failures of competence. In other words, there are some tasks in which a particular form of reasoning can be identified as present in children as young as preschool age. In other forms of the same task, however, even adults appear deficient in exhibiting the skill.

These findings make it doubtful that emergence of a singular cognitive structure at a specific point in time—whether Piaget’s formal operational structure or some different structure—can account adequately for the progress along multiple fronts that we examine in this chapter. Nonetheless, to anticipate our conclusions, we shall end up maintaining that Piaget was very much on the right track in identifying thinking about one’s own thought as a hallmark of cognitive development in the 2nd decade of life. We can assign such a capability a modern-sounding name, like metacognition or executive control. But what needs to be abandoned is the idea that we can pinpoint its emergence to some narrow window of months or years in late childhood or early adolescence, or indeed any time. Even preschoolers can be metacognitive when, for example, they recognize an earlier false belief that they no longer hold (Harris, Chapter 19, this *Handbook*, this volume), while examples of adults’ failures to be sufficiently metacognitive are myriad.

In what has perhaps been a final blow to any “immaculate transition” (Siegler & Munakata, 1993) model of developmental change, microgenetic research (Kuhn, 1995; Kuhn & Phelps, 1982; Siegler & Crowley, 1991; Siegler, Chapter 11, this *Handbook*, this volume) revealed that individuals simultaneously have available not just one but multiple potential cognitive strategies they might apply to a problem. Some of these are more and others less advanced. Development, then, entails gradual shifts in the frequency of usage of various strategies, with better strategies being used more frequently and weaker strategies less frequently. The microgenetic model of change, note, implicates some meta-level executive that manages strategy selection. We return to it in more detail later. For now, the implication is that we must forego any simple account of emergence of a singular structure that drives all of cognitive development, in favor of examining multiple strands of development that may have commonalities as well as unique characteristics.

Before we can abandon singular accounts in favor of multidimensional ones, however, we must consider an-

other very different kind of singular account—one that explains developmental change not in terms of emergence of a qualitatively new structure but rather in terms of quantitative change in the cognitive system, specifically quantitative increase in its processing ability. How far do hypotheses of this kind take us in accounting for cognitive development, and what evidence exists with respect to them? We address this question in the next section.

BRAIN AND PROCESSING GROWTH

The evidence likely to be most influential in stimulating interest in adolescent cognition in the next decade is not evidence about cognition itself but rather evidence about development of the brain.

The Developing Brain

Neuroimaging techniques have become available in recent years that allow precise longitudinal examination of changes in brain structure in the years from middle childhood into middle adulthood. These studies have made it clear that the brain continues to develop into and through the adolescent years. The area of greatest change after puberty is the prefrontal cortex. It is implicated in what have come to be called “executive” functions (Nelson, Thomas, & de Haan, Chapter 1, this *Handbook*, this volume), which include monitoring, organizing, planning, strategizing—indeed any mental activity that entails managing one’s own mental processes—and is also associated with increase in impulse control.

Modern longitudinal neuroimaging research reports two kinds of change, one in the so-called “gray matter,” which undergoes a wave of overproduction (paralleling one occurring in the early years) at puberty, followed by a reduction, or “pruning,” of those neuronal connections that do not continue to be used. A second change, in so-called “white matter,” is enhanced myelination, that is, increased insulation of established neuronal connections, improving their efficiency (Giedd et al., 1999). By the end of adolescence, this evidence suggests, teens have fewer, more selective, but stronger, more effective neuronal connections than they did as children.

Notable about this neurological development is the fact that it is at least in part experience driven. It cannot be viewed in the traditional unidirectional manner simply as a necessary or enabling condition for cognitive or behavioral change. Instead, the activities a young ado-

lescent chooses to engage in, and not to engage in, affect which neuronal connections will be strengthened and which will wither. These neurological changes in turn further support the activity specialization, in a genuinely interactive process that helps to explain the widening individual variation, already noted, that appears in the 2nd decade of life. We have more to say about this later.

Processing Speed

What developments in cognitive function might these neurological advances support? Improvements in information processing may be of three major kinds. The clearest of the three is increase in processing speed. The most common measures of processing speed require naming a series of numbers or familiar words. Processing speed can also be measured simply as reaction time to a stimulus (Luna, Garver, Urban, Lazar, & Sweeney, 2004). In each of these cases, the pattern is clear. Response time has been found to decrease on measures of processing speed from early childhood roughly through mid-adolescence (Demetriou, Christou, Spanoudis, & Platsidou, 2002; Kail, 1991, 1993; Luna et al., 2004).

Inhibition

While reaction time is a measure of how rapidly one can make a response, another cognitive function that is at least as important is the ability to inhibit a response. Although they are related, it is useful to make a distinction between two types of inhibition, especially as different research paradigms have been employed to investigate them.

In the first type, emphasis is on irrelevant stimuli that have the potential to interfere with processing and the challenge is to ignore them, that is, inhibit any attention to them, in favor of attending to stimuli relevant to the task at hand. This type of inhibition is typically referred to under the headings of selective attention or resistance to interference. In an early classic study, Maccoby and Hagen (1965) demonstrated that the superior performance of adolescents over children on a learning task was attributable not only to their greater attention to the stimuli that were to be remembered but also to their reduced attention to irrelevant stimuli that were also present. Older participants actually performed more poorly than younger ones on a test of memory for the irrelevant stimuli. Increasing ability to

ignore attention to irrelevant stimuli during the childhood years has also been reported in other studies (Hagen & Hale, 1973; Schiff & Knopf, 1985). Included are studies based on the most common test of the ability to screen out irrelevant stimuli, the Stroop (1935) color-naming test, in which color names are printed on non-match color swatches and the task is to report either the names while ignoring the actual colors or the colors while ignoring names (Demetriou, Efklides, & Platsidou, 1993; Tipper, Bourque, Anderson, & Brehaut, 1989). A different kind of interference from competing stimuli arises not from simultaneous but from previously presented material. Kail (2002) reports a decline between middle childhood and adulthood in proactive interference—the interference of previously presented material in present recall. Adolescents and adults are better able than children to screen out and disregard the previous material.

A second type of inhibition has received less attention, despite its potential importance. It is the ability to inhibit an already established response in contexts where it is not appropriate to exhibit it. For example, an individual may be instructed to inhibit a response that has become routine whenever a particular signal is given. Performance on these tasks improves until mid-adolescence (Luna et al., 2004; Williams, Ponesse, Schacher, Logan, & Tannock, 1999). In another paradigm designed to assess response inhibition, a “directed forgetting” technique has been used in studies of memorization of word lists. In this paradigm, the individual is instructed to forget words that have already been presented and hence to inhibit them in subsequent free recall. During recall, improvement occurs across childhood in the ability to inhibit words under “forget” instructions, as well as to withhold production of incidentally learned words (Harnishfeger, 1995). Young children, in contrast, typically display no difference in frequencies of production of words they were instructed to forget and those they were instructed to remember.

In sum, the evidence is ample that both resistance to interfering stimuli and inhibition of undesired responses develop across the childhood years and into adolescence. It has even been suggested that they may play a role in the developmental improvement observed in basic memory tasks, notably digit span, that have been employed as measures of processing capacity (Bjorklund & Harnishfeger, 1993; Harnishfeger, 1995). It should be noted, however, that the evidence regarding inhibition of inappropriate responses comes from para-

digm in which the individual is instructed to inhibit the undesirable response. We have less information about response inhibition in the important condition in which individuals must make their own decisions regarding the desirability of a response and hence which responses to exhibit and which to inhibit. We have more to say about this form of inhibition in examining the topic of executive control.

Processing Capacity

In addition to speed and inhibition, a third processing dimension which may undergo developmental change is processing capacity. Here things become decidedly less clear, the primary reason being that different researchers operationalize this construct in different ways. At least two different components are involved. One, emphasized by Pascual-Leone (1970), is short-term storage space. The other, emphasized by Case (1992) in his revision of Pascual-Leone’s theory, is operating space, which arises when the individual must manipulate the information rather than only store and reproduce it. The familiar construct “working memory” in some contexts has been used in the operating space sense and in others in the storage sense.

Developmentally increasing processing speed, as Case and his colleagues have proposed (Case, 1992; Case, Kurland, & Goldberg, 1982; Case & Okamoto, 1996), reduces the space required for operations, leaving more space available for short-term storage. The net result is greater processing efficiency, rather than any absolute increase in capacity. Others (Cowan, 1997; Demetriou et al., 2002), however, dispute Case’s claim that processing speed and processing capacity are causally related, as opposed to independently increasing or mediated by a third variable such as increasing knowledge.

Whether processing capacity increases in an absolute sense or only as a by-product of increased efficiency, there remains the question of how to measure it. Pascual-Leone (1970), Case (1992, 1998; Case & Okamoto, 1996), and, more recently Halford (Halford & Andrews, Chapter 13, this *Handbook*, this volume; Halford, Wilson, & Phillips, 1998), have all proposed systems to identify the processing demands of a task, and, by implication, the processing capacity of an individual based on his or her performance on the task. Case, for example, identified progress from tasks requiring attention to a single dimension to tasks requiring the coordination of two dimensions (Case & Okamoto, 1996). In a parallel

but not identical approach, Halford and his colleagues define the processing capacity required by a task by invoking the concept of structural complexity, indexed by the number of dimensions that must be simultaneously represented if their relations are to be understood. They present data for a number of tasks suggesting that this number increases developmentally from early childhood to early adolescence (Halford & Andrews, Chapter 13, this *Handbook*, this volume).

In sum, there is general agreement across studies that processing continues to improve in the 2nd decade of life, but there is little agreement about the particulars. There are several distinct components of processing ability and there is no universal agreement as to how they are related. Do speed and capacity develop independently or do they influence one another? The same question can be asked with respect to speed and inhibition (Luna et al., 2004). Do processing improvements take place in a domain-general manner, as some researchers maintain (Gathercole, Pickering, Ambridge, & Wearing, 2004; Swanson, 1999), or do improvements differ across domains, as others claim (Demetriou et al., 2002)? Perhaps most importantly, the challenge of achieving widely agreed upon measures of processing capacity remains. Tasks involving capacities to represent versus store versus manipulate mental symbols are likely to produce divergent capacity estimates. Moreover, the goal of producing “pure” measures of capacity remains elusive. Supporting this conclusion is the fact that we have yet to identify conclusively the set of factors that contribute to developmentally increasing performance on what might appear to be the simplest, most straightforward measure of capacity of all—digit span. Indeed, all the factors we have noted—capacity, efficiency, speed, inhibition—as well as several others—familiarity, knowledge, strategy—have been implicated (Bjorklund & Harnishfeger, 1990; Case et al., 1982; Harnishfeger, 1995).

Information Processing and Reasoning

In turning to the question of how processing improvement figures in the development of thinking and reasoning, it is hardly surprising that we encounter a similar degree of uncertainty. The claim is rarely made that development at the neurological level or an increase in the number of pieces of information that can be simultaneously processed is the direct and sole cause of a qualitatively new form of reasoning. The

emergence and development of the new form must be accounted for at the psychological level. Still, processing increases may function as necessary conditions that create the potential for the emergence of new capabilities, allowing a child, for example, to solve a problem she was previously unable to or to devise a new approach to a familiar problem.

Demetriou et al. (2002) have undertaken the most wide-ranging empirical investigation to date of the relations between developing information-processing capacities and developing reasoning skills in a cross-sequential design in which children 8 to 14 years of age were assessed initially and again at two subsequent yearly intervals. Assessments included processing speed, capacity, and inhibition, as well as several kinds of reasoning; each skill was examined in three domains—verbal, numerical, and spatial. The authors’ conclusion is that of a necessary-but-not-sufficient relation. Processing improvements, they say, “open possibilities for growth in other abilities. In other words, changes in these functions may be necessary but not sufficient for changes in functions residing at other levels of the mental architecture” (p. 97).

Unfortunately, however, the measurement uncertainties we have alluded to make it difficult for the authors to definitively rule out any directions of causality. Performance improves with age on all of the various tasks they administer. But even the sophisticated analytic methods they use do not allow them to conclude with certainty what causal relations may exist, due to measurement uncertainties. The reasoning tasks in particular are necessarily brief and arbitrarily chosen, for example, four syllogisms and four analogies in the verbal domain, and even the authors acknowledge in their discussion that an improved “yardstick for specifying differences between concepts or problems” is needed. With respect to the numerical reasoning problems, for example, they conclude, “the four levels of difficulty in the numerical operations task (each defined by 1 to 4 unknown operations) are not equally spaced in terms of attainment age” (p. 132). A further complication is the varying patterns the authors obtain in the three content domains, leading them to conclude that processing capabilities are specific to the kind of information being processed.

Demetriou et al. (2002) make it clear that processing capabilities can be no more than necessary conditions for thinking, and they stress the importance of what they label “top-down” as well as “bottom-up” influences. In particular they emphasize the role of a “hypercognitive” or executive operator which “may participate

and contribute to the relations between all other processes and abilities" (p. 127). This top-down direction of influence, note, extends not just to thinking but to the processing capabilities themselves. In addition to bottom-up processing capacity, performance on a short-term memory task may be affected not just by top-down application of strategies but by skill and knowledge with respect to what strategies are useful, how to implement them, and facility in doing so (Cowan, 1997). These multiple possibilities contribute further to the challenge of obtaining any definitive measure of capacity.

Demetriou et al. (2002) conclude finally that all of "the various processes interact dynamically during development, so that change in each process is shaped both by its own internal dynamics and contributions originating from other processes" (p. 128). Few are likely to disagree with the general conclusion, but leaving all possibilities open does not help define a path toward the understanding of developing higher-order thinking. It also leaves the door open to the likelihood of individual developmental pathways, assuming one's individual experiences affect how information-processing capabilities and higher-order cognitive activities interact. Thus, in turning now to an examination of these high-order forms of thinking, we must keep in mind developing information-processing capabilities without expecting that they will by themselves explain what is observed to develop in the higher-order realm.

DEDUCTIVE INFERENCE

In the remaining sections of this chapter, we examine kinds of thinking with respect to which there exists evidence of development during the 2nd decade of life. We begin with deductive inference not because it is the most important, either in children's intellectual development or in the research literature. Rather, we adopt a loosely historical approach, beginning with deductive inference because it was the first form of higher-order reasoning to be the topic of extensive systematic developmental research. The historical reason is in large part its connection to Inhelder and Piaget's theory of formal operations. Their theory was interpreted as claiming the formal operational stage to mark the advent of propositional reasoning, and drawing inferences from the propositions that make up formal syllogisms was taken as an index of this ability.

Most extensively studied have been classical syllogisms that assert conditional relations between cate-

gories, that is, *if p, then q*. In the traditional syllogistic reasoning task, the initial major premise—*if p, then q*—is presented, followed by one of four secondary premises, either *p* (known as the *modus ponens* form), *q*, *not-p*, or *not-q* (known as the *modus tollens* form). The respondent is asked if a conclusion follows. The *modus ponens* form allows the conclusion *q*: If *p* is asserted to be the case and it is known that *if p, then q*, it follows that *q* must be the case. Similarly, the *modus tollens* form allows the conclusion *not-p*: If *not-q* is asserted and it is known that *if p, then q*, it follows that *p* cannot be the case (because if it were, *q* would be the case and we know it is not). The other two forms, however, having *q* or *not-p* as secondary premises, allow no definite conclusion. Another extensively researched task is the selection task (Wason, 1966). In this case, instead of a secondary premise, the reasoner is asked to indicate which of the four cases (*p*, *not-p*, *q*, and *not-q*) would need to be examined in order to verify the truth of the major premise (*if p, then q*). (Here the answer is the two determinate cases—*p*, to verify that *q* follows, and *not-q*, to verify that *p* is not the case.)

The empirical data on children and adults' performance on these kinds of deductive inference tasks have been reviewed periodically by a number of authors (Braine & Romain, 1983; Klaczynski, 2004; Markovits & Barrouillet, 2002; O'Brien, 1987). Two conclusions have emerged consistently. One reflects what we have referred to earlier as the paradox of early competence and later lack of competence. Provided the content and context are facilitative, even quite young children are able to respond correctly at least to the two determinate syllogism forms (Dias & Harris, 1988; Hawkins, Pea, Glick, & Scribner, 1984; Kuhn, 1977; Romain, Connell, & Braine, 1983). The majority of adults, in contrast, do not respond correctly in the standard form of the selection task (Wason, 1966). The evidence, then, does not support any sudden onset, or even marked transition, in competence to engage in propositional reasoning.

The other consistent conclusion is the sizable effect of proposition content on performance. In short, what it is that is being reasoned about makes a great deal of difference (Klaczynski & Narasimham, 1998; Klaczynski, Schuneman, & Daniel, 2004; Markovits & Barrouillet, 2002). These consistent findings have led investigators to reject as implausible the acquisition of a general, content-free set of rules applicable across any content. In the words of Markovits and Barrouillet (2002), "The

idea that most reasoners are able to use content-free reasoning procedures in any systematic way appears highly unlikely given the very large sources of variation in inferential performance observed" (p. 33).

The Critical Role of Meaning

Contemporary investigators of deductive inference have turned their efforts to proposing models of how reasoning with conditional propositions does take place. There is general agreement that representation of the problem content is critical and mediates performance. Cheng and Holyoak (1985) emphasized semantic form, rather than specific content. If p , q , for example, may be interpreted causally, as in "p makes q happen," or as a statement of permission, as in "You must have q to do p." Adults, they found, performed significantly better in the selection task when the proposition was stated in the latter form, rather than the neutral if p , q form. This was so even when the content was not spelled out and remained simply the letters p and q .

Although semantic meanings such as permission, obligation, and causality facilitate representation of propositions and reasoning about them, Klaczynski and Narasimham (1998) question the claim that each of these semantic concepts (e.g., permission, obligation, causality) has its own concept-specific reasoning scheme. Rather, inference rules appear isomorphic across schemes (Braine, 1990). Markovits and Barrouillet (2002) developed a model based on Johnson-Laird's (1983) mental model theory to predict the difficulty of various syllogistic forms. Their model attributes developmental improvements in deductive reasoning tasks to increased capacity to manipulate multiple mental models and greater availability of such models (see Halford & Andrews, Chapter 13, this *Handbook*, this volume, for further description). Their model, however, is also consistent with the simpler attribution that Klaczynski (1998) concludes accounts for most of the performance variance, namely, the availability of mental representations of alternatives.

Consider, for example, the two propositions, "If Tom studies, he'll pass the exam," and "If Tom cheats, he'll pass the exam." Respondents of all ages are more likely to respond correctly to the two indeterminate syllogism forms when they occur in an example like the second proposition, compared to the first. For affirming the consequent, q (Tom passed the exam), respondents may correctly note in the second example that it is indeterminate whether Tom cheated. In the example of the first

proposition, by contrast, they are more likely to falsely conclude that Tom studied hard. The likely reason is that in the case of the cheating proposition they can readily represent alternative antecedents, that is, possible causes of Tom's success other than cheating, leading to recognition that the antecedent does not follow from the consequent and that the true antecedent remains indeterminate. In the first (Tom studies) proposition, these alternatives come to mind less readily. Similarly for the other indeterminate syllogism form, denying the antecedent (*not-p*)—Tom didn't study hard or Tom didn't cheat—respondents are more likely to recognize that no conclusion follows when presented the second proposition (because not cheating leaves open multiple alternative consequents). Semantic content, or meaning, we must conclude, then, significantly enhances or impedes deductive reasoning.

What Develops?

An account of the factors determining success on indeterminate syllogism forms assumes the bulk of researchers' attention since it is performance on the indeterminate forms that shows the only clear developmental change. On the two determinate forms (*modus ponens* and *modus tollens*), performance is very good (75% correct) by late childhood (and in many studies by an even earlier age) and at near ceiling level by late adolescence, indicating little developmental change (Klaczynski et al., 2004; Klaczynski & Narasimham, 1998). These forms are correctly answered by use of a simple biconditional (or mutual implication)—*if p, q* and *if q, p*—that is mastered even by young children: p and q simply "go together," such that if one is present so is the other and if one is absent so is the other. At the other end of the complexity continuum, performance in the standard selection task similarly shows no clear developmental change (Foltz, Overton, & Ricco, 1995; Klaczynski & Narasimham, 1998). Performance improves modestly in some respects and declines in others, remaining poor through adulthood and strongly content-dependent (Cheng & Holyoak, 1985; Klaczynski & Narasimham, 1998).

On the indeterminate syllogism forms, in contrast, a low level of correctness in childhood and early adolescence increases modestly by late adolescence, although content effects remain strong and performance remains far from ceiling (Barrouillet, Markovits, & Quinn, 2001; Klaczynski et al., 2004; Klaczynski & Narasimham,

1998). To what should this improvement be attributed? One possibility is willingness to make an indeterminacy judgment. However, in contexts in which children have been assured that “it’s okay not to be sure,” school-aged children (Kuhn, Schauble, & Garcia-Mila, 1992) and even preschoolers (Fay & Klahr, 1996) have been shown to be willing to suspend judgment, so it does not appear to be the acknowledgment of indeterminacy itself that is the stumbling block.

Another possibility is increased availability of alternatives due to an expanding knowledge base (Klaczynski et al., 2004), which leads to the correct recognition of indeterminacy. This remains a potential contributor that cannot be excluded but, again, seems not to tell the whole story. It is worthy of note in this respect that content familiarity itself does not predict performance on syllogistic reasoning problems. Klaczynski (2004) offers the example of the two propositions, “If a person eats too much, she’ll gain weight” and “If a person grows taller, she’ll gain weight.” The former is more familiar, but performance on the indeterminate syllogistic forms of the latter is superior, due to the greater availability of alternatives, as elaborated earlier.

While task context and knowledge play a significant role, the determining factor must be the nature of the mental processing that occurs. One simple hypothesis is that incorrect responders terminate processing prematurely, with the tendency to do so diminishing into and through adolescence. Fay and Klahr (1996) explained failures to make correct indeterminacy judgments among preschoolers in exactly this way, although the tasks they examine are much simpler ones. In what they termed a “positive capture” strategy, children often made a determinate selection among alternatives and declared the problem solved as soon as they encountered one that met the stipulated criterion, ignoring the existence of other alternatives that also met the criterion. Similarly, we shall see in turning to inductive reasoning in the next section, children (and sometimes adults) are likely to rely on a “co-occurrence” inference strategy (Kuhn, Garcia-Mila, Zohar, & Andersen, 1995), judging that two co-occurring events are related as cause and effect without considering other alternatives that also co-occur with the events. In the conditional reasoning context considered here, children rely first on the inference rule that is simplest and most readily available in their repertoires, the biconditional— p and q “go together”—and consider the problem no further.

Klaczynski (2004) points to more developed meta-cognitive skills as key in the adolescent’s increasing likelihood of inhibiting premature termination and continuing processing long enough to consider alternatives and recognize their implications with respect to indeterminacy. Ready availability of such alternatives of course supports doing so, as we have noted. We return through the remainder of this chapter to accounts of development in which the ability to inhibit initial responses figures prominently.

When Knowledge and Reasoning Conflict

Before concluding our examination of deductive reasoning, it remains to highlight another important factor that significantly affects deductive reasoning performance—the truth status of the premises (Markovits & Vachon, 1989; Morris & Sloutsky, 2002; Moshman & Franks, 1986). Children become increasingly able into and during adolescence to reason deductively irrespective of their belief in the truth or falsity of the premises being reasoned about. This capability extends beyond syllogistic reasoning and indeed was identified by Inhelder and Piaget (1958) as a foundation of the stage of formal operations. Consider an 8-year-old, for example, who is well able to perform a standard task assessing mastery of hierarchical classification, judging that in a vase containing roses and other flowers, all the roses are flowers. Now imagine asking this child to solve the following deductive inference problem:

All wrestlers are police officers.

All police officers are women.

Assume the two previous statements are true; is the following statement true or false?

All wrestlers are women.

Children rarely are able to judge such conclusions as valid deductions from the premises, despite their empirical falsity, and fail to see their logical necessity (Moshman & Franks, 1986; Pillow, 2002). By early adolescence, the distinction between truth and validity begins to appear. But even older adolescents and adults continue to make errors in deductive reasoning when the premises are counterfactual (Markovits & Vachon, 1989).

Inhelder and Piaget (1958) maintained categorically that children, having not reached the stage of formal op-

erations, are unable to reason about the hypothetical and are confined to mental operations on the empirical world. But the distinction is not as clear-cut as they implied. Children are able to exercise their imaginative capabilities in creative ways: “Imagine a world in which . . .” and simple counterfactuals are a routine part of the school curriculum, for example, “Suppose you had 9 marbles and gave 4 to a friend.” As the deductive operations get more complex, however, as in the above example, a conflict arises between trusting the deductive operations (which seem trustworthy enough when content is neutral) or trusting your own knowledge.

Overcoming this conflict implicates the executive, or metacognitive, processes that have been suggested play a role in improvements in performance on deductive reasoning problems involving indeterminacy. In the present case, two meta-level components may be involved. One is increasing meta-level understanding of the deductive inference form, that is, its validity, dependability, independence from content, and utility. The other is increasing meta-level awareness and management of one’s own system of beliefs, making it possible to “bracket,” that is, temporarily inhibit, these beliefs, in order to allow the deductive system to operate, with the understanding that this suspension of belief is only temporary. Response inhibition capacities are implicated here (Handley, Capon, Beveridge, Dennis, & Evans, 2004; Simoneau & Markovits, 2003), a fact we return to in further examination of executive processes.

The importance of belief inhibition is also supported by findings that deductive reasoning performance is susceptible to improvement in children by introducing a fantasy context (Dias & Harris, 1988; Kuhn, 1977; Leavers & Harris, 1999; Morris, 2000). If belief is suspended by the fantasy context, it can’t conflict with the conclusions reached through deductive reasoning, and the practice in suspending belief stands to benefit the reasoning process once the fantasy context is withdrawn. From each of these perspectives, then, belief inhibition appears key.

Deduction and Thinking

Throughout this chapter, we consider meta-level understanding *about* reasoning strategies—their purpose, power, limitations, range of applications—as at least as important as performance-level knowledge of how to execute these strategies (Kuhn, 2001a). In the case of de-

ductive inference, this meta-level competence involves understanding of the purpose and value of deductive inference itself. This brings us to the final question we must address in this section. Is the development of deductive reasoning competence central to the development of mature, effective thinking? Does logic govern thought? The role of the deduction paradigm in research on thinking has been debated in recent years, leading one prominent researcher in the field of deductive reasoning to speculate that deductive tasks may involve simply the “application of strategic problem solving in which logic forms part of the problem definition” (Evans, 2002). Evans recommends that the deduction paradigm be supplemented with other methods of studying reasoning.

While Evans’s recommendation seems sound, indeed hard to quarrel with, the extensive research literature on the development of deductive reasoning does point in several useful directions. One is toward the necessity of abandoning any view of deductive reasoning capability as a singular competence or one that emerges at a discrete point in the life cycle. As we observed, some forms of deductive reasoning are within the grasp of preschoolers while others elude even adults. The other direction is toward the role of executive processes that deploy, monitor, and manage inference rules, rather than simply execute them. These meta-level operators are implicated in the response inhibition that appears critical to deductive reasoning, allowing the temporary suspension of belief that permits the deductive system to operate and avoiding premature termination of processing that enables alternatives to be considered and indeterminacy recognized.

As for the specific findings from developmental research on deductive reasoning, we propose that mastery of the indeterminate syllogistic forms is secondary to development of ability to reason independently of the truth status of the premises—a broad, flexible, and powerful mental skill that allows us to disembed a representation of meaning from its context. With respect to mastery of the indeterminate syllogistic forms, adolescents and adults have learned to use these forms in practical, if not strictly logical, ways, drawing on their real-world knowledge to decide which interpretation applies. Thus, “If you drive too fast, you’ll have an accident” readily invokes alternative antecedents and hence interpretation as the formal logical conditional. “If you drink too much, you’ll have a hangover,” in contrast,

invokes the simpler (logically incorrect) biconditional. Little confusion arises over this difference in everyday reasoning.

When knowledge and deduction conflict, on the other hand, real-world knowledge does not scaffold reasoning. To the contrary it must itself be managed and controlled, enabling the deductive system to function. Weak executive control, we see through the remainder of this chapter, makes it difficult to temporarily inhibit one's beliefs, so as to enable the reasoning process to operate independently of them, causing a number of different kinds of limitations. This skill does show improvement in the years between late childhood and late adolescence, but its absence remains an obstacle to good thinking throughout adolescence and adulthood. We turn now to inductive reasoning, where we find its role is crucial.

INDUCTIVE AND CAUSAL INFERENCE

One of the final issues we addressed in examining deductive reasoning—its relevance in everyday thinking—is one we can bypass entirely in examining inductive reasoning. There is simply no question about the fundamental role that inductive reasoning plays in thinking and in cognitive development. Children (and adults) confront enormous amounts of data, some consistent and some inconsistent over time, and they must construct meaning out of this wealth of information. An extended, and we will argue ultimately unproductive, debate has existed as to whether children approach this task as empiricists or theorists. In other words, do they rely strictly on observed frequencies of associations to determine “what goes with what” as an indication of how the world is organized, or do they impose theoretical constructions on their encounters with data?

These are the same questions that Gelman and Kalish (Chapter 16, this *Handbook*, this volume) confront in asking how young children form their early concepts. The field has seen some evolution in this respect. Keil (1991), for example, at one time proposed that young children were initially empiricists, forming their concepts on an entirely associationist basis, and later overlaid a theoretical structure on this associational base. Subsequently, however, Keil rejected this view in favor of the position that children's thinking is from the very

beginning theoretical. In other words, children try to make sense of a concept, rather than simply accept it as a statistical compilation of the features whose frequency associations define it. This sense-making effort influences the features they see as central versus peripheral to the concept, as much or more than statistical frequency of association. In Keil's (1998) words, “a system of covariation detection procedures must interact with a framework of expectations about causal patterns” (p. 378).

This is exactly the position we take here with respect to the formation of the more complex forms of understanding being constructed by older children, adolescents, and adults. Most often, their concern is with relations between concepts, relations that are commonly construed as causal. Does alcohol affect a person's judgment? Does this clothing style make one popular? A set of existing ideas is brought to contemplation of the topic, and the task becomes one of achieving coordination between these ideas and new information that becomes available. It is not a matter of identifying one or the other as more important (Koslowski, 1996).

There are thus two potentially problematic questions in examining inductive reasoning that we can set aside—Is it relevant? Does explanation *or* evidence govern it? Another question, however, that must be confronted squarely is the question of competence, and it appears to be a formidable one. Is the child on the cusp of adolescence a competent inductive reasoner? Here we face two strikingly disparate literatures. One, focused on infancy and early childhood, emphasizes the impressive causal inference skills evident in early childhood. The other, focused on adolescents and adults, highlights limitations in causal inference skills that remain characteristic into and throughout adulthood. Our task in this section, then, is to take account of both of these literatures and formulate a portrayal of the development of inductive inference skills in the years in between.

Evidence for Early Competence

We begin our task with an examination of research on early competence. A wealth of evidence exists that even young infants make causal inferences, recognizing an association for example, between one of their own actions (e.g., moving an arm) and an external event (Cohen & Cashon, Chapter 5, this *Handbook*, this volume). We focus here on the more advanced inference skills dis-

played by preschool children who are asked to identify causes in a multivariable context. Multivariable contexts (ones in which multiple events co-occur with an outcome and are potential causes) are the ones people of all ages most often face in everyday experience and therefore are the ones we focus attention on here.

Schulz and Gopnik (2004) present evidence of 4-year-olds' ability to isolate causes in a multivariable context. Children observed a monkey handpuppet sniff varying sets of three plastic flowers, one red, one yellow, and one blue. An adult first placed the red and blue flowers in a vase and brought the monkey up to sniff them. The monkey sneezed. The monkey backed away, returned to sniff again, and again sneezed. The adult then removed the red flower and replaced it with the yellow one, leaving the yellow and blue flowers together in the vase. The monkey came up to smell the flowers twice and each time sneezed. The adult then removed the blue flower and replaced it with the yellow flower, leaving the red and yellow flowers together in the vase. The monkey came up to smell the flowers and this time did not sneeze. The child was then asked, "Can you give me the flower that makes Monkey sneeze?" Seventy-nine percent of 4-year-olds correctly chose the blue flower.

Our task is one of reconciling findings such as these with a sizable body of data on multivariable causal inference in older children, adolescents, and adults that portrays a more complex picture of causal reasoning skill. When individuals coordinate prior expectations with new information, as is usually the case, causal inference becomes more challenging and we see quite different patterns of performance. Here the findings of numerous investigators show the influence of theoretical expectation on the interpretation of data and the ubiquity of faulty causal inference (Ahn, Kalish, Medin, & Gelman, 1995; Amsel & Brock, 1996; Cheng & Novick, 1992; Chinn & Brewer, 2001; Klaczynski, 2000; Klahr, 2000; Klahr, Fay, & Dunbar, 1993; Koslowski, 1996; Kuhn, Amsel, & O'Loughlin, 1988; Kuhn et al., 1992, 1995; Lien & Cheng, 2000; Schauble, 1990, 1996; Stanovich & West, 1997). When theoretical expectations are strong, individuals may ignore the evidence entirely and base inferences exclusively on theory. Or they may make reference to the evidence but represent it in a distorted manner, characterizing it as consistent with their theoretical expectations when it in fact is not. Or they may engage in "local interpretation" of the data (Klahr et al., 1993; Kuhn et al., 1992), recognizing only

those pieces of data that fit their theory and failing to acknowledge the rest.¹

Coordinating Theory and Evidence

This biased processing of information about the world remains commonplace into and through adulthood. At the time of the 2004 presidential election, for example, three-fourths of Bush supporters, but less than a third of Kerry supporters, reported believing that Iraq provides substantial support to Al Qaeda, despite the findings of the 9/11 Commission that there was no evidence of significant support from Iraq ("When No Fact Goes Unchecked," 2004).

Should it be assumed that people engage in intentional misrepresentation of the information they are exposed to? Most of the time, it appears, this is not the most likely explanation. A more likely one is insufficient control over the interaction of theory and evidence in one's thinking (Kuhn, 1989). Under such conditions of weak control, thinking is based on a singular representation of "the way things are" with respect to the phenomena being contemplated, and new information is seen only as supporting—or, more aptly, "illustrating"—this reality. New information is not encoded as distinct from what is already known.

Under such conditions, new information can still modify understanding, but the individual may not be aware that this has taken place. A consequence is that individuals remain largely unaware regarding the source of their knowledge. When asked, "How do you know (that A is the cause of O)?" they make mistakes in attributing the inference to the new information they are contemplating, versus their own prior understanding

¹In a subsequent experiment Schulz and Gopnik (2004) show that young children similarly behave less consistently when the causal effect portrayed conflicts with their prior knowledge, for example, presentation of an adult making a machine operate by saying "Machine, please go." Most children (75%) imitated the adult when asked to make the machine go. They were unlikely to generalize this learning (that people can cause machines to operate by speaking to them) to a new context, however. The authors conclude that there exists a tension "between children's prior beliefs and their assimilation of novel information" (Schulz & Gopnik, 2004) and that additional research is needed to determine how the two interact—a position in fact very similar to the one taken here.

(Kuhn et al., 1988, 1992, 1995; Schauble, 1990, 1996). This uncertainty regarding the source of one's knowledge parallels that observed on the part of preschool children who exhibit confusion regarding the source of their knowledge about simple events (Harris, Chapter 19, this *Handbook*, this volume). Thus, preschoolers answer the question of how they know a runner has won the race not with evidence ("He's holding the trophy") but with an explanation of why this state of affairs makes sense (e.g., "Because he has fast sneakers") (Kuhn & Pearsall, 2000).

Is there evidence of developmental progress in this respect? Kuhn et al. (1988, 1995) compared children, early adolescents, and adults with respect to evidence evaluation and inference skills and found some improvement in the years between middle childhood and early adulthood, despite the far from ideal performance of adults. Among sixth graders, the proportion of evidence-based inferences was about 25%, compared to roughly 50% for noncollege young adults. Following an evidence-focus probe ("Do these results here tell you anything about whether X has an effect?"), these percentages rose to 60% and 80%, respectively (Kuhn et al., 1988).

Once the evidence is attended to, are younger individuals more likely to exhibit biased interpretation than older ones? Here, improvement with age appears more fragile. Individual variation, however, is high, a fact we return to. Individuals were regarded as showing belief bias if they were more likely to interpret the evidence when it was consistent with their previously assessed theories, and/or they interpreted identical evidence differently as a function of its consistency with their theories. Roughly half of sixth graders exhibited one or both forms of bias in their interpretations of both covariation and noncovariation evidence (Kuhn et al., 1988). Among adults, this percentage dropped to 35%, although only for covariation evidence. (For noncovariation evidence, it remained at the sixth-graders' level of 50%.)

Interpreting Covariation Evidence

The challenge of sound inductive inference is far from met simply by attending to the data. Even if the data are faithfully registered, the opportunity for inferential error remains strong, a major contributor continuing to be the potentially biasing effects of theoretical expectation. Much evidence exists of unjustified inductive inferences of a relation, usually causal, between two

variables, based on minimal evidence, notably as minimal as a single co-occurrence of two events (Klahr et al., 1993; Kuhn et al., 1988, 1992, 1995; Schauble, 1990, 1996). Because the events occurred together in time and/or space, one is taken to be the cause of the other, despite the presence of other covariates. This "false inclusion" is of course common in everyday thought at all ages. Thus, when community college students were told about an effort to improve student performance in which a new curriculum, teacher aides, and reduced class size were all introduced in various combinations (Kuhn et al., 2004), they sometimes relied on as little as a single instance in which multiple factors were introduced as potential evidence for the role that one or more of the factors had played in the outcome. The following is a typical inference, "Yes, a new curriculum is beneficial, because here where they had it the class did well."

False inclusion based on a single instance shows some decline in frequency in the years from late childhood to early adulthood (Kuhn et al., 1988, 1995, 2004). Adults are more likely than children to base their causal inferences on a comparison of two instances, rather than a single instance of co-occurrence of antecedent and outcome. Also showing developmental decline are instances of false exclusion, in which a variable is inferred to be noncausal (i.e., have played no role in the outcome) based on no, or a single instance of, evidence.

Even inferences based on comparisons of multiple instances can be fallacious if additional covariates are not controlled and causality is attributed to the wrong variable. These kinds of errors are ubiquitous in everyday life. A personal example that stands out in the first author's mind is one of her teen-aged son needing to be picked up late one night from a party that had gotten out of hand and listening to his frustrated father lament, "Drinking and trouble—haven't you figured out the connection?" Despite the late hour and his shaky state, the teenager advanced a lengthy argument to the effect that his father had the causality all wrong and the trouble should be attributed to other covariates, among them bad luck.

When presented with two or more multiple-covariate instances for possible inferences, performance in inhibiting unwarranted inferences and drawing warranted ones does improve between late childhood and adulthood in this "natural experiment" context (Kuhn & Brannock, 1977; Kuhn & Dean, 2004). We postpone further discussion of this improvement, however, to a later section in which we examine the more common research

design in which individuals are given the opportunity to select their own instances for investigation and, hence, conduct controlled experimentation.²

What is notable and bears emphasis with respect to performance in the “natural-experiment” context of inductive inference is the extent to which the factors we have identified as important are similar to those we identified as important in the case of deductive inference. Both involve inhibition. One is the ability to inhibit the premature responding that terminates processing and prevents one from considering alternatives (in this case, additional covariates). The other is the ability to “bracket,” that is, temporarily inhibit, one’s beliefs, in order to accurately represent evidence and enable the inference system to operate. Both of these abilities, in turn, involve meta-level, or executive, control of mental processes, which we can accordingly hypothesize is increasing during the age period in which we see improvements in reasoning performance.

Coordinating Effects of Multiple Variables: Mental Models of Causality

We have focused on the cognitive challenges encountered in isolating the relation between an individual variable and outcome embedded in a multivariable context. What happens when more than one causal factor has been identified and the task becomes one of identifying how they operate in conjunction, either additively or interactively? Kuhn and colleagues (Keselman, 2003; Kuhn, Black, Keselman, & Kaplan, 2000; Kuhn & Dean, 2004; Kuhn et al., 2004) identify an inadequate mental

model of multivariable causality as a further source of error affecting inductive causal inference in this case. Here we use the “mental model” terminology in this more generic sense, rather than its typical usage referring to mental representations of particular physical phenomena.

The implicit assumption underlying research in the adult causal inference literature is that people’s understanding of multiple causality reflects a standard scientific model: Multiple effects contribute to an outcome in an *additive* manner; as long as background conditions remain constant, these effects are expected to be *consistent*, that is, the same antecedent does not affect an outcome on one occasion and fail to do so on another, or affect the same outcome differently on one occasion than another. A more complex model, encompassing *interactive* effects, presumes understanding of the simpler main effects of an additive model. Indeed, all of science is predicated on such a model. It is not clear how the world would operate in the absence of these assumptions, and hence it is not surprising that research on causal inference (Cheng, 1997) assumes such a model.

Data from the reasoning of both children and adults, however, bring that assumption into question (Kuhn & Dean, 2004; Kuhn et al., 2004). Least likely to be present is the recognition of potential interactivity and its distinction from additivity of multiple causes. When provided the amounts of pollution caused by each of three individual pollutants in a factory, for example, and asked what the pollution level would be if all three pollutants were present, no sixth graders and only 12% of college adults recognized the potential interactivity and hence indeterminacy; others simply added the individual effects, identical to what they had done in a parallel problem of how many logs three boys together would chop based on knowledge of their individual chopping outputs (Kuhn et al., 2004). These results are consistent with findings that even young children are able to add or average outcomes based on the joint effects of two variables when asked explicitly to do so (Dixon & Moore, 1996; Dixon & Tuccillo, 2001; Wilkening & Anderson, 1982). Yet, even adults tend not to differentiate additive and interactive causes when thinking about multiple factors affecting an outcome. This lack of differentiation is not surprising when we note that there exist no natural language equivalents to distinguish the two cases. If we say for example, “Get a good night’s sleep and eat a good breakfast and you’ll do really well,” we are neither required nor encouraged to distinguish

² Still another form of reasoning that shows a similar developmental pattern is correlational reasoning, in which the pattern of relation between two variables is probabilistic rather than absolute. In the case of two binary variables, errors in assessing their relation arise from failure to consider all four cells in the resulting cross-tabulation. For example, in assessing whether lawyers are rich, the reasoner may take into account only his or her knowledge of positive cases (of rich lawyers), neglecting to compare them to poor lawyers or to rich and poor nonlawyers. Again, performance on these kinds of problems, which entail proportional reasoning (specifically, comparing two proportions), improves from childhood through adolescence but remains far from perfect among adults (Arkes & Harkness, 1983; Klaczynski, 2001b; Kuhn, Phelps, & Walters, 1985; Schustack & Sternberg, 1981).

between an additive and interactive model as applying in this situation.

When we turn to the simpler case of variables that are additive in their effects, however, limitations in intuitive mental models of causality appear equally severe. In the absence of explicit instruction to add or average effects, neither additivity nor consistency across instances can be assumed. Keselman (2003) asked sixth graders to investigate and make inferences regarding the causal role of five variables on an outcome (earthquake risk), as well as asking them to make outcome predictions for two new cases representing unique combinations of levels of the variables. Three of the five variables had additive effects on the outcome and the remaining two had no influence. After each prediction, the question was asked, "Why did you predict this level of risk?" All five variables were listed and children were instructed to indicate as many of them as had influenced their prediction judgment. The variables indicated were regarded as ones *implicitly* judged to be causal, as the respondent did not explicitly state them to be causal, saying only that they had entered into the prediction judgment. The variables named as causal in response to direct questions as to whether or not the variable played a causal role were taken as *explicit* causal judgments.

Consistency between explicit and implicit causal judgments was low. Over half of the children justified one or both of their predictions by implicating a variable they had explicitly judged to be noncausal. More than 80% failed to implicate as contributing to the outcome one or more variables they had previously explicitly judged to be causal. Overall, fewer features were implicated as contributory in the implicit attributions than were explicitly stated to be causal. Consistency was low not only between explicit and implicit causal attributions, but also across predictions. Almost three quarters of children failed to implicate the same variable(s) as having causal power across the two prediction instances. Finally, and most directly relevant to the additive model, roughly half of the students justified each of their predictions by appealing to the effect of only a single (usually shifting) variable. This behavior is consistent with the phenomenon known as discounting in the social psychology literature, in which identification of one cause of an outcome leads to the discounting of others, a phenomenon that has been observed by age 8 or 9 and throughout adulthood (Sedlak & Kurtz, 1981).

Adults do better in each of these respects (Kuhn & Dean, 2004), but their performance remains far from

the normative scientific model of multivariable causality. About half of the members of a community choral group, representative of a broad cross-section of the adult population, showed inconsistency between implicit and explicit causal judgments. Almost half were inconsistent in causal attributions across three prediction questions. Like the sixth graders, these adults failed to implicate as causal in their implicit attributions as many variables as they needed to in order to yield correct predictions. Over a quarter appealed to the effect of only a single variable in their prediction judgments, and over half appealed to the effect of only two variables.³

We can thus point to an inadequate mental model of multivariable causality as a constraint on children's and even many adults' ability to reason about the simultaneous, additive effects of multiple variables. Additional challenges, we have seen, come into play when individuals bring new evidence to bear on their causal models and to coordinate them with theoretical expectations. Does experience in coordinating effects of multiple variables improve this mental model? This question is one part of the more general question to which we now turn. As children grow older and progress into and through adolescence, do they improve in their ability to integrate the new information they encounter with their existing understandings? In other words, do children become better learners?

LEARNING AND KNOWLEDGE ACQUISITION

Although the study of children's learning has only recently come back into style (Siegler, 2000; Chapter 11, this *Handbook*, this volume), learning clearly plays a central role in the lives of children of all ages. Moreover, older children and adolescents have had more time and opportunities to learn, and as a result they clearly know more than younger children. Differences in knowledge, then, are certainly a large part of what makes children and adolescents different from one another. The question addressed in this section, and indeed throughout the

³ A further challenge arises in detecting an inverse relation between a variable and outcome and integrating that relation with others that may be present (Kuhn et al., 1988; Lafon, Chasseigne, & Mullet, 2004). Children commonly confuse an inverse relation with independence (Kuhn et al., 1988).

chapter, is whether this is the only difference. What else may contribute to the difference between younger and older individuals? In particular, in this section, we ask whether the learning process itself differs with age.

Cross-Sectional Age Comparisons

Two studies (Kuhn et al., 1995; Kuhn & Pease, in press) we review here have the objective of examining exactly this question. We focus on the simpler Kuhn and Pease study first. Young adults and 12-year-olds were presented the teddy bear shown in Figure 22.1a. The participant assisted the interviewer in outfitting the bear with seven accessories, producing a bear that now appeared as shown in Figure 22.1b. The interviewer presented the situation of a charity group raising funds and having the bears to give to donors as token gifts. In an effort to improve donations, it was explained, the charity wanted to try dressing the bear up a bit. They could afford to add a

few accessories and had to choose which ones. Participants were asked to choose two accessories they thought most likely to increase donations and the two least likely to do so. This content domain was selected to make it unlikely that either age group could be regarded as more knowledgeable in making these choices.

The participant was then presented results of some “test runs” involving these four accessories. A sequence of five instances, presented cumulatively, involving different combinations of the accessories, established that two accessories (one the participant believed effective and one the participant believed ineffective) increased donations and the other two did not. The most successful combination was presented as the fifth instance, such that the correct answer could simply be “read off” from this instance and no complex inferential reasoning was required. Nonetheless, neither group was entirely successful in learning the information presented. Adults, however, showed a higher rate of success than

Figure 22.1 Teddy bear, with and without accessories. *Source:* From “Do Children and Adults Learn Differently?” by D. Kuhn and M. Pease, in press, *Journal of Cognition and Development*. Reprinted with permission.

the 12-year-olds: 75% reported the correct answer, versus 35% of the younger group.

How should one account for superior learning on the part of the adult group? Conceptualizing learning as change in understanding (Schoenfeld, 1999) and ruling out a number of alternative explanations, Kuhn and Pease (in press) proposed that the older participants made better use of a meta-level executive to monitor and manage learning. This executive allowed them to maintain dual representations, one of their own understanding (of the relations they expect or see as most plausible) and the other of new information to be registered. It is this executive control that enables one to temporarily set aside or “bracket” existing beliefs and thereby effectively inhibit their influence on the interpretation of new data. In the absence of this executive, there exists only a singular experience—of “the way things are”—as a framework for understanding the world. This executive control, manifested in response inhibition and bracketing, is of course exactly what we encountered earlier as a central factor in the development of deductive and inductive inference.

Kuhn and Pease’s (in press) findings of less effective learning by preadolescents compared to adults were substantiated in a more extensive microgenetic study (Kuhn, 1995; Siegler, Chapter 11, this *Handbook*, this volume) of learning at these two age levels (Kuhn et al., 1995). Participants were observed over multiple sessions spanning several months as they sought to learn which variables were effective and which were not in contexts involving both physical content (e.g., the speed of model boats down a canal) and social content (e.g., the popularity of children’s TV programs). Again, in both physical and social domains, the adult group was more effective in acquiring the new information.

Because participants conducted their own investigations within these domains, the context allowed them great explanatory freedom. If an outcome appeared to conflict with expectations with respect to one feature, these implications could be avoided simply by shifting to other features to do the explanatory work. What the results made most clear is what the process of knowledge acquisition is not, and that is a process of accessing and accumulating evidence until one feels one has enough to draw a conclusion. Instead, theoretical belief shapes the process at each point—in the evidence that is chosen for examination, the way in which the evidence is interpreted, and the conclusions that are drawn. The

challenge, then, is not simply one of correctly “reading” the data, but of coordinating theories and evidence. New knowledge does not simply add to or displace existing knowledge; the new and old must be coordinated and reconciled. Both children and adults, Kuhn et al. (1995) found, drew conclusions virtually from the outset, on the basis of minimal or no data, and then changed their minds repeatedly. But the children remained more strongly wedded to their initial theories, and drew on them more than on the new evidence they accessed, as a basis for their conclusions.

Both age groups did less well when the content was social rather than physical. To the extent theories in the social domain are more detailed, vivid, and/or affectively potent, a weak executive operator may make it more difficult to maintain dual representations (of theory and evidence). Less potent representations on the theory side, in the case of physical phenomena, may give the two representations a better chance to co-exist, while an executive seeks to coordinate them.

Microgenetic analysis in the Kuhn et al. (1995) research made possible the dual objectives of tracing not only the acquisition of knowledge over time but, also, the evolution of the knowledge-acquisition strategies that were responsible for generating that knowledge. Here the now widely observed findings from microgenetic research (Siegler, Chapter 11, this *Handbook*, this volume) emerge. At both ages, individuals displayed not just one but a variety of different strategies, ranging from less to more effective. Over time, what changes is the frequency of usage of these strategies, with a general decline over time in the usage of less effective strategies and increase in the use of more powerful ones. It is this process of change that Siegler terms his “overlapping waves” model. Our interest has been in the meta-level operators that execute this strategy selection and how they may develop in a way that has positive effects on the performance level (Kuhn, 2001a, 2001b). Since participants in the Kuhn et al. (1995) research conducted their own investigations of the domain, we discuss this work further in the next section on inquiry and scientific reasoning. Here, we return to the question of what it can tell us about how the learning process changes developmentally.

The Development of Learning

Should it be concluded, then, that the learning process undergoes developmental change? Some years ago,

Carey (1985) answered this question with a categorical no, claiming there was no reason to believe that the learning process operated any differently in children than in adults. The findings described here suggest that Carey's sweeping claim, while likely true with respect to some kinds of learning, is not categorically correct. A great deal of the learning children and adults engage in, both in and out of school, is simple associative learning. It is not mindful learning, and there is no evidence to indicate that the nature of associative learning processes undergoes developmental change. Learning that is conceptual, in contrast—that is, involves change in understanding—requires cognitive engagement on the part of the learner, and hence an executive that must allocate, monitor, and otherwise manage the mental resources involved. These executive functions, and the learning that requires them, do show evidence of developing.

At the same time, Kuhn and Pease's (in press) findings show that developmental change of this sort is highly variable. Some 12-year-olds performed as well as the typical adult, and some adults performed no better than most 12-year-olds. The pattern in this respect is quite different from that observed in the case of the many childhood cognitive attainments described in this volume that are closely age linked. When, as here, progress is more variable, microgenetic research is especially valuable in affording insight into the kinds of experience that foster change and the nature of the process. We look further at the insights offered by microgenetic research in the next section.

The microgenetic method has been held responsible for blurring the distinction between development and learning (Kuhn, 1995, 2001b). While the distinction between the two may not be as rigid as theorists of the Piagetian era in the 1960s and 1970s held it to be, it does not follow that there remain no useful distinctions at all. Learning what recordings are on this week's "Top 100" List and learning that conflicting ideas can both be right are different kinds of learning in numerous important respects (among them generalizability, reversibility, and universality of occurrence). What is important is recognizing the process of change as one that has multiple parameters. When the process is examined microgenetically, it becomes possible to begin to characterize it in terms of many such parameters. It is more research of this sort that is required to support the claim that these change processes themselves undergo change as individuals mature.

INQUIRY AND SCIENTIFIC THINKING

Modern research in developmental psychology on the development of scientific thinking began very narrowly, in the form of replication studies seeking to confirm the findings reported by Inhelder and Piaget (1958) in their volume *The Growth of Logical Thinking from Childhood to Adolescence*. The bulk of these replication studies focused even more narrowly on the "control of variables" or "controlled comparison" investigative strategy, which Inhelder and Piaget reported did not appear until the early adolescent years. Using Piagetian tasks in which participants were required to investigate simple physical phenomena such as a pendulum or the flexibility of rods, Inhelder and Piaget's findings were upheld with respect to children's difficulty with these tasks and evidence of improvement from childhood to adolescence, but it was also found that even older adolescents and adults did not always perform successfully (Keating, 1980; Neimark, 1975). Relatively little discussion occurred, however, regarding the broader educational or practical significance of these findings. Assuming these tasks were valid indicators of the ability to engage in scientific thinking, was it important for most people to be able to think scientifically?

Does Children's Thinking Need to Become "Scientific"?

In the early twenty-first century, the picture could not be more different. What has come to be called "inquiry" has found its way into the American national curriculum standards for science (National Research Council, 1996) for every grade beginning with 2nd or 3rd through 12th and appears in a large majority of state standards as well. Inquiry often appears in social studies and even language arts standards as well (Levstik & Barton, 2001). In the national science standards, the goals of inquiry learning for Grades 5 to 8, for example, are the following (National Research Council, 1996):

- Identify questions that can be answered through scientific investigations.
- Design and conduct a scientific investigation.
- Use appropriate tools and techniques to gather, analyze, and interpret data.
- Develop descriptions, explanations, predictions, and models using evidence.

- Think critically and logically to make the relationships between evidence and explanations.

Under “Design and conduct a scientific investigation,” subskills identified include “systematic observation, making accurate measurements, and identifying and controlling variables.”

It is worth asking, then, what scientific thinking is and why it is so important, such that, within a few decades, it has come to be so widely embraced as an educational goal. Defining scientific thinking as “what scientists do” does not work very well, since very few children will grow up to become professional scientists, few enough certainly that educating all children toward this end in elementary school seems scarcely appropriate or worth the effort involved. Nor is defining scientific thinking operationally in terms of the control-of-variables strategy satisfactory, since few people, children or adults, have the opportunities or inclination to conduct controlled experiments in the course of their everyday activities.

The position we take here is to regard scientific thinking as central to science but not specific to it (Kuhn, 1996, 2002). The definition of scientific thinking we adopt is *intentional knowledge seeking* (Kuhn, 2002). This definition encompasses any instance of purposeful thinking that has the goal of enhancing the seeker’s knowledge. As such, scientific thinking is a human activity engaged in by most people, rather than a rarefied few. It connects to other forms of thinking studied by psychologists, such as inference and problem-solving. We characterize its goals and purposes as more closely aligned with argument than with experimentation (Kuhn, 1993; Lehrer, Schauble, & Petrosino, 2001). Scientific thinking is frequently social in nature, rather than a phenomenon that occurs only inside people’s heads.

From their earliest years, children construct implicit theories that enable them to make sense of and organize their experiences. In a process that has come to be referred to as *conceptual change*, these theories are revised as new evidence is encountered bearing on them. Unlike scientific thinking, early theory revision occurs implicitly and effortlessly, with little indication of conscious awareness or intent. Young children think *with* their theories, rather than *about* them. In the course of so doing they may revise these theories, but they are unlikely to be aware that they are doing so. As a result, as we noted earlier in the discussion of inductive reason-

ing, they are typically uncertain regarding the source of their knowledge.

It is the intention to seek knowledge that transforms implicit theory revision into scientific thinking. Theory revision becomes something one *does*, rather than something that happens to one outside of conscious awareness. To seek knowledge is to recognize that one’s existing knowledge is incomplete, possibly incorrect—that there is something new to know. The process of theory-evidence coordination accordingly becomes explicit and intentional. Newly available evidence is examined with regard to its implications for a theory, with awareness that the theory is susceptible to revision and that its modification may be an outcome of the process.

In this framework, it becomes possible to reconcile the shortcomings in scientific thinking identified in this chapter with the “child as scientist” perspective adopted by authors such as Gelman and Kalish (Chapter 16, this *Handbook*, this volume) and Gopnik, Meltzoff, and Kuhl (1999). As theory builders, children are indeed young scientists (or scientists big children) virtually from the beginning. There is no evidence to indicate that children’s construction and elaboration of theories as means of understanding the world take place in a qualitatively different way than they do for lay adults or scientists (although this is not a question that has been thoroughly researched). Where the difference arises is in the intentional, consciously controlled coordination of these theories with new evidence. Here the research evidence is plentiful that children execute this process less skillfully than most adults and certainly less skillfully than professional scientists.

The Process of Inquiry

As Klahr (2000) notes, very few studies of scientific thinking encompass the entire cycle of scientific investigation, a cycle we characterize as consisting of four major phases: inquiry, analysis, inference, and argument. A number of researchers have confined their studies to only a portion of the cycle, most often the evaluation of evidence (Amsel & Brock, 1996; Klaczynski, 2000; Koslowski, 1996), a research design that links the study of scientific reasoning to research on inductive causal inference. We postpone discussion of argument to a later section, and we focus here on studies in which participants direct their own investigations and seek their own data as a basis for their inferences, hence involving at least the first three phases

of the cycle (Keselman, 2003; Klahr, 2000; Klahr et al., 1993; Kuhn et al., 1992, 1995, 2000; Kuhn & Phelps, 1982; Penner & Klahr, 1996; Schauble, 1990, 1996). These studies offer a picture of how the strategies associated with each phase of scientific investigation are situated within a context of all the others and how they influence one another.

Studies of individuals engaged in scientific inquiry, or intentional knowledge seeking, have been at the same time both cross-sectional and microgenetic. In other words, initial strategies of individuals of different age levels can be compared cross-sectionally. If the individuals continue to engage in investigative activity over multiple sessions, change can be observed at two levels—in the products of their inquiry, that is, the knowledge they acquire, and in the strategies of inquiry, analysis, and inference used to generate that knowledge.

The studies by Klahr and his associates (Klahr, 2000; Klahr et al., 1993) have followed children and adults asked to conduct investigations of the function of a particular key in controlling the behavior of an electronic robot toy, or, in another version, the behavior of a dancer who performs various movements in a computer simulation. To do this, individuals need to coordinate hypotheses about this function with data they generate, or, in Klahr's (2000) terminology, to coordinate searches of an hypothesis space and an experiment space.

The microgenetic studies by Kuhn and associates, as well as those by Schauble (1990, 1996), Keselman (2003), and Penner and Klahr (1996) examine what we regard as a prototypical form of scientific inquiry—the situation in which a number of variables have potential causal connections to an outcome and the investigative task is to choose instances for examination and on this basis to identify causal and noncausal variables, with the goals of predicting and explaining variations in outcome. Examined in these studies in their simplest, most generic form, at the same time these are common objectives of professional scientists engaged in authentic scientific inquiry.

Studies originating in both Klahr's and Kuhn's laboratories have portrayed very similar overall pictures. Adults on average exhibit more skill than children or young adolescents at each stage of the process. The younger group is more likely to seek to investigate all factors at once, to focus on producing outcomes rather than analysis of effects, to fail to control variables and, hence, to choose uninformative data for examination, and to engage in what Klahr refers to as “local interpre-

tation” of fragments of data, ignoring other data that may be contradictory. Klahr (2000) concludes that, “adult superiority appears to come from a set of domain-general skills that . . . deal with the coordination of search in two spaces” (p. 119).

Kuhn et al. (1995) compared the progress of children and adults as they continued their investigations in multiple content domains over a period of months. Adults both started at a slightly higher level and progressed further. Although the strategies of both groups improved, the investigations of the older group overall yielded more valid conclusions and fewer invalid conclusions than those of the younger group. Unsurprisingly, as a result, they learned more about the causal structure of the domain they were investigating. Yet, microgenetic analysis of the change process confirmed the now common finding that individuals of both ages displayed not just one but a variety of different strategies ranging from less to more effective. Kuhn et al. (1995) concluded, “Rather than a unidimensional transition from a to b, the change process must be conceptualized in terms of multiple components following individual (although not independent) paths” (p. vi). This was the case with respect to *inquiry* strategies, which range from “generate outcomes” to “assess the effect of X on outcome”; with respect to *analysis* strategies, which range from “ignore evidence” to “choose instances that allow an informative comparison”; and with respect to *inference* strategies, which range from “unsupported claims” to “representations in relation to both consistent and inconsistent evidence” (Kuhn, 2002).

Consistent with other microgenetic research (Siegler, Chapter 11, this *Handbook*, this volume), over time the frequency of usage of less effective strategies diminished and the frequency of more effective strategies increased. If we accept that the density of exercise accelerates developmental change without altering its essential characteristics (Kuhn, 1995), the question of interest becomes one of identifying the mechanisms underlying this change process. In postulating mechanisms, Siegler (this volume) emphasizes the need for associations with the more frequent, less effective strategies to be weakened. While similarly emphasizing the relinquishment of less effective strategies as a more formidable obstacle than strengthening new ones, Kuhn (2001a, 2001b) proposed that knowledge at the meta-level is as important as that at the performance level and plays a major role in what happens there. Portrayed in the right side of Figure 22.2 (Kuhn, 2001b) are the strategies

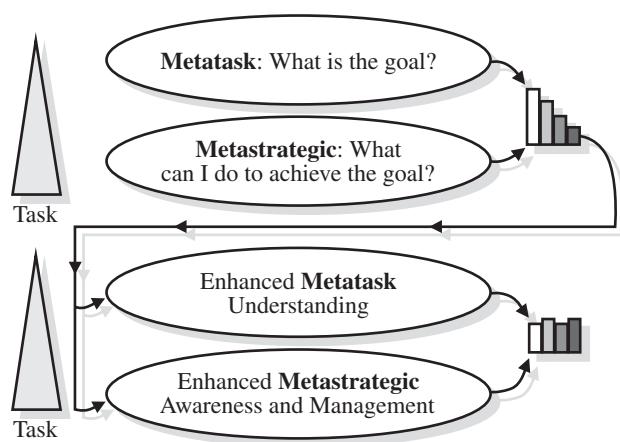

Figure 22.2 Diagram of shifting distribution of strategy usage. *Source:* From “Why Development Does (and Doesn’t) Occur: Evidence from the Domain of Inductive Reasoning,” by D. Kuhn, in *Mechanisms of Cognitive Development: Neural and Behavioral Perspectives*, R. Siegler and J. McClelland (Eds.), 2001, Mahwah, NJ, Erlbaum. Reprinted with permission.

that coexist and are available for use (comparable to Siegler’s “overlapping waves” model, this volume). In the progress depicted from the upper to the lower half of the diagram in Figure 22.2, the less effective strategies to the left become less frequent and the more effective strategies to the right more frequent (in this case, yielding a temporary, transitional result of all strategies of roughly equal strategy). Implicated in this change are the meta-level operators that appear in the center of the diagram, representing the individual’s understanding of the task goal, understanding of the strategies he or she has available to apply, and awareness of the need to coordinate the two in selecting a strategy. Feedback from the performance level should enhance meta-level understanding, further enhancing performance, in a continuous process.

Strategic progress with continued engagement not only occurred in both age groups, Kuhn et al. (1995) found, but was maintained when new problem content was introduced midway through the sessions. A further indication that strategies were not confined to specific content was the emergence of new strategies at about the same time in the social and physical domains, even though performance in the social domain overall lagged behind. No simple predictors of change emerged, such as feedback discrepant from expectations, and it was hypothesized that the sense of effectiveness produced by good strategies may be as potent a source of change (Pressley & Hilden, Chapter 12; Siegler, Chapter 11,

this *Handbook*, this volume). Finally, and importantly, the most prevalent change to occur overall was not the emergence of any new strategies but the decline of ineffective ones, in particular the inhibition of invalid causal inference.

Supporting the Development of Inquiry Skills

We have noted that the intellectual skills examined in this chapter, unlike the large majority of those addressed in the other chapters in this volume, cannot be counted on to routinely develop. In the case of deductive inference, this has not been an issue of wide concern. In the case of inductive inference, it has received somewhat wider attention, to a large extent in the context of discussions of critical thinking. As we noted at the outset of this section, inquiry skills have become a focus of very wide concern to educators. As a result, considerable attention has been devoted to how these skills might be most effectively promoted in young preadolescents or adolescents.

Studies dating back to the 1970s (Case, 1974; Kuhn & Angelev, 1976) established that the isolation- and control-of-variables strategy could be taught. But that evidence by no means resolves the matter of identifying the most effective educational interventions, an objective that goes beyond the scope of the present chapter. Most recently, Chen and Klahr (1999) and Klahr and Nigam (2004) present data that brief direct instruction effectively teaches control of variables and on this basis they advocate it as the most efficient, desirable method. At the same time, studies already described here by Kuhn et al. (1992, 1995, 2000) and by Schauble (1990, 1996) document that preadolescents develop this skill and others when they engage in dense exercise in problem-solving situations that require them. Preadolescents are unlikely to show much progress in the brief single session of self-directed activity that Klahr and Nigam (2004) employ as a control condition, but over time and sustained engagement, microgenetic studies show predictable patterns of advancement, as we have noted.

What strengths might this labor intensive, time inefficient means of fostering the development of inquiry skills have over the efficiency of simple, brief direct instruction? The most important in our view has to do with the metastrategic level of understanding that may accompany strategic learning (Kuhn, 2001a, 2001b). If we exclude unconscious strategy usage, when an individual voluntarily initiates use of a strategy to address a

problem, the individual presumably does so with some degree of intention and hence belief that the strategy will serve his or her objectives. This metastrategic understanding is not necessarily present or of the same quality when one is following an instruction to use the strategy. The implications are significant with respect to how the individual may act when the instructional context is withdrawn and the individual resumes voluntary control of his or her own behavior. Intent underlying use of the strategy will remain difficult to identify with any certainty.

The second strength has to do with the fact that inquiry is a complex, multifaceted activity. It is more than a single strategy that we want to see young students of science acquire. If we are to achieve the much desired objective of involving students in "authentic" science (Chinn & Malhotra, 2001), the integrity of the whole must be respected. As we have noted, weaknesses in the inquiry process arise long before one gets to the phase of designing and interpreting experiments. A first, critical phase is formulating a question to be asked. Unless the student understands the purpose of the activity as seeking information that will bear on a question whose answer is not already known, inquiry often degenerates into an empty activity of students securing observations for the purpose of illustrating what they already take to be true (Kuhn, 2002). In the context of multiple variables potentially affecting an outcome, students who have developed an understanding of the need to access an available data base as a source of information may nonetheless initially pose ineffective questions, in particular by intending to discover the effects of all variables at once. And it may be this ineffective intention that then leads them to simultaneously manipulate multiple variables (in effect overattending to them, rather than underattending by failing to control them, as is often assumed).

Kuhn and Dean (2005) in the context of an extended intervention otherwise confined to exercise, added the simple suggestion to students that they choose a single variable to try to find out about. This simple intervention had a pronounced effect on their investigation and inference strategies, greatly enhancing the frequency of controlled comparison and valid inference, relative to a control group, in both the original and a new context. This finding documents, certainly, the complex multifaceted nature of inquiry. But it also highlights that more is involved in mastery than the ability to execute effective strategies.

The understanding associated with the initial phase of the inquiry process is most critical because it gives meaning and direction to what follows. If a question is identified that seems worth asking and the ensuing activity seems capable of answering, the stage is set for what is to follow. In the multivariable context of isolation of variables and controlled comparison, the individual may cease to vary other variables across two-instance comparisons because of an increasing sense that they are not relevant to the comparison being made. Once they are left alone, and thereby "neutralized" as Inhelder and Piaget (1958) described it, the way is prepared for increased usage and increasing metastrategic understanding of the power of controlled comparison. But the most important message here is that we need to look beyond the control-of-variables strategy as a narrow procedure to teach students to execute. Rather, it should be conveyed as a tool that serves as a resource for them to draw on in seeking answers to the questions that they may pose.

DECISION MAKING

Are adolescents more competent decision-makers than children? Are they less competent decision makers than adults? The developmental changes in inference and reasoning noted thus far in this chapter would lead to a hypothesis of age differences in judgment and decision making, which presumably are the result of exercise of reasoning processes. Unfortunately, the research evidence regarding children's and adolescents' decision-making is limited.⁴ To date, it consists almost entirely of administering to children and adolescents a number of the decision scenarios that have been used in research with adults and in which many adults have been found to make decisions that violate sound decision-making principles (Kahneman & Tversky, 1996; Stanovich & West, 1998, 1999, 2000). We report here how children and adolescents perform on these tasks, relative to the levels of performance observed among adults. We begin, however, with several studies of a different mold, having to do with simple judgments of preference.

⁴We do not review here programs that have been devised to teach good decision-making to adolescents. These programs are largely based on work with adults, and evidence regarding their effectiveness is limited (Beyth-Marom, Fischhoff, Jacobs, & Furby, 1991).

Preference Judgments

Consider the following kind of problem, presented to 8-year-old and 12-year-old children by Bereby-Meyer, Assor, and Katz (2004).

In a computer store, Ron is offered four computer games that he can afford:

- The first one is interesting, has not-so-good voice quality, and comes with an option to add players.
- The second is not interesting, has not-so-good voice quality, and comes with an option to add players.
- The third one is not interesting, has good voice quality, and lacks an option to add players.
- The fourth one is interesting, has not-so-good voice quality, and lacks an option to add players.

Which computer game is the best choice for Ron?

In a parallel study (Capon & Kuhn, 1980), preferences of kindergarteners, fourth graders, eighth graders, and young adults were solicited regarding real, physically present objects—pocket-sized notebooks of two colors, binding types (side or top), shapes, and surfaces. At the end of the study, they were given their most preferred notebook to keep. They were also asked for separate preference judgments regarding the four dimensions themselves.

Results of the two studies are similar in many respects. Bereby-Meyer et al. (2004) observed some improvement with age, but they found frequent use at both ages of what they term the lexicographic error, in which judgment is based on a single dimension. Similarly, Capon and Kuhn (1980) found that rarely before adulthood did participants take more than a single dimension into account in making preference judgments for the notebooks, despite the fact that at all ages the majority indicated preferences on at least three of the four dimensions in making dimension preference judgments.

The data from these studies are notable in particular as they parallel the findings by Keselman (2003) and by Kuhn and Dean (2004) noted earlier in the section on inductive inference. A large majority of sixth graders failed to implicate as contributing to an outcome one or more variables they had previously explicitly claimed to be causal. Fewer variables were implicated as contributory in implicit attributions (associated with prediction judgments) than were explicitly attributed as causal, and half of the participants justified their predictions by appealing to the effect of only a single variable. It is dif-

ficult to attribute such patterns in the preference judgment study to capacity limitations, versus dispositional factors. The requested preference judgment regarding the dimension (e.g., color) is elicited, but it does not follow that a respondent cares enough about it to integrate status on this dimension into his or her object preference judgments. Still, the fact that in the inductive inference context, where it is clearly normative to do so, sixth graders (and even older individuals) do not attend to all dimensions they implicate as causal suggests that individuals may experience difficulty in attending to and integrating all of the multiple dimensions they would in fact wish to enter into preference judgments of objects, and that developmental factors may be relevant.

Decision-Making Judgments

Klaczynski (2001a, 2001b) has collected the most comprehensive age-comparative data on children's and adolescents' decision-making judgments. He administered to young adolescents (average age 12) and older adolescents (average age 16) several of the most widely known decision scenarios in which adult errors have been documented. He reports improved rates of correct responding with age (see Table 22.1) in each of the following four scenarios. Two other scenarios that did not show clear age improvement were the conjunction fallacy (in which the conjunction of A and B is judged more likely than A alone) and hindsight bias (Kahneman & Tversky, 1996).

1. **Contingency:** A doctor has been working on a cure for a mysterious disease. Many people are getting sick from the disease, so the doctor has been working very hard. Finally, he created a drug that he thinks will cure people of the disease. Before he can begin to sell it, he has to test the drug. He selected 14 people for his test and compared how sick these people were after getting the drug to 7 people who did not get the drug. Of those who got the drug, 8 were cured and 6 were still sick. Of those who did not get the drug, 4

TABLE 22.1 Proportion of Correct Responses in Decision Scenarios by Age Group

	Young	Older
Contingency	.35	.52

were cured and 3 were still sick. What effect did the drug have? (5-point choice scale ranges from -2 to $+2$).⁵

2. *Statistically-based (versus anecdotally based) decision:* Ken and Toni are teachers who are arguing over whether students enjoy the new computer-based teaching method used in some math classes. Ken's argument is, "Each of the 3 years that we've had the computer class, about 60 students have taken it. They have written essays on why they liked or didn't like the class. Over 85% of the students say they have liked it. That's more than 130 of 150 students." Toni's argument is, "Stephanie and John (the two best students in the school, both high-honors students) have complained about how much they hate the computer-based class and how much more they like regular math classes. They say a computer can't replace a good teacher" (4-point choice scale offered as to which course to take).
3. *Gambler compensation fallacy:* When playing video poker, the average person beats the computer one in every four tries (25% of the time). Julie, however, has just beaten the computer six out of eight times (75% of the time). What are her chances of winning the next time she plays? A range of response options is offered. The compensation fallacy is identified when the respondent indicates a likelihood lower than the objective probability.
4. *Outcome bias:* In these problems, a high-failure likelihood that has a favorable outcome is compared with a low-failure likelihood with an unfavorable outcome. The quality of each decision is rated on a 7-point scale. Outcome bias is calculated by subtracting ratings for the high-failure-likelihood event from those for the low-failure-likelihood event.

The fourth scenario, outcome bias, was scored based on the degree of bias shown. The quality of the decision was rated on a 7-point scale (7 = high). Outcome bias was determined by subtracting ratings on the high probability with negative outcome problems from ratings on the low probability with positive outcome problems. Summed across two problem domains, bias scores could range from -12 to $+12$, with positive scores indicating bias. Mean score for the young adolescents was 4.21 and

for the older adolescents 2.78, thus indicating a decline in outcome bias with age.

Klaczynski did not include adults in this study, so we cannot say with certainty whether the older teens performed any less well than would have adults from an equivalent population. The adult literature has reported these to be common judgment errors, however, so older teens did not perform substantially worse, if at all inferior to, adults. In a further study, Klaczynski (2001a) did compare the performance of young and older adolescents to that of young adults, but he employed different problems, notably the well-known sunk-cost fallacy:

- A. You are staying in a hotel room on vacation. You paid \$10.95 to see a movie on Pay TV. After 5 minutes, you are bored and the movie seems pretty bad. How much longer would you continue to watch the movie?
- B. You are staying in a hotel room on vacation. You turn on the TV and there is a movie on. After 5 minutes, you are bored and the movie seems pretty bad. How much longer would you continue to watch the movie?

Because sunk costs are irretrievable, they should be ignored and decisions in the two situations should be the same. Here, Klaczynski found, all age groups were susceptible to the sunk-cost fallacy (choosing to watch longer in situation A than in situation B), with only 16% of young adolescents (average age 12), 27% of older adolescents (average age 16), and 37% of adults responding correctly.

In sum, then, the picture is one of modest improvement during the teen years toward an asymptote characteristic of the adult population—an asymptote itself of a very modest level, with the average adult at least as likely to make an incorrect judgment as a correct one in response to most of the scenarios.

Dual-Process Theory

Drawing on theories of Sloman (1996), Evans (2002) and others, Klaczynski (2004, 2005) proposes a "dual-process" theory to account for the development of decision-making skills. Cognitive development, Klaczynski proposes, is not in fact unidimensional, proceeding along a singular course as traditional theories espouse, but rather occurs along two trajectories. One is an experiential system and the other an analytic system. The major contrasting characteristics of the two systems appear in Table 22.2. The two systems are thought to be

⁵This problem is in fact equivalent to the earlier discussed correlation problem.

TABLE 22.2 Contrasting Attributes of Two Cognitive Systems in Dual-Process Theories of Cognitive Development

Experiential System	Analytic System
Unconscious	Consciously controlled
Effortless	Effortful
Automatic	Volitional
Fast	Deliberate
Holistic	Analytic
Intuitive	Reflective
Contextualized	Decontextualized

in competition with one another, especially in contexts like the decision scenarios considered here, in which they yield opposing judgments.

Developmentally, Klaczynski (2004, 2005) proposes, the experiential system is always present and remains the predominant system. It is useful and adaptive; were it not for its rapidity and automaticity, information processing would be overburdened. Developmental change may occur, however, in the degree to which the experiential system predominates. The potential to respond experientially increases with age, Klaczynski suggests, but also in the process of becoming more prominent with age are increasingly powerful metacognitive operators. These metacognitive operators have the potential to invoke the analytic system. Once invoked, the analytic system has the dual tasks of inhibiting the experiential system and doing its own primary work, which entails extracting the decontextualized representations that will lead to correct judgments.

The major limitation of this dual-process model of cognitive development is that there at present is little direct empirical evidence available to substantiate it. The model does fit the developmental decision-making data, however, and a number of Klaczynski's secondary findings are also consistent with it. He accounts, for example, for the finding that a "logical person" cue ("Think about this situation from the perspective of a perfectly logical person") enhances performance on the grounds that it induces uncertainty about whether to use one's normal experiential processing mode. On the other hand, there is no consistent evidence for developmental change occurring separately in two distinct systems. Despite two earlier reports of increased susceptibility to certain of the fallacies during adolescence (Davidson, 1995; Jacobs & Potenza, 1991), Klaczynski did not replicate these findings and found no evidence of increased reliance on experiential processing with age on any task.

At the same time, at a broader level, a dual-process model fits well with the data on deductive and inductive inference examined thus far in this chapter. Two factors that figure prominently in both kinds of inference were, first, response inhibition capability, particularly the premature termination of processing that precludes consideration of alternatives, and, second, the ability to bracket, or temporarily inhibit, one's beliefs, in order to accurately represent data and allow the inference system to operate. Both of these involve competing systems, one effortless and intuitive and the other deliberate and reflective. And both point to the importance of a meta-level executive that mediates selection of the more reflective, less contextualized alternative.

It is worth keeping the dual-process model in mind as a model that may come to have considerable utility as a framework for understanding a wide range of phenomena in the study of reasoning and cognitive development. Ultimately, however, the utility of the dual-process model as a framework for understanding cognitive development can only be established when efforts are made to relate a broader range of phenomena to it. The forced-choice judgments that children make to the well-known decision-making scenarios do not reveal a great deal about the thinking that underlies their choices or how that thinking may change with age. In this respect, research on children's decision making follows the model established by the adult decision-making literature, in which the reasoning associated with judgments is viewed with suspicion and only the judgments themselves are regarded as valid data (Janis & Klaczynski, 2002; Shafir, Simonson, & Tversky, 1993). In the next section, we turn to a very different line of inquiry—research on argument skills—in which the reasoning that underlies a judgment becomes the major focus of interest.

ARGUMENT

In turning to the topic of argument, we encounter a paradox. Educators seeking to develop students' intellectual skills would consider it a great achievement if students became proficient in generating, evaluating, and engaging collaboratively in reasoned argument. Yet, the study of reasoning by cognitive psychologists has been devoted almost entirely to solitary problem solving, and there has been comparatively little interest in empirical research on argument skills and their development. Until fairly recently, most of what we know about children's and adolescents' argument skills has come from educators rather than psychologists.

The terms *argument* and *argumentation* reflect the two senses in which the term *argument* is used, as both product and process. An individual constructs an argument to support a claim. The dialogic process in which two or more people engage in debate of opposing claims can be referred to as *argumentation* or *argumentative discourse* to distinguish it from argument as product. Nonetheless, implicit in argument as product is the advancement of a claim in a framework of evidence and counterclaims that is characteristic of argumentative discourse, and the two kinds of argument are intricately related (Billig, 1987; Kuhn, 1991).

Individual Arguments

Most of the empirical research on argument has been devoted to individual argument as product and we begin with it.

Producing Arguments

Educators at all levels have long lamented students' weaknesses in producing a cogent argument in support of a claim in their expository writing. By asking adolescents and adults to generate arguments in individual verbal interviews, Kuhn (1991) probed whether these weaknesses reflect poorly developed writing skills or deficits that are more cognitive in nature. Individual argument skills remained poor among adolescents even when the possibly inhibiting factor of producing written text was removed. Only on average about one-third of a teen sample was able to offer a valid supporting argument for their claim regarding an everyday topic (e.g., why prisoners return to crime when they're released), a percentage that increased only very modestly to near one half among adults. Unsuccessful participants tended to offer pseudoevidence for their claims, in the form of an example or script (e.g., of a prisoner returning to crime), rather than any genuine evidence to support a claim as to the cause of the outcome in question. Similarly in the minority were those adolescents or adults who were able to envision counterarguments or rebuttals to their claims. Although chronological age (from adolescence through the sixties) was not a strong predictor of skill, education level was a significant predictor.

Other empirical research is consistent with a picture of poorly developed argument skills (Brem & Rips, 2000; Glassner, Weinstock, & Neuman, 2005; Knudson, 1992; Means & Voss, 1996; Perkins, 1985; Voss & Means, 1991). In particular there is a consistent picture of arguments that are confined to the merits of one's

own position, without attention to alternatives or opposing arguments. Kuhn, Shaw, and Felton (1997) compared the performance of young teens (seventh and eighth graders) and young adults (community college students) in producing arguments in favor of or opposing capital punishment. The two groups were equally likely to address both sides of the argument (31% of teens and 34% of adults did so); the remainder confined their arguments to supporting their own position. Adults, however, were somewhat more likely to present these arguments in a framework of alternatives. (For example, they might argue that life imprisonment is a better alternative than capital punishment, or, equally well, that life imprisonment is not a viable alternative and capital punishment is therefore necessary.) Only 6% (3 individuals) of the teens, versus 23% of the adults, offered such arguments (Kuhn et al., 1997). Overall, however, the available research indicates only slight improvement during the adolescent years in the ability to produce sound arguments.

Evaluating Arguments

In other studies, participants have been asked to evaluate the strength or soundness of an argument presented to them in support of a claim (Kuhn, 2001a; Neuman, 2002; Weinstock, Neuman, & Tabak, 2004). Kuhn (2001a) reported a tendency on the part of eighth graders to focus on the content of the claim rather than the nature of the argument supporting it, hence producing the typical justification, "This is a good argument because it [the claim] is true." A comparison group of community college students were better able to separate their belief in the truth or falsity of the claim from their evaluation of the strength of the argument.

Several authors have examined the influence of one's belief regarding the claim on the evaluation of arguments supporting or opposing it (Klaczynski, 2000; Koslowski, 1996; Stanovich & West, 1997). These studies report that the same arguments are scrutinized more thoroughly and evaluated more stringently if they contradict the evaluator's beliefs than if they are supportive of these beliefs, paralleling findings from the scientific reasoning literature that individuals evaluate identical evidence differently if it is belief-supportive versus belief-contradictory (Kuhn et al., 1988, 1995; Schauble, 1990, 1996). Klaczynski (2000), for example, studied early adolescents (mean age 13.4) and middle adolescents (mean age 16.8) classified by self-reported social class and religion. They were asked to evaluate fictitious research studies in which it was concluded that one social class or

one religion was superior to the other on some variable. At least one major and several minor validity threats were present in each study. Participants indicated the strength of the conclusion on a scale from 1 (very weak) to 9 (extremely well-conducted) and wrote accompanying justifications. The performance of the older group was superior in critiquing the studies. Both age groups, however, exhibited a positive bias toward studies that portrayed their group favorably, critiquing these studies less severely, although only for the religion grouping. Moreover, the extent of this bias did not diminish with age; on one indicator it in fact increased.

In another study, Klaczynski and Cottrell (2004) asked children of 9, 12, and 15 years of age to evaluate normative arguments against the sunk-cost decision-making fallacy described in the preceding section, as well as nonnormative ("waste not") arguments supporting the fallacy. Overall, at all ages, the normative arguments against the fallacy were rated as better than the nonnormative ones. When individuals were exposed to both kinds of arguments in conjunction, however, only the 15-year-olds showed significant improvement in subsequent decisions in sunk-cost kinds of problems. The authors explain these results in terms of the dual-process theory. Only the adolescents, they claim, engage in the "metacognitive intercession" that enables them to inhibit the more primitive experientially based heuristic, even though the more advanced analytic solution is understood by and potentially available to many of the younger children as well.

Argumentive Discourse

The preceding research presents a consistent picture. There may be slight improvement along some dimensions during the adolescent years, but skills in producing or identifying sound arguments generally remain poor. Identifying more precisely the potential sources of difficulty and distinguishing among them remains a task for further research, although indications are that the meta-level skills involved in bracketing one's own beliefs figure importantly. We turn shortly to the question of primary interest to educators—how these skills can be improved. Graff (2003) makes the claim that developing arguments to support a thesis in expository writing is difficult for students because the task fails to reproduce the conditions of real-world argument, which is dialogic. In the absence of a physically present interlocutor, the student takes the writing task to be one of

stringing together a sequence of true statements, avoiding the complication of stating anything that might not be true. The result is often a communication in which both reader and writer are left uncertain as to why the argument needs to be made at all. Who would want to claim otherwise? If students plant a "naysayer"—an imaginary opponent—in their written arguments, Graff suggests, as a scaffold for the missing interlocutor, their essays become more like authentic arguments and hence more meaningful.

Graff's idea implies that individuals may exhibit stronger argument skills in the dialogic context of argumentive discourse than they do in producing their own individual arguments in support of a claim. Some research has been done observing the argumentive discourse of groups of young children in naturalistic settings (Anderson et al., 2001; Pontecorvo & Girardet, 1993). But, as noted earlier, there has until recently been relatively little systematic analysis of dyadic argumentive discourse at different age levels, to examine its characteristics compared to those of individually generated arguments.

Felton and Kuhn (2001) asked junior high school and community college students to engage in a discussion of the merits of capital punishment with a peer whose view opposed theirs. The pair was asked to talk for 10 minutes and to try to come to agreement if they could. Each of the utterances in the dialog was classified according to whether its function was (a) to advance exposition of the speaker's claims or arguments or (b) in some way to address the partner's claims or arguments. Among teens, an average of 11% of utterances were in the latter, other-focused category. Among adults, this percentage rose to 24%. Thus, while some improvement appears during adolescence, the weaknesses observed in dialogic argument in some ways resemble those observed in individual arguments, with only a minority of arguers going beyond exposition of their own position. Only infrequently do we see the genuine exchange that is the mark of authentic discourse. Why might this be? Felton and Kuhn (2001) suggest that attention to the other person's ideas and their merits may create cognitive overload, or it simply may not be recognized as part of the task. Most likely, both factors are at work—both procedural and meta-level limitations constrain performance.

As a result, dialogic argument is reduced to an activity curiously like that of individual argument. The objective is the same in both cases—to make the most compelling case possible as to the merits of one's posi-

tion. If I do a good enough job, my position will prevail due to its merits, outshining any competitors, whose arguments will merely fade away into oblivion. In the case of individual argument, the task is taken on as a solitary endeavor. In the case of dialogic argument, the task is similarly individual but two people engage in it simultaneously, juxtaposing their respective efforts in a turn-taking format.

If the demands of participating in discourse create cognitive overload, and individual argument production is itself demanding, as suggested earlier, what would happen if we removed both of these demands? Kuhn and Udell (in press) explored this question by presenting participants with the following kind of simple forced-choice item:

You are told to drink fruit juice instead of soda. You like soda better. Which is the best argument for you to make?

Fruit juice is too sweet.

Soda keeps you alert.

On 10 such items, middle-school, high-school, and adult participants all showed a preference for alternatives supporting the preferred action over those arguing against the nonpreferred action. Mean number of choices arguing against the nonpreferred action showed a marginally significant increase (from 2.48 to 3.04) between middle school and high school groups and a non-significant difference between high school and adult groups. In a second study, however, in which participants were allowed to generate their own arguments with no constraints, both community and university adults substantially increased the extent to which these arguments included ones addressing the opposing position, while younger participants improved only slightly. Yet, in a final study, it was established that middle school students had no difficulty producing arguments against the opposing position when these were explicitly solicited. Thus, younger individuals had the cognitive competence to address opposing positions, but did not see a need to do so.

Supporting the Development of Argument Skills

The preceding findings suggest that when argument tasks are stripped of both social role demands and ver-

bal production demands, the tendency to leave the opposing side of an argument unaddressed largely remains, despite presence of the requisite competence. This result points to the likelihood of meta-level factors constraining performance. In other words, the arguer does not understand the dual goals of argument—to identify and challenge the opponent's unwarranted claims, and to secure commitments in support of one's own claims (Walton, 1989). We return to this likelihood in examining epistemological understanding in the next section.

First, we summarize studies that have been conducted with the objective of enhancing argument skills, where these can be distinguished and assessed apart from students' broader academic skills in verbal and written expression and communication. Following Billig (1987), Graff (2003), and Kuhn (1991), the dialogic context of argumentation, which is implicit as well in individual expository arguments, seems the surest ground on which to base such efforts. The now large body of research employing the microgenetic method (Kuhn, 1995; Siegler, Chapter 11, this *Handbook*, this volume), in which cognitive skills have been shown to develop as a result of frequent engagement with problems that require them, provides a rationale for engaging students in dense practice of argument. The intent is that this practice will allow them to see its benefits at the same time that they are exercising and gradually developing the skills needed to execute it well.

Kuhn et al. (1997) observed junior-high-school students engaged in dialogic arguments over a period of weeks with a series of different classmates who held opposing (or, in some cases, agreeing) positions on capital punishment. Students were paired with a different partner each week, and the pair was asked to talk for 10 minutes and to try to come to agreement if they could. They later repeated this same activity with a new partner, until each participant had engaged in a total of five dialogs. In a later study (Felton, 2004), the design was similar except this time students alternated in roles of participants and peer advisors, the latter role intended to heighten students' reflective awareness of their argumentative discourse. After a dialog, the two participants met with their respective peer advisors (who had observed the dialog). Participants and advisors together reviewed the dialog (scaffolded by a checklist that encouraged them to identify what were termed "reasons," "criticism," and "defense"), examining the quality of what each participant had offered within each category, and considering what the participant might have done

better and why. Pre-post differences following this experience were encouraging, especially as they mirrored the cross-sectional differences between teens and adults observed by Felton and Kuhn (2001), suggesting that the induced development was of the same character as naturally occurring development (Kuhn, 1995). Specifically, students decreased the proportion of utterances devoted to exposition of their own views and increased the proportion devoted to arguments against the other's position (counterargument). These gains transferred to students' dialogs on a new topic that had not been discussed previously. Hence, students had not simply learned more about the topic they were discussing. Rather, there was reason to think that they had increased their skill in argumentative discourse itself. Moreover, students who participated in the reflective activity with peer advisors showed greater gains than those in a comparison group who only engaged in the dialogs (Felton, 2004). And finally, participation in dialogic argumentation led to improvement in students' individual arguments as well (Felton, 2004; Kuhn et al., 1997), a finding also reported by Reznitskaya et al. (2001) in a study of group discourse among younger children.

One limitation of this method is that it engages young people in the relevant activity without offering them a reason to be engaged in it. Kuhn and Udell (2003) and Udell (2004) thus devised a more structured intervention in which students were organized into pro and con teams (based on their initial opinions) and engaged in various activities over a 10-week period toward a goal of a "showdown" debate with the opposing team. After several sessions devoted to developing and evaluating their own arguments, the teams exchanged arguments and then generated counterarguments to the opposing team's arguments, related evidence to both their own and the opposing team's arguments, and, finally, generated rebuttals to the opposing team's counterarguments. Progress occurred in the same directions as observed in the preceding studies, particularly a sizeable increase in counterargument. A comparison group who participated only in the initial phase of developing their own arguments showed some, but more limited, progress. Udell (2004) extended this design to a topic of personal relevance (teen pregnancy) as well as a more impersonal one (capital punishment) and found that gains following the pregnancy-topic intervention transferred to the capital punishment topic, but transfer did not occur in the reverse direction.

At the beginning of this intervention, students clearly wanted to win. By the end, they still wanted to win, but by now they cared deeply about their topic and had developed a richer understanding surrounding it, even though none of the participants had much initial knowledge. But had students learned anything about argument itself? Had they come to see a point to arguing, beyond prevailing, being the winner? Had they progressed from winning to knowing as a conceptual justification for their activity? Had they constructed an understanding of argument itself? The only possible answer is incompletely, at best. But to address the question more fully, we turn to our final topic—young people's developing understanding of knowledge and knowing.

UNDERSTANDING AND VALUING KNOWING

In this section, we turn to the question of what children come to understand about their own and others' thinking and knowing as they enter and progress through the second decade of life. Here we encounter another striking disconnect, for young children's understanding and awareness of their mental functions, particularly memory, has been the topic of pioneering work by Flavell and others (see Pressley & Hilden, Chapter 12, this *Handbook*, this volume); more recently, the study of young children's "theory of mind," as it has come to be called, has assumed a prominent place in the field of cognitive development (see Harris, Chapter 19, this *Handbook*, this volume). Another entirely distinct body of work on epistemological understanding originated with the pioneering study of college students by Perry (1970) and, until recently, has been confined largely to the period of late adolescence and young adulthood (Hofer & Pintrich, 1997, 2002). Largely ignored has been the decade between middle childhood and late adolescence, the study of which has the potential to connect these two disparate literatures.

Epistemological Understanding and Scientific Thinking

We begin our summary of developing understanding of knowing and knowledge with preschoolers' attainment of false belief understanding because we claim this early development is fundamental to the developments that follow (Table 22.3). Three-year-olds regard beliefs

Table 22.3 Levels of Epistemological Understanding

Level	Assertions	Knowledge	Critical Thinking
Realist	Assertions are <i>copies</i> of an external reality.	Knowledge comes from an external source and is certain.	Critical thinking is unnecessary.
Absolutist	Assertions are <i>facts</i> that are correct or incorrect in their representation of reality.	Knowledge comes from an external source and is certain but not directly accessible, producing false beliefs.	Critical thinking is a vehicle for comparing assertions to reality and determining their truth or falsehood.
Multiplist	Assertions are <i>opinions</i> freely chosen by and accountable only to their owners.	Knowledge is generated by human minds and therefore uncertain.	Critical thinking is irrelevant.
Evaluativist	Assertions are <i>judgments</i> that can be evaluated and compared according to criteria of argument and evidence.	Knowledge is generated by human minds and is uncertain but susceptible to evaluation.	Critical thinking is valued as a vehicle that promotes sound assertions and enhances understanding.

as faithful copies of reality; they are received directly from the external world, rather than constructed by the knower. Hence, there are no inaccurate renderings of events, nor any possibility of conflicting beliefs, since everyone perceives the same external reality. Thus, children of this age make the classic false-belief error of unwillingness to attribute to another person a belief they themselves know to be false (Perner, 1991).

Not often noted about the development of false-belief understanding is its foundational status in the development of scientific thinking, which we have examined as the coordination of theory and evidence. Three criteria must be met if it is to be claimed that one is engaged in the coordination of theory and evidence. First, the theoretical claim must be recognized as falsifiable. Second, evidence must be recognized as the means of falsification, and third, theoretical claim and evidence must be recognized as distinct epistemological categories—evidence must be distinguishable from the theory itself and bear on its correctness.

The 3-year-old who fails to recognize the possibility of a false belief meets none of these criteria. A single, true state of affairs is directly apprehended. Hence, theory and evidence do not exist as distinct epistemological categories. Thus, when asked for justification for a knowledge claim (that an event occurred), preschoolers are likely to respond with a theory as to why occurrence of the event is plausible rather than with evidence that it did in fact occur (Kuhn & Pearsall, 2000). (Thus, as noted earlier, preschool children respond with the explanation “because he has fast sneakers” rather than the evidence “because he’s holding the trophy” as how they know that the boy pictured won the race.) Their error parallels the one made by older individuals justifying

more complex claims, typically causal relations between two variables, who confuse a theoretical explanation that a claim is plausible with evidence that it is true (Kuhn, 1991; Kuhn et al., 1995). Critics of the claim that children especially and even adults confuse theory and evidence have often failed to recognize the claim as one about epistemological understanding, that is, about the failure to recognize theory and evidence as distinct epistemological categories.⁶

⁶Thus, Ruffman, Perner, Olson, and Doherty (1993), for example, show that children can coordinate theory and evidence in the sense of drawing appropriate inferences from evidence (e.g., dolls who choose red food over green food) to theory (the dolls prefer red food to green) or from theory to evidence (in the form of a prediction of the dolls’ food choice). The correspondences between theories and patterns of evidence that a child is able to identify increase in complexity with development. The one thing identification of correspondences between theories and patterns of evidence does not entail, however, is a firm differentiation between the two. Theory and evidence can “fit together,” in the sense of being consistent with and implying one another, in the absence of a recognition of their differing epistemological status. Similarly, Sodian, Zaitchik, and Carey (1991) asked children to choose the more informative of two tests to find out if a mouse was large or small by placing food in a box overnight. The child was asked to choose between a box with a large opening (able to accommodate either size mouse) or one with a small opening (which only the small mouse could pass through). The task thus required the child to make a strategic choice of the more informative of two potential forms of evidence. Confusion between the theory (big mouse or small mouse) and the evidence (big or small opening) is not at issue.

Coordinating Objective and Subjective Elements of Knowing

Later in the preschool years, the human knower, and knowledge as mental representations produced by knowers, finally come to life. Once it is recognized that assertions are produced by human minds and need not necessarily correspond to reality, assertions become susceptible to evaluation vis-à-vis the reality from which they are now distinguished. Here the potential for scientific thinking emerges.

The products of knowing, however, for a time still remain more firmly attached to the known object than to the knower. Hence, while inadequate or incorrect information can produce false beliefs, these errors are easily correctable by reference to an external reality—the known object. To be wrong is simply to be misinformed, mistaken, in a way that is readily correctable once the appropriate information is revealed. At this *absolutist* level of epistemological understanding, knowledge is thus regarded as an accumulating set of certain facts (Table 22.3).

Researchers studying the development of epistemological understanding have characterized childhood as a period in which the absolutist level of thought prevails. Although details vary across different researchers, there is general agreement that further development proceeds toward transition to a broad level of multiplism or relativism, as early as the beginning and by at least the end of adolescence, followed by, in at least some individuals, an evaluativist level (Hofer & Pintrich, 1997, 2002; see Table 22.3 for summary).

This further progress in epistemological understanding can be characterized as an extended task of coordinating the subjective and the objective elements of knowing (Kuhn, Cheney, & Weinstock, 2000). At the realist and absolutist levels, the objective dominates. Typically, with adolescence comes the likelihood of a radical change in epistemological understanding. The discovery that reasonable people—even experts—disagree is the likely source of recognizing the uncertain, subjective aspect of knowing. This recognition initially assumes such proportions, however, that it eclipses recognition of any objective standard that could serve as a basis for evaluating conflicting claims. Adolescents commonly fall into “a poisoned well of doubt” (Chandler & Lalonde, 2003), and they fall hard and deep. At this *multiplist* (sometimes called *relativist*) level, knowledge consists not of facts but of opinions, freely chosen

by their holders as personal possessions and accordingly not open to challenge.

Knowledge is now clearly seen as emanating from the knower, rather than the known, but at the significant cost of any discriminability among competing knowledge claims. This lack of discriminability may be confused with tolerance. Because everyone has a right to their opinion, all opinions are equally right. That ubiquitous slogan of adolescence—“whatever”—holds sway. Hoisting oneself out of the “whatever” well of multiplicity and indiscriminability is much harder than the quick and easy fall into its depths. By adulthood, many, though by no means all, adolescents will have reintegrated the objective dimension of knowing and achieved the understanding that while everyone has a right to their opinion, some opinions are in fact more right than others, to the extent they are better supported by argument and evidence. Justification for a belief becomes more than personal preference. “Whatever” is no longer the automatic response to any assertion—there are now legitimate discriminations to be made. Rather than facts or opinions, knowledge at this *evaluativist* level of epistemological understanding consists of judgments, which require support in a framework of alternatives, evidence, and argument.

Beginning with King and Kitchener (1994), a trend in this area has been to assess epistemological thinking with detailed coding schemes of extended interview material.⁷ The broad sequence from absolutist to multiplist to evaluativist can be captured fairly well, however, with just two simple questions. Kuhn et al. (2000) portrayed numerous scenarios in which two neutral characters, Robin and Chris, disagreed about something, for example which of two authors is the better one. For each scenario, respondents were asked first whether only one was right or whether both Robin and Chris could “have some rightness.” If they answered that both could have some rightness, they were then asked the second question of whether one person’s view could be better or more right than the other’s. The response that only one person could be right was classified absolutist. The re-

⁷We address only that literature on epistemological understanding that is developmental in nature, that is, that regards this understanding as undergoing some systematic developmental change. Another set of researchers not reviewed here has treated the construct primarily as an individual-difference variable of a cognitive-style nature and focused empirical study largely on adults.

sponse that both could be right but one view could be no more right than the other was classified multiplist, and the response that both could have some rightness but one could be more right was classified evaluativist.

Kuhn et al. (2000) found that progression to the multiplist and evaluativist levels occurred in a domain-specific, rather than uniform, manner. Progression to the multiplist level occurred most readily in domains of personal taste and aesthetic judgments, while individuals were more likely to remain absolutist in their thinking in the domains of values and factual claims. In progression to the evaluativist level, however, this order was reversed. Here, although the subjective element of knowing that underlies the transition to multiplism was most readily acknowledged in the domains of tastes and aesthetic judgments, it proved easier to reintegrate the objective element of knowing required for the transition to evaluativist thinking in the domain of factual judgments (e.g., explanations of how the brain works) and harder to do so in the domain of aesthetic judgments—exactly the reverse. (Value judgments proved difficult for both transitions.) Developmentally, progress (from absolutist to multiplist to evaluativist) appeared in comparisons of 5th graders to 8th graders and 8th graders to 12th graders; 12th-grade respondents had reached levels equal to those of community college adults. Performance differences across domains were largely replicated in a study (Wainryb, Shaw, Langley, Cottam, & Lewis, 2004) assessing a younger sample with respect to the earlier phases of the progression, lending further support to the conclusion that epistemological understanding develops in a domain-specific manner.

What Difference Does Epistemological Understanding Make?

In examining the development of epistemological understanding, we encounter a domain in which development is far from universal. The single most common pattern among adolescents and adults, Kuhn et al. (2000) found, was the solidly multiplist one. Absolutist thinking continued to be shown by some 12th graders in all domains but that of personal taste, and less than half of 12th graders or adults had achieved evaluativist thinking in any domain.

This same lack of universality appeared in dimensions of cognitive development examined in previous sections—the development of skills of argument, certainly, and even those of inquiry and decision-making. It is in

areas such as these, then, that the interests of developmentalists and those of educators converge, reflected in the fact that literature we have cited comes from educational as well as developmental psychology. Attention turns naturally to what conditions can be identified that might support the development in question, given its less than frequent occurrence. The interests of developmentalists have also converged to a degree with those of differential psychologists, who conceptualize developmental variation more in terms of individual differences in intellectual traits or styles that may predict performance (Stanovich & West, 1997, 1998, 1999).

Epistemological understanding is one variable that has been treated in this manner. Kokis, Macpherson, Toplak, West, and Stanovich (2002), for example, administered to 10-, 11-, and 13-year-olds a range of cognitive tasks similar to those administered to adults in previous work (Stanovich & West, 1997, 1998). They included inductive, deductive, and probabilistic reasoning, as well as an IQ measure and a composite measure of various “cognitive style” traits that included aspects of epistemological understanding. Replicating findings for adults, the style measure, it was found, accounted for additional variance in performance beyond IQ (which was a better predictor of performance than age). The conclusion these authors draw is that dispositional factors, not just competence factors, figure importantly in performance.

Several authors have focused more specifically on the relation between level of epistemological understanding and argument skill, reporting a relation between the two (Kardash & Scholes, 1996; Kuhn, 1991; Mason & Boscolo, 2004; Weinstock & Cronin, 2003; Weinstock et al., 2004). Kuhn (2005) makes a conceptual case for this relation: If facts can be ascertained with certainty and are readily available to anyone who seeks them, as the absolutist understands, or, alternatively, if any claim is as valid as any other, as the multiplist understands, there is little reason to expend the intellectual effort that argument entails. One must see the point of arguing to engage in it. This connection extends well beyond but certainly includes science, and in the field of science education a number of authors have made the case for the connection between productive science learning and a mature epistemological understanding of science as more than the empirical verification of facts (Carey & Smith, 1993; Metz, 2004; Smith, Maclin, Houghton, & Hennessey, 2000). For scientific inquiry to be valued as a worthwhile enterprise, it must be understood to occupy an epistemological ground other than the accumulation of

undisputed facts dictated by absolutism or the suspension of judgment dictated by multiplism.

In their recent empirical work, Mason and Boscolo (2004) assessed the level of epistemological understanding of 10th and 11th graders. Using the Kuhn et al. (2000) instrument, they found students on average to be at the multiplist level. Students were divided into three groups—those who scored lower than average (hence, showing at least some absolutist thinking), those at the average level, and those above average (hence, showing at least some evaluativist thinking). On a separate occasion, argument skill was assessed by asking students to write a concluding paragraph to an essay that presented two opposing views regarding genetically modified food. The authors also assessed students' level of interest, degree of knowledge, and beliefs regarding the topic. Only epistemological level was predictive of the quality of the concluding paragraph the student produced. Only students in the highest epistemological group were likely to undertake any sort of reconciliation of the two positions, even the minimal one of suggesting that more information was needed. Students at the lower epistemological levels were likely to refer to only one position or to simply consecutively list the two contrasting positions in their summary.

Kuhn (2005; Kuhn & Park, in press) has gone on to predict that advancement in epistemological understanding supports the development of intellectual values, specifically the commitment to intellectual discussion and debate as the soundest basis for choosing between competing claims and resolving conflicts. Across cultural and subcultural groups of children and parents, level of epistemological understanding was (inversely) related to endorsement of items like this one:

Many social issues, like the death penalty, gun control, or medical care, are pretty much matters of personal opinion, and there is no basis for saying that one person's opinion is any better than another's. So there's not much point in people having discussions about these kinds of issues.

In sum, after years of relative orphan status, the study of epistemological understanding has undergone a surge of attention and interest, prompted by Hofer and Pintrich's (1997) review, and the indications are that this attention is well deserved. The child's or adolescent's understanding of the intellectual activities of thinking and knowing is not an isolated epiphenomenon of interest only in a philosophical vein. To the contrary, it may provide a foundation that is critical in influencing what both adolescents and adults are disposed to do intellectually, as opposed to what they

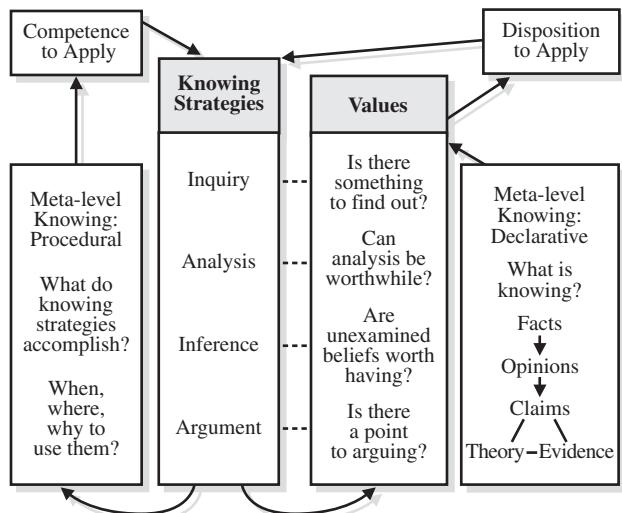

Figure 22.3 Components of knowing. Source: From "How Do People Know?" by D. Kuhn, 2001, *Psychological Science*, 12, pp. 1-8. Reprinted with permission.

are competent to do—a distinction that has itself begun to receive broader attention (Kuhn, 2001a; Perkins, Jay, & Tishman, 1993; Stanovich & West, 1999, 2000). A diagram proposing a summary of these relations appears in Figure 22.3 (from Kuhn, 2001a). The implication is that, by the second decade of life, disposition becomes a construct that cannot be ignored.

CONCLUSIONS: LEARNING TO MANAGE ONE'S MIND

During the second decade of life, individuals continue to learn and to develop, in universal but also increasingly individual directions. The conceptual distinction between development and learning remains problematic, although the microgenetic method has made a contribution in highlighting their commonalities. In this chapter, we have taken the position that although the boundaries have become blurred, there remain real and significant distinctions between the two kinds of change. Development is generally progressive, irreversible, and generalizable, while learning need have none of these characteristics. The distinction has remained salient, for example, within our own research on inquiry, in which students will tell us that they have been finding out about what affects the speed of boats or risk of earthquakes, which indeed they have, while at the same time our microgenetic observations document that they have been developing skills that have to do with how one finds out about anything.

Where development and learning come together is in similarities in process, and hence the microgenetic method is useful in studying both. This is so largely because earlier conceptions of learning as formation of S-R bonds or strengthening of habits have been replaced by contemporary models in which learning is more likely to be defined as "change in understanding" (Schoenfeld, 1999). We thus need models more like those of development to characterize the process—that is, models that characterize change in terms of reorganization of patterns of thought, rather than strengthening of associations or habits.

What do we know about the nature of the change process? The phenomena reviewed in this chapter are consistent with a process in which multiple forms (of varying strengths and hence probabilities of occurrence) coexist over extended periods of time. Over time this distribution of probabilities shifts, as less effective forms are exercised less often and more effective ones more frequently (Kuhn, 1995, 2001b; Kuhn et al., 1995; Siegler, 2000; Chapter 11, this *Handbook*, this volume). Although new forms do emerge, first emergence rarely indicates the beginning of consistent usage, and the majority of change is of this shifting-frequency variety.

Two other features of this change process are of particular significance during the years of transition from childhood to adulthood. One is the fact that exercise (of existing forms) may be a sufficient condition for change (Kuhn, 1995). An implication, which we return to, is that adolescents are likely to get even better at what they are already good at, thus increasing the range and diversity of developmental pathways. The other is the importance of abandoning old, less effective forms, a challenge that in many cases exceeds that of adopting new, more effective ones. Interestingly, in a psychotherapeutic context, when a client finally abandons a self-limiting behavior, we do not hesitate to regard this event as an instance of positive change. In the case of cognitive development, however, we tend to focus only on attainment of new forms as markers of progressive change.

Finally, of greatest relevance in the present context is any age-related change that may occur in the change process itself. Evidence we have examined in this chapter suggests that as children enter their second decade, an increasingly strong executive may begin to develop. This executive assumes a role of monitoring and managing the deployment of cognitive resources as a function of task demands. As a result, cognitive functioning, and learning itself, become more effective (Kuhn & Pease, in press).

Emergence and strengthening of this executive is arguably the single most important and consequential intellectual development to occur in the second decade of life. Although he largely did not address its significance beyond the narrow confines of logic, in this respect we must grant that Piaget was on the right track in pointing to "thinking about one's own thought" as the major cognitive advance of the adolescent years. Today we are more likely to refer to metacognition or executive function as nascent functions in the early years that have the potential to come to full flower in the second decade, although they by no means always do so.

Broadly speaking, we know, young adolescents begin to acquire much more control over their activities and lives than they experienced as children. Hence, they have more discretion over how and where their cognitive resources will be deployed. Modern culture has introduced them to the art of dividing attention among multiple kinds of input. The executive thus fills a much needed role in determining how that attention will be allocated.

The developing executive also affords increasing ability to inhibit initial responses (generated by the experiential component in the dual-process model) and to process further, when one judges doing so to be worth the effort. And finally, and critically, it affords a level of metacognitive awareness that makes it possible to temporarily "bracket" the perspective dictated by one's own beliefs or understanding, in order to extract decontextualized representations, disembedded from a particular context, and to determine their implications. Without this skill, deductive, inductive, and argumentative reasoning are all severely impaired.

A stronger executive implies that development is increasingly governed from the "top down." This is not to say that most adults, as well as children and teens, don't apply "bottom-up" habitual patterns of thinking and behaving much of the time. But during the second decade of life young people, we have claimed, increasingly develop the potential to manage and deploy their cognitive resources in consciously controlled and purposefully chosen ways. A major implication is that disposition—to do or not to do x or y—becomes increasingly important (Kuhn, 2001a; Perkins, Jay, & Tishman, 1993; Stanovich & West, 1997, 1998, 2000). And disposition is governed by more than the competence to execute procedures. For these reasons, we have emphasized the larger picture that includes meta-level *understanding* of strategies—what they do or do not buy one—in relation to task goals, as well as values as a critical link mediating

understanding and disposition. This larger structure presents a considerably more complex picture of what it is that needs to develop. Unsurprisingly, no simple change mechanism exists that can assume the entire explanatory burden.

Early Adolescence as a Second Critical Period

Stronger executive control of intellectual processes, we have suggested, differentiates the second decade of life from the first. Another difference is the extent and range of individual variability. In the second decade, individual variation becomes much more pronounced. All children within the normal intellectual range can be counted on to have exhibited certain universal developmental progressions in their thinking by age ten. They will also have learned a great deal about the world, much of it universally shared; many, however, will also have acquired expertise within domains of individual interest, although even here there are certain asymptotes—10-year-olds very rarely master calculus or advanced physics.

After the first decade of life, however, development along universal pathways, as we have seen, does not continue to the most advanced levels for everyone. Many adults cease to show any development beyond the level achieved by the typical early adolescent. Variation in positions along developmental pathways becomes pronounced. In addition, within specific content domains the range and depth of individually acquired expertise becomes much greater than it was in childhood. The processes involved in learning in “core domains,” which all people encounter, and “noncore domains,” which only some individuals choose to explore, may nonetheless be the same (Gelman, 2002).

How should we explain this heightened variability, and what are its implications? One level of explanation lies in the brain. Early adolescence, we noted, is a second developmental period during which a sequence of overproduction and pruning of neuronal connections occurs. This pruning of unused connections is guided by the activities in which the young teen engages. Both brain and behavior, then, together begin to become more specialized. To this evolution we add teens’ increasing freedom and personal control—on the one hand in managing and deploying their intellectual resources to accomplish a task, and, on the other, more broadly, in choosing the activities in which they will invest themselves and in managing their lives.

As we have noted, simply through concentrated engagement in the activities they choose, adolescents get even better at what they are already good at, thus increasing the range and diversity of individual pathways. By early adolescence, individuals are indeed producers of their own development (Lerner, 2002). One consequence of these choices is an increasingly firm sense of personal identity—“this is who I am”—and, particularly, “this is what I’m good at” (and its even more potent complement, “this is what I’m no good at”). Evidence suggests that what happens at this age may be as influential as what happens in the first years of life (Feinstein & Bynner, 2004). Potential attainment in both core and noncore domains—in both universal and individual directions—can be encouraged and supported or left to wither, with enormously disparate results.

As we suggested in the section on epistemological understanding, during this second critical period it is disposition, as much or more than competence, that ought to be the focus of those concerned with supporting adolescents’ intellectual development. To a greater extent than children, teens attribute meaning and value (both positive and negative) to what they do and draw on this meaning to define a self. Positively valued activities lead to behavioral investment which leads to greater expertise and hence greater valuing, in a circular process that has taken hold by early adolescence. The selfless curiosity and exploration characteristic of the early childhood critical period have likely gone underground and are difficult to detect. An implication is that the valuing of intellectual engagement can certainly be supported by those who work with young adolescents, but better results can be expected to the extent the way has been laid by activities involving genuine intellectual engagement in the years leading up to the second decade (Kuhn, 2005).

Understanding Development by Studying Both Origins and Endpoints

What are the implications for those seeking to investigate intellectual development during the second decade of life? One that follows fairly directly from what has just been said is the need to conduct more studies of adolescent cognition in the situated contexts of the activities in which teens choose to invest their intellectual resources. We are certainly taking a risk in drawing conclusions from investigations confined to artificial problems, constructed for research purposes, that bear no clear relation to the kinds of thinking that adolescents

do in their daily lives. At the same time, the ability to decontextualize—to extract a generalized representation distinct from its specific context—remains a critical developmental achievement that needs to be studied further, especially across different reasoning contexts.

The emphasis we have placed on disposition, in addition to competence, suggests the importance of continued study of mechanism. We are dealing with a decade of life in which not everything that has the potential to develop does. Yet, continued development is more likely in this second decade than in the decades thereafter. The “good enough” intellectual environment that suffices to support the basic transitions characteristic of childhood cognitive development is apparently not good enough to support universal attainment of the cognitive capabilities that have the potential to develop during the second decade of life. The implications are strong ones in terms of both social policy and research. With respect to policy, investment of resources may have dividends at this life stage greater than at any other. With respect to research, the need to understand mechanism is, at this level, arguably even more urgent. Developmental research has a fundamental role to play in identifying developmental pathways. But its role is equally critical in identifying the factors that make this development more likely to occur.

We noted early in this chapter that the current focus in cognitive development research is on earliest origins in the first years of life. In time, the pendulum may well swing back toward greater interest in older children and adolescents and what they have to tell us about development. Diamond and Kirkham (2005), noting that early modes of responding are not outgrown or discarded but rather need to be overcome and managed, assert that we need to study the extremes of early childhood to fully understand adults. Arguably, the reverse is fully as true. We need to study its entire path and endpoint—to know where it’s headed—in order to fully understand the significance of an early form. Indeed, that is exactly what developmental analysis is all about. We hope here to have illustrated to readers that it can be worthwhile to look beyond the earliest years in seeking to understand the what and how of cognitive development.

Subject Index

- Absolutist level of epistemological understanding, 983
Abstract/concrete development, 617–619
Abstract constructions. *See* Linguistic constructions
Accessible models, information processing and, 457–458
Achromatic discriminations, 121
Action representations in drawings, 869–870
Active intermodal matching, 220
Actor-environment fit, 189–190
Acuity, visual, 114–116
Adapted mind, 614–617
Adaptive combination perspective on spatial processing development, 749–755
categorical coding, 752
distance coding, 750–752
effect of experience, 753–754
hierarchical combination, 752–753
Adaptors (gesture), 337
ADHD. *See* Attention deficit hyperactivity (ADHD)
Ad hoc models, information processing, 436–437
Adjectives, acquisition of, 315–320
basic level categories as an entry point, 317
cross-linguistic work, 318–320
developmental work, 316–318
linking adjectives to object properties, 316–317
moving beyond the basic level, 317–318
Adolescent development, 953–989
argument, 978–982
brain and processing growth, 957–960
complexity and value of developmental analysis, 954–957
critical period, early adolescence as second, 988
decision making, 975–978
deductive inference, 960–964
inductive and causal inference, 964–968
knowing, understanding/valuing, 982–986
learning and knowledge acquisition, 968–971
mind, learning to manage, 986–989
scientific thinking and inquiry, 971
what develops, 955–957
Adult attachment interview (AAI), 837–838
Adult plasticity, 16–17
Adult work, primacy of, 662
Affect displays, gesture as, 337
Affordances, 189–196, 200–201
actor-environment fit, 189–190
creating, 200–201
parents' role in promoting action, 200
perceiving, 189–196
specificity of learning, 193–195
tools expanding possibilities for action, 200–201
Alerting/vigilance/arousal, 43
Ambiguity argument, 111, 112–113
Amygdala, 38
Analogy, schematization and; linguistic constructions, 287
Anatomical/cultural change, chronology of, 641
Animacy:
conceptual development of, 703–704
infant cognition, animate-inanimate distinction, 244–245
Animals. *See also* Primates, nonhuman:
culture and, 637, 642–647
human linguistic communication versus that of other species, 255–256
A-not-B task:
information processing example, comparing models, 448–454
dynamic systems model, 451–452, 453
neural network model, 449–451
spatial cognition, 742–743
Area, concept of, 596
Argument(s), 978–982
argumentive discourse, 980–981
evaluating, 979–980
individual, 979–980
producing, 979
supporting development of skills in, 981–982
Arithmetic:
development of (*see* Mathematical understanding)
New Guinea, cultural evolution of in, 651–652
Arts, 859–895, 915–920
domain similarities/differences, 936–940
drawing, 859–881, 895
evolutionary base, 860
historical and theoretical approaches, 860–863
overview/introduction, 859
picture production: major milestones in development, 869–879
picture recognition/comprehension/preference: major milestones in development, 863–869
skill improvement and age, 880–881
universality versus cultural specificity of drawing schemas, 879–880
extraordinary achievement in, 915–920
conceptual versus perceptual orientation, 918
identity as an artist, 919–920
markers of extraordinariness, 916–920
versus ordinary development, 916
preocity, 917–918
realistic versus stylistic goals, 918–919
talent, 917
music, 839, 881–895
absolute pitch, 893–894
evolutionary base, 882–883
figural understanding, 894–895
historical and theoretical approaches, 883–884
perception, infant, 884–888
perception/comprehension, post-infancy, 888–890
production through song, infancy, 891–893

- Arts (*Continued*)
- production through song, post-infancy, 891–893
 - skill improvement and age, 893–895
 - overview/introduction, 859, 895
- Association and rules, role of in cognitive development, 625–626
- Associationism, 110
- Associative learning:
- conceptual development, 710–711
 - limits of similarity and associations, 712–715
 - neural bases of cognitive development, 30–31
- Attachment history, narrative/event memory and, 409–410
- Attachment Q-sort (AQS), 838
- Attention:
- alerting, vigilance, or arousal, 43
 - nonexecutive aspects of, 43–44
 - orienting, 43–44
- Attentional control, 41–43
- Attention deficit hyperactivity (ADHD):
- basal ganglia circuitry, 30
 - strategies instruction and Meichenbaum's analyses, 528
- Auditory function, developmental plasticity, and neural bases of, 14–15
- Auditory world of infant, 58–95
- building from input during the first year, 83–92
 - beginnings of grammar, 91–92
 - beginnings of word recognition, 88–89
 - learning phonology and phonotactics, 84
 - listening for meaning, 89–91
 - word segmentation, 84–88
- future directions, 92–95
- constraints on learning, 93
 - domain specificity and species specificity, 93–94
 - relationship between auditory processing and speech perception, 92–93
- implicit discovery of cues in the input, 80–81
- higher-level units, 81
 - stress and phonotactic cues, 80–81
- infant audition, 59–72
- development of auditory apparatus, 59–60
 - development of auditory scene analysis, 70–71
 - frequency coding, 60–63
 - implications for development of speech perception, 71–72
 - intensity coding, 63–67
 - measuring auditory development, 60–61
 - perception of loudness, 65–67
 - perception of pitch, 62–63
 - perception of timbre, 65
 - spatial resolution, 69–70
 - temporal coding, 67–69
- infant speech perception and word learning, 72–80
- perception of prosodic attributes of the speech signal, 77–78
 - perception of speech signal, 78–80
 - perception of visible information in speech, 76–77
 - phonetic perception, first studies, 72–75
 - preference for speech, 75–76
- learning mechanisms, 81–83
- overview/introduction, 58–59, 94–95
- units for computations, 83
- Autism:
- linguistic constructions, 291–292
 - social cognition, 842–844
 - theory of mind, 842–844
- Autonoetic awareness, 402
- Axons:
- development of, 10
 - disorders of, 11
- Balance scale:
- comparison of models, 438–444
 - reasoning and problem solving, 597–599
- Base-10 knowledge, 791–792
- Behavioral flexibility, 169–170
- Behaviorism, 4
- Beliefs:
- social cognition, 823–826
 - understanding second-order, 836–837
- Biological domain, culture, 663–670
- Biology. *See* Neural bases of cognitive development
- Blindness, gesturing and, 353–354
- Boundary assignment, visual perception, 134, 137
- Brain development. *See* Neural bases of cognitive development
- Calcium-regulated transcriptional activator (CREST), 10–11
- Capability argument, 111, 113
- Case and agreement, linguistic constructions, 267–268
- Case Grammar, 256
- Categorization:
- conceptual development, 696–701
 - individuals versus categories, 700–701
 - infant, 234–240, 569–570
 - categorization paradigms, 235
 - connectionist models, 237–239
 - feature correlations and categorization, 235–237
 - perceptual versus conceptual categories, 239–240
 - reasoning and problem solving, 569–570
 - levels of, 562–563, 696–698
 - natural kinds versus arbitrary groupings, 698–700
 - prototypes and family resemblance, 562
 - reasoning and problem solving, and changed theories of, 561–563
 - spatial cognition, and development of categorical coding, 752
 - theory-based, 562
- Causation:
- causal learning, 717–718
 - conceptual development, 705–706
 - inductive and causal inference, 964–968
 - infants' understanding of events:
 - complex causal chains, 231–233
 - complex event sequences, 233–234
 - simple causal events, 228–231
 - recognition of cause in infancy, 567
 - universals in expression of causativity, 324–325
- CCC (cognitive complexity and control) theory, 563–564
- Cell adhesion molecules (CAMs), 10
- Cell migration, 9–10
- Change, dimensions of cognitive, 479
- breadth of change, 479, 494–496
 - basic phenomena, 494–495
 - influences of child and environment, 495
 - theoretical questions and implications, 495–496
- path of change, 479, 487–490
- basic phenomena, 487–489
 - influences of child and environment, 489–490
 - theoretical questions and implications, 490
- rate of change, 479, 490–494
- basic phenomena, 491–492
 - influences of child and environment, 492–493
 - theoretical questions and implications, 493–494
- source of change, 479, 496–499
- basic phenomena, 496–498
 - influences of child and environment, 498
 - theoretical questions and implications, 498–499
- variability of change, 479, 480–487
- basic empirical phenomena, 480–484
 - between-child, 485–486
 - influences of child and environment, 484–486
 - significance for analyzing change, 482–483
 - significance for identifying change mechanisms, 483–484
 - significance for predicting change, 481–482
 - significance of within-child, 481–484
 - theoretical implications and questions, 486–487
- Child-directed-speech (CDS), 260

- Chomskian generative grammar, 257
 Chromatic/achromatic attributes, 121. *See also* Color vision
 Chromatic deficiency hypothesis, 123
 Chromatic discriminations, 121
 Cognition, infant. *See* Infant cognition
 Cognitive domains, 627–629
 Cognitive science and cognitive development, 609–629. *See also* Neural bases of cognitive development
 adapted mind, 614–617
 developmental universals, 626–627
 domains, 627–629
 earliest periods of cognitive development, 610–617
 generality/specificity, 626–629
 initial state, 611–614
 overview/introduction, 609–610, 629
 patterns of change, 617–622
 development from concrete to abstract, 617–619
 difference between learning and development, 621–622
 nature of conceptual change, 619–621
 representational formats underlying developmental change, 622–624
 role of association and rules, 625–626
 role of implicit and explicit thought in cognitive development, 624–625
 Cognitive strategies. *See* Strategies, cognitive
 Collaborative strategic reading, 536
 Color vision, 120–124
 assessing, 122–123
 brightness, 120–121
 chromatic/achromatic attributes, 121
 hue, 120–122
 origins of hue discrimination, 121–122
 psychological attributes, 120–121
 saturation, 120–121
 Comforting/helping, in infancy, 818–820
 Complexity, reasoning and, 563–567
 relational complexity (RC) metric, 565–567
 summary of research, 567
 Composition, drawing, 868, 879
 Comprehension strategies instruction, 532–537
 collaborative strategic reading, 536
 1980s-era studies, 534–535
 reciprocal teaching, 533–534
 transactional strategies instruction, 535–536
 Computational models/approaches. *See* Information processing
 Conceptual development, 687–724
 animacy, 703–704
 causation, 705–706
 competing metaphors of dictionary/encyclopedia, 702
 conceptual diversity, 693–702
 categories versus individuals, 700–701
 concepts encoded in language versus those that are not, 694–696
 implications for children's concepts, 701–702
 levels of categorization, 696–698
 natural kinds versus arbitrary groupings, 698–700
 current approaches to children's concepts, 690–693
 empiricist approaches, 691–692
 naïve theory approaches, 692–693
 nativist approaches, 690–691
 essence, 708
 experience and individual variation, 718–723
 function, 706–708
 historical background, 689–690
 individual variation, 719–721
 cognitive style, 720–721
 expertise, 719–720
 mechanisms of conceptual acquisition and change, 709–718
 associative mechanisms, 710–711
 causal learning, 717–718
 conceptual placeholders, 715–717
 conceptual variation, 714–715
 constraints, 714
 context-sensitivity, 712
 interleaving, 723–724
 labels, 712–714
 limits of similarity and associations, 712–715
 modes of construal, 716–717
 similarity, 711–712
 words as pointers, 715–716
 nonobvious properties, 706–708
 ontology, 703–705
 overview/introduction, 687, 693, 723–724
 relevance/importance of, 688–689
 theories, concepts embedded in, 702–709
 Concrete/abstract development, 617–619
 Conditional reasoning, mental models in, 592–594
 Conditioning or associative learning, 30–31
 CONLERN, 147, 150, 241
 Conservation and quantification, 577–585
 age of attainment of conservation, 580–582
 compensation and, 578–580
 number, 582–585
 perceptual factors and, 578–580
 Consolidation and storage, event memory, 387–388, 399–400
 CONSPEC, 147, 150, 241
 Constructions, linguistic. *See* Linguistic constructions
 Constructive Learning Architecture (CLA), 230
 Constructivism/constructivist perspective:
 information-processing account of infant face processing, 242–244
 information-processing approach, infant cognition, 216–217
 information processing models, 456–457
 mathematical understanding, 778–779
 theory of perceptual development, 110–112
 visual perception, 110–112
 Content-independent cognition, 567–568
 Contour junctions, detection/classification of, 136–137
 Contrast sensitivity, 116–119
 Crawling, 176–177
 Creativity, 908
 Culture, 636–678
 animals and, 637, 642–647
 arithmetic across cultures, 794–795
 chronology of anatomical and cultural change, 641
 cognition and, synthetic framework for, 639–640
 cultural history, 637–638, 647–659
 cross-sectional comparisons, 648–650
 IQ scores, change in, 658–659
 long-distance transport of raw materials, 647
 longitudinal studies, 650–652
 production of second-order tools, 647
 production/use of simple machines, 647
 semeiosis, 647
 social differentiation, and education, 652–658
 spatial structural organization of living sites, 647
 defined, 637–639
 development, 637–638, 639
 drawing schemas, universality versus cultural specificity of, 879–880
 hominization and, 640–642
 ideal and material in, 638–639
 linguistic constructions, and intention-reading and cultural, 286–287
 living primates, 637, 642–647
 narrative differences, event memory, 410–411
 ontogeny, 659–674
 importance of parental beliefs, 662
 independence of children's motivation, 662
 intertwining of biology and cultural practices in conceptual development, 663–670
 number, 664–666
 primacy of adult work, 662
 proximal locus of development: activity settings and cultural practices, 660–663

- Culture (*Continued*)
 overview/introduction, 636–637
 patterns, shared/distributed, 638
 phylogenetic development and, 640
 word learning, cross-linguistic evidence, 303, 318–320
- Darwinian competition, 799–802
 selection, 801–802
 variability and competition, 799–801
- Data analysis issues, 475–477
 graphical techniques, 475–476
 inferential statistical techniques, 476–477
- Deafness, and gesture, 346–349
- Decision making in adolescence, 975–978
 contingency, 976–977
 decision-making judgments, 976–977
 dual-process theory, 977–978
 gambler compensation fallacy, 977
 outcome bias, 977
 preference judgments, 976
 statistically-based (versus anecdotally-based) decisions, 977
- Deduction:
 critical role of meaning, 961
 thinking and, 963–964
 indeterminate syllogisms, 961–962
 induction and, 592
 inference, 960–964
 relational problems of, 591–592
 what develops, 961–962
 when knowledge and reasoning conflict, 962–963
- Delayed non-match-to-sample (DNMS) task, 24
- Dendrites:
 development of, 10–11
 disorders of, 11
- Depth in drawings:
 perceiving, 866
 representing, 877–878
- Depth perception:
 familiar size, 133
 interposition cues, 132–133
 pictorial, 131–134
 stereoscopic, 129–131
- Determinacy, logical and empirical, 594–595
- Developmental universals, 626–627
- Development versus plasticity and, 17–19
- Development in second decade. *See* Adolescent development
- Dialogue, function and preverbal, 816–817
- Dictionary versus encyclopedia metaphor, 702
- Dimensional Change Sort (DCCS) task, 563–565
- Directional selectivity, motion perception, 124–125
- Distance:
 coding (spatial cognition), 750–752
 reasoning and problem solving; time, speed, and, 595–596
- Doubt/uncertainty, understanding, 834–836
- Down syndrome:
 autism versus, 843
 false-belief task, 843
 linguistic constructions, 291
- Drawing, 859–881, 895
 evolutionary base, 860
 historical and theoretical approaches, 860–863
 overview/introduction, 859
 picture production: major milestones in development, 869–879
 action representations, 869–870
 aesthetic properties, 878–879
 composition, 879
 depth representation, 877–878
 expression, 878–879
 graphic representations, 870–874
 human form representation, 870–874
- realism, 874–878
 style, 879
 trajectory from intellectual to visual realism, 875–876
- picture recognition/comprehension/preference: major milestones in development, 863–869
 acquisition of an intentional theory of pictures, 865–866
 aesthetic perception, 866–868
 aesthetic responses, 868–869
 components (four) of understanding representational nature of pictures, 863–866
 composition, 868
 depth perception, 866
 evaluating quality, 869
 expression, 866–867
 realism, appeal of, 868
 recognizing difference between a picture and what it represents, 863–864
 recognizing representational status of pictures, 864–865
 recognizing similarity between a picture and what it represents, 863
 regularity, appeal of, 868–869
 style, 867–868

 pictorial depth perception, 131–134
 stereoscopic depth perception, 129–131
 maps and models, 759–760
 mature competence, 737–740
 mental rotation, 31–32, 755–756
 modularity, 746–749
 navigation, 35, 756–758
 neural bases of cognitive development, 31–35
 nonnormative contexts, 765–766
 overview/introduction, 734–735
 pattern processing, 32–33
 perspective taking, 755–756
 referent system, 740–741
 representing spatial relations between viewer and environment, 755–758
 spatial language, 760–761
 symbolic representations, 741, 758–761
 visual impairment, 766
 visuospatial recognition and recall memory, 34–35
 visuospatial working memory, 33–34
 Williams syndrome, 765–766
- Spatial structural organization of living sites, cultural history, 647
 Specific Language Impairment (SLI):
 information processing approaches, 434
 linguistic constructions, 292
 Speech perception, infant, 72–80. *See also* Auditory world of infant
 implications of infant audition for development of, 71–72
 perception of prosodic attributes of speech signal, 77–78
 perception of visible information in speech, 76–77
 phonetic perception, first studies, 72–75
 preference for speech, 75–76
 relationship between auditory processing and, 92–93
 Speed/time/distance, reasoning and, 595–596
 SRT (serial reaction time) task, 27–31
 Stability, perceiving motion and, 126
 Static form perception, 143–144
 Statistical techniques, inferential, 476–477
 Stereoscopic depth perception, 129–131
 Strange Situation, 838
 Strategies, cognitive, 511–547
 definition of strategy, 512–513
 elaboration, 517
 future directions, 545–547
 information-processing model of intentional, strategic memory, 519–526
 metacognition, 521–523
 strategy knowledge as procedural knowledge, 521
 working/short-term memory, 519–521
 world knowledge, 523–525
 information-processing theory (1960s), 515–518
 instructional applications, 531–543
 collaborative strategic reading, 536
 comprehension strategies instruction, 532–537
 mathematical problem solving, 538–540
 reciprocal teaching, 533–534
 scientific reasoning, argument skills, and strategies, 540–542
 transactional strategies instruction, 535–536
 word recognition, 531–532
 writing strategies instruction, 537–538
- instruction with exceptional children, 527–531
 Meichenbaum's analyses of attention deficit hyperactivity, 528
 strategies use by gifted students, 530
 students with learning disabilities, 529–530
 students with mental retardation, 528–529
 memory strategies, classical research on development of, 513–515
 organizational strategies, 516–517
 overview/introduction, 511–512, 543–545
 preschoolers, strategies-productive, 518–519
 remembering instructions, 519
 retrieving hidden objects, 518–519
 reasoning, 559–561
 implicit versus explicit process, 561
 mental models and analogy, 561
 verbal strategies, 560–561
 rehearsal strategies, 515–516
 strategy use as coordination of information-processing components, 526–527
 verbal list learning strategies, 515–518
 Stream of consciousness, 832–834
 Stress and phonotactic cues, infant audition, 80–81
 Structuralism, 110
 Style:
 artistic:
 drawing, 867–868, 879
 music, 890
 cognitive, 720–721
 Syllogisms, 961–962
 Symbolic processes in reasoning, 561
 Symbolic spatial representations, 741, 758–761
 Synaptogenesis, 11–12
 background, 11
 development, 11
 disorders, 12
 synaptic plasticity, 12
 synaptic pruning, 11–12
 Syntactic roles, marking, 265–269
- Talent, defined, 911
 Teachers and gesture, 359–361
 Teasing/hurting, infant social cognition, 821–822
 Teddy bear illustration, 969
 Temperament, event memory, narrative, and, 408–409
 Temporal coding, infant audition, 67–69
 Temporal order, memory for, 25–26
 Texture, 128, 132
 Theory of mind:
 autism, 842–844
 culture, 644–645, 666–667
 emerging contours in children's, 850–851
 individual differences in pretend play, 844–845
 language and, 845–847
 naïve psychology and, 666–667
 nonhuman primates, 644–645, 839–841
 universal core, 841–842
- Thinking:
 gesture's role in, 361–365
 problem solving (*see* Reasoning)
 social cognition, and thoughts, memories, and the stream of consciousness, 832–834
- Timbre, perception of, 65
 Time/speed/distance, reasoning and, 595–596
 Tools:
 culture and, 644, 647
 motor development and, 200–201
 Transactional strategies instruction, 535–536
 Transformational Generative Grammar, 256
 Transitive inference, 585–589
 Transitivity of choice and learning of order, 589–591
 Traumatic events, memory for, 414–416

- Tritan test, 123
 Trust, social cognition and, 848–850
- Uncertainty/doubt, understanding, 834–836
 Uniform loss hypothesis, color vision, 123
 Unity, object, 137–142, 226–227
 Universals, 324–325, 626–627
 Up-down symmetry, 242
 Usage-Based Linguistics, 257–258
- “Value added” thinking, 4–5
 Velocity sensitivity, visual perception, 125–126
 Verbal constructions, 279–281
 Verbal strategies, reasoning and problem solving, 560–561
 Verb learning, 320–326
 - children’s use of syntax, 321–323
 - cross-linguistic evidence and constraints on, 323–325
 - informational differences between nouns and verbs, 320–321
 - role of input in, 325–326
 - syntactic and semantic types of arguments, 323–324
 - universals and constraints on locative verbs, 325
 - universals in expression of causativity, 324–325
- Verbal list learning strategies, 515–518
 Veridicality, 474–475
 Vernier acuity, 115
 Vigilance/alerting/arousal, 43
 Violation of expectation paradigm, 219, 222
 Visual arts. *See* Drawing
 Visual efficiency hypothesis, 123
 Visual evoked potential (VEP), 115–116
 Visual function, neural bases of cognitive development:
 - adult plasticity, 16–17
 - developmental plasticity, 15–16
 - memory and visual priming, 28
 - visuospatial module, 39
 - visuospatial recognition and recall memory, 34–35
 - visuospatial working memory, 33–34
- Visual impairment, spatial cognition and, 766
 Visual perception, infant, 109–152
 - basic visual sensitivities in infancy, 114–126
 - color vision, 120–124
 - contrast sensitivity, 116–119
 - motion perception, 124–126
 - orientation sensitivity, 119
 - pattern discrimination, 119–120
 - space perception, 126–134
 - visual acuity, 114–116
 - face perception, 146–150
 - future directions, 152
 - hardwiring versus construction, 151–152
 - levels of analysis, 150–151
 - object perception, 134–146
 - boundary assignment, 137
 - contour junctions, detection/classification of, 136–137
 - edge detection and edge classification, 135–136
 - multiple tasks in, 134–135
 - nonrigid unity and form, 144–145
 - object unity, 137–142
- optical transformations, 143
 size perception, 145–146
 static form perception, 143–144
 three-dimensional form, 142–145
 overview/introduction, 150–152
 space perception, 126–134 (*see also* Spatial perception/cognition)
 theories of perceptual development, 110–114
 - constructivist view, 110–112
 - contemporary situation, 113–114
 - ecological view, 112–113
- Walking skill, 178–180. *See also* Motor development
 Waves theory, overlapping, 477–479
 Williams syndrome:
 - linguistic constructions, 291
 - spatial cognition, 765–766
- Wisconsin Card Sorting Task (WCST), 42
 Word(s):
 - combinations, 262
 - open- and closed-class, 305
 - order, 265–267
 - as pointers, 715–716
 - recognition:
 - beginnings of, 88–89
 - strategies instruction, 531–532
 - segmentation, first year, 84–88
 - Word learning, 299–327
 - cross-linguistic evidence, 303
 - first steps into (broad initial link between words and concepts), 306–309
 - advantages of broad initial link, 309
 - familiarization phase, 307
 - object categories or a broader range of concepts, 308–309
 - specificity of initial link, 307–309
 - test phase, 307
 - words or sounds, 308
 - foundational capacities, 304–306
 - discovering words and word-sized units, 304–305
 - identifying relevant concepts, 305–306
 - interpreting intentions of others, 306
 - future research, 326–327
 - gateway between linguistic and conceptual organization, 299–302
 - later steps into (more specific links between kinds of words and kinds of concepts), 309–326
 - adjectives, 315–320
 - nouns, 303, 309–315
 - verbs, 320–326
 - overview/introduction, 302–304
 - puzzle of, 300–302
 - structure, input versus mind, 303–304
 - Working memory:
 - executive functions, 40–41
 - production systems, 430
 - strategies instruction, 519–521
 - World knowledge, 523–525
 - Writing strategies instruction, 537–538
- Zinacantan, historical change and cognitive change in, 650
